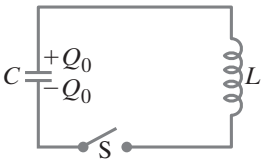
This electric car is having its electric batteries charged by induction. The flat device, connected to a cord and plug, contains a coil of wire and so does that part of the car above it. The changing current (ac) in the flat device induces an emf in the car's coil. That induced emf charges the car's batteries. This is an example of mutual inductance (like a transformer). Electric cars can also be charged by a direct connection.



Any coil of wire has a self-inductance, and a changing current in it causes an emf to be induced in its circuit. Such inductors are useful in many circuits.

CHAPTER 30

# Inductance, Electromagnetic Oscillations, and AC Circuits

**CHAPTER-OPENING QUESTION—Guess now!**

Consider a circuit with only a capacitor $C$ and a coil of many loops of wire (called an inductor, $L$) as shown. If the capacitor is initially charged $(Q = Q_0)$, what will happen when the switch S is closed?

**(a)** Nothing will happen—the capacitor will remain charged with charge $Q = Q_0$.

**(b)** The capacitor will quickly discharge and remain discharged $(Q = 0)$.

**(c)** Current will flow until the positive charge is on the opposite plate of the capacitor, and then will reverse—back and forth.

**(d)** The energy initially in the capacitor $\left(U_E = \frac{1}{2}Q_0^2/C\right)$ will all transfer to the coil and then remain that way.

**(e)** The system will quickly transfer half of the capacitor energy to the coil and then remain that way.

We discussed in the last Chapter how a changing magnetic flux through a circuit induces an emf in that circuit. Before that we saw that an electric current produces a magnetic field. Combining these two ideas, we could predict that a changing current in one circuit ought to induce an emf and a current in a second nearby circuit, and even induce an emf in itself. We already saw an example in the previous Chapter (transformers), but now we will treat this effect in a more general way in terms of what we will call mutual inductance and self-inductance. Almost every circuit contains some inductance (sometimes very little), which we have ignored up to now. But in the real world of electronic circuits, inductance is often of great importance. In fact inductance, along with resistance and capacitance, are the three main elements in simple circuits as we discuss later in this Chapter. The concept of inductance also gives us a springboard to treat energy storage in a magnetic field.

# 30–1 Mutual Inductance

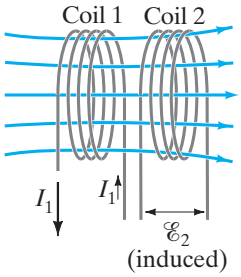

**FIGURE 30–1** A changing current in one coil will induce a current in the second coil.

If two coils of wire are near each other, as in Fig. 30–1, a changing current in one will induce an emf in the other. (A transformer—Chapter 29—is but one example.) Let us apply Faraday's law to coil 2: the emf $\mathscr{E}_2$ induced in coil 2 is proportional to the rate of change of magnetic flux passing through it. This changing flux in coil 2 is produced by a changing current $I_1$ in coil 1, and it is often convenient to express the emf in coil 2 in terms of the current in coil 1.

We let $\Phi_{21}$ be the magnetic flux in each loop of coil 2 created by the current in coil 1. If coil 2 contains $N_2$ closely wrapped loops, then $N_2\Phi_{21}$ is the total flux passing through coil 2. If the two coils are fixed in space, $N_2\Phi_{21}$ is proportional to the current $I_1$ in coil 1; the proportionality constant is called the **mutual inductance**, $M_{21}$, defined by

$$M_{21} = \frac{N_2\Phi_{21}}{I_1}. \qquad \textbf{(30–1)}$$

The emf $\mathscr{E}_2$ induced in coil 2 due to a changing current in coil 1 is, by Faraday's law,

$$\mathscr{E}_2 = -N_2\frac{d\Phi_{21}}{dt}.$$

We combine this with Eq. 30–1 rewritten as $\Phi_{21} = M_{21}I_1/N_2$ (and take its derivative) and obtain

$$\mathscr{E}_2 = -M_{21}\frac{dI_1}{dt}. \qquad \textbf{(30–2)}$$

Equation 30–2 relates the change in current in coil 1 to the emf it induces in coil 2. If the two coils are fixed in space, the mutual inductance $M_{21}$ of coil 2 with respect to coil 1 is a "constant" in that it does not depend on $I_1$; $M_{21}$ depends on "geometric" factors such as the size, shape, number of turns, and relative positions of the two coils, and also on whether iron (or some other ferromagnetic material) is present. For example, if the two coils in Fig. 30–1 are farther apart, fewer lines of flux can pass through coil 2, so $M_{21}$ will be less. For some arrangements, the mutual inductance can be calculated (see Example 30–1). More often it is determined experimentally.

Now consider the reverse situation: when a changing current in coil 2 induces an emf in coil 1. In this case,

$$\mathscr{E}_1 = -M_{12}\frac{dI_2}{dt}$$

where $M_{12}$ is the mutual inductance of coil 1 with respect to coil 2. It is possible to show, although we will not do it here, that $M_{12} = M_{21}$. Hence, for a given arrangement we do not need the subscripts and we can let

$$M = M_{12} = M_{21},$$

so that

$$\mathscr{E}_1 = -M\frac{dI_2}{dt} \qquad \textbf{(30–3a)}$$

and

$$\mathscr{E}_2 = -M\frac{dI_1}{dt}. \qquad \textbf{(30–3b)}$$

The SI unit for mutual inductance is the **henry** (H), where $1\ \text{H} = 1\ \text{V}\cdot\text{s/A} = 1\ \Omega\cdot\text{s}$.

**EXAMPLE 30–1** **Solenoid and coil.** A long thin solenoid of length $\ell$ and cross-sectional area $A_1$ contains $N_1$ closely packed turns of wire. Wrapped around it is an insulated coil of $N_2$ turns, Fig. 30–2. Assume all the flux from coil 1 (the solenoid) passes through coil 2, and calculate the mutual inductance.

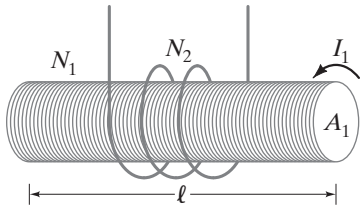

**FIGURE 30–2** Example 30–1.

**APPROACH** We first determine the flux produced by the solenoid, all of which passes uniformly through coil $N_2$ (as well as $N_1$), using Eq. 28–4 for the magnetic field inside a solenoid:

$$B = \mu_0 \frac{N_1}{\ell} I_1 = \mu_0 n I_1,$$

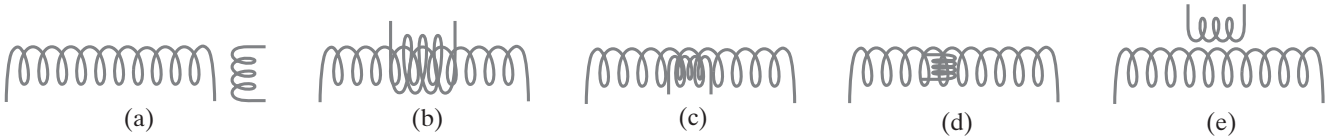
where $n = N_1/\ell$ is the number of loops in the solenoid per unit length, and $I_1$ is the current in the solenoid.

**SOLUTION** The solenoid is closely packed, so we assume that all the flux in the solenoid stays inside the secondary coil. Then the flux $\Phi_{21}$ through coil 2 is

$$\Phi_{21} = BA_1 = \mu_0 \frac{N_1}{\ell} I_1 A_1.$$

So the mutual inductance is

$$M = \frac{N_2 \Phi_{21}}{I_1} = \frac{\mu_0 N_1 N_2 A_1}{\ell}.$$



**NOTE** We calculated $M_{21}$; if we had tried to calculate $M_{12}$, it would have been difficult. Given $M_{12} = M_{21} = M$, we did the simpler calculation to obtain $M$. Note again that $M$ depends only on geometric factors, and not on the currents.

**CONCEPTUAL EXAMPLE 30–2** **Reversing the coils.** How would Example 30–1 change if the coil with $N_2$ turns was inside the solenoid rather than outside the solenoid?

**RESPONSE** The magnetic field inside the solenoid would be unchanged. The flux through the coil would be $BA_2$ where $A_2$ is the area of the coil $N_2$, not of the solenoid as in Example 30–1. Solving for $M$ would give the same formula except that the area $A_1$ would be replaced by the area $A_2$ of coil $N_2$, and $M$ would be smaller because we have changed the configuration.

**EXERCISE A** Which solenoid and coil combination shown in Fig. 30–3 has the largest mutual inductance? Assume each solenoid is the same.

**FIGURE 30–3** Exercise A.

A transformer is an example of mutual inductance in which the coupling is maximized so that nearly all flux lines pass through both coils. Mutual inductance has other uses as well, including inductive charging of cell phones, electric cars, and other devices with rechargeable batteries, as we discussed in Section 29–6.

Mutual inductance can sometimes be a problem. Any changing current in a circuit can induce an emf in another part of the same circuit or in a different circuit even though the conductors are not in the shape of a coil. The mutual inductance $M$ is usually small unless coils with many loops and/or iron cores are involved. However, in situations where small voltages are being used, problems due to mutual inductance often arise. Shielded cable (or coaxial), in which an inner conductor is surrounded by a cylindrical grounded conductor (Fig. 28–12), is often used to reduce the problem.

## 30–2 Self-Inductance; Inductors

The concept of inductance applies also to a single isolated coil of $N$ turns. When a changing current passes through a coil (or solenoid), a changing magnetic flux is produced inside the coil, and this in turn induces an emf in that same coil. This induced emf opposes the change in flux (Lenz's law); it is much like the back emf generated in a motor. For example, if the current through the coil is increasing, the increasing magnetic flux induces an emf that opposes the original current and tends to retard its increase. If the current is decreasing in the coil, the decreasing flux induces an emf in the same direction as the current, thus tending to maintain the original current. If this inductance (coil) is in a circuit, it thus can provide a source of emf, in addition to any battery present or other sources of emf.

The magnetic flux $\Phi_B$ passing through the $N$ turns of a coil is proportional to the current $I$ in the coil, so we define the **self-inductance** $L$ (in analogy to mutual inductance, Eq. 30–1) as

$$L = \frac{N\Phi_B}{I}. \tag{30–4}$$

Then the emf $\mathscr{E}$ induced in a coil of self-inductance $L$ is, from Faraday's law,

$$\mathscr{E} = -N\frac{d\Phi_B}{dt} = -L\frac{dI}{dt}. \tag{30–5}$$

Like mutual inductance, self-inductance is measured in henrys. The magnitude of $L$ depends on the size and shape of the coil and on the presence of an iron core. Self-inductance (inductance, for short) can be defined, as above, for any circuit or part of a circuit.

An ac circuit always contains some inductance, but often it is quite small unless the circuit contains a coil of many loops or turns. A coil that has significant self-inductance $L$ is called an **inductor**. Inductance is shown on circuit diagrams by the symbol

[inductor symbol]

An inductor may also have significant (ordinary) resistance, which should also be shown in a circuit diagram separately. Inductance can serve a useful purpose in certain circuits. Often, however, inductance is a nuisance in a circuit. Precision resistors are often wire wound and thus would have inductance as well as resistance. The inductance can be minimized by winding the insulated wire back on itself in the opposite sense so that the current going in opposite directions produces little net magnetic flux; this is called a **noninductive winding**.

If an inductor has negligible resistance, it is the inductance (or induced emf) that controls a changing current. If a source of changing or alternating voltage is applied to the coil, this applied voltage will just be balanced by the induced emf of the coil (Eq. 30–5). Thus we can see from Eq. 30–5 that, for a given $\mathscr{E}$, if the inductance $L$ is large, the change in the current will be small, and therefore the current itself if it is ac will be small. The greater the inductance, the less the ac current. An inductance thus acts something like a "resistance" to impede the flow of alternating current. We use the term *reactance* or *impedance* for this quality of an inductor. We will discuss reactance and impedance in ac circuits more fully in Sections 30–7 and 30–8. We shall see that reactance depends not only on the inductance $L$, but also on the frequency of the ac source. Here we mention one example of its importance. The resistance of the primary in a transformer is usually quite small, perhaps less than 1 $\Omega$. If resistance alone limited the current in a transformer, tremendous currents would flow when a high voltage was applied. Indeed, a dc voltage applied to a transformer can burn it out. It is the induced emf (or reactance) of the coil that limits the current to a reasonable value.

Common inductors have inductances in the range from about 1 $\mu$H to about 1 H (where 1 H = 1 henry = 1 $\Omega \cdot$ s).

**EXAMPLE 30–3** **Solenoid inductance.** (*a*) Determine a formula for the self-inductance $L$ of a long tightly wrapped solenoid containing $N$ turns of wire in its length $\ell$ and whose cross-sectional area is $A$. (*b*) Calculate the value of $L$ if $N = 100$, $\ell = 5.0\,\text{cm}$, $A = 0.30\,\text{cm}^2$ and the solenoid is air filled.

**APPROACH** To determine the inductance $L$, it is usually simplest to start with Eq. 30–4, so we need to first determine the flux.

**SOLUTION** (*a*) According to Eq. 28–4, the magnetic field inside a solenoid (ignoring end effects) is constant: $B = \mu_0 nI$ where $n = N/\ell$. The flux is $\Phi_B = BA = \mu_0 NIA/\ell$, so

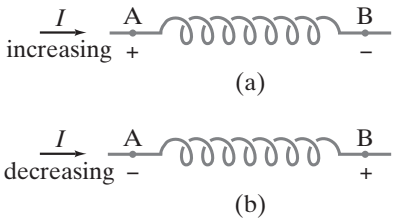
$$L = \frac{N\Phi_B}{I} = \frac{\mu_0 N^2 A}{\ell}.$$

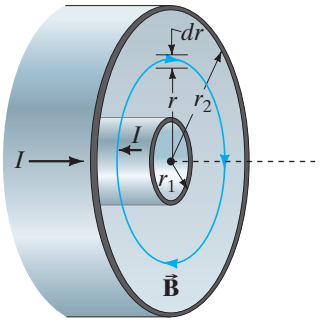
(*b*) Since $\mu_0 = 4\pi \times 10^{-7}\,\text{T} \cdot \text{m/A}$, then

$$L = \frac{(4\pi \times 10^{-7}\,\text{T} \cdot \text{m/A})(100)^2(3.0 \times 10^{-5}\,\text{m}^2)}{(5.0 \times 10^{-2}\,\text{m})} = 7.5\,\mu\text{H}.$$

**NOTE** Magnetic field lines "stray" out of the solenoid (see Fig. 28–15), especially near the ends, so our formula is only an approximation.

**CONCEPTUAL EXAMPLE 30–4** **Direction of emf in inductor.** Current passes through the coil in Fig. 30–4 from left to right as shown. (*a*) If the current is increasing with time, in which direction is the induced emf? (*b*) If the current is decreasing in time, what then is the direction of the induced emf?





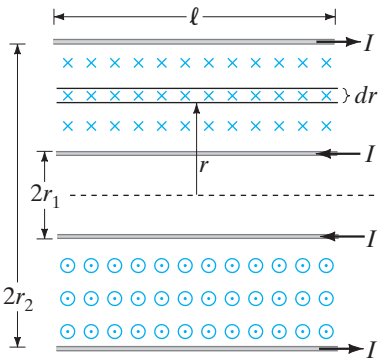


**FIGURE 30–4** Example 30–4. The + and − signs refer to the induced emf due to the changing current, as if points A and B were the terminals of a battery (and the coiled loops were the inside of the battery).

**RESPONSE** (*a*) From Lenz's law we know that the induced emf must oppose the change in magnetic flux. If the current is increasing, so is the magnetic flux. The induced emf acts to oppose the increasing flux, which means it acts like a source of emf that opposes the original source of emf driving the current. So the induced emf in the coil acts to oppose $I$ in Fig. 30–4a. In other words, the inductor might be thought of as a battery with a positive terminal at point A (tending to block the current entering at A), and negative at point B.

(*b*) If the current is decreasing, then by Lenz's law the induced emf acts to increase the flux—like a source of emf reinforcing the original emf. The induced emf acts to increase $I$ in Fig. 30–4b, so in this situation you can think of the induced emf as a battery with its negative terminal at point A to attract more current (conventional, +) to move to the right.

(a)

(b)

**FIGURE 30–5** Example 30–5. Coaxial cable: (a) end view, (b) side view (cross section).

**EXAMPLE 30–5** **Inductance of coaxial cylinders.** Determine the inductance per unit length of a coaxial cable whose inner conductor has a radius $r_1$ and the outer conductor has a radius $r_2$, Fig. 30–5. Assume the conductors are thin hollow tubes so there is no magnetic field within the inner conductor, and the magnetic field inside both thin conductors can be ignored. The conductors carry equal currents $I$ in opposite directions.

**APPROACH** We need to find the magnetic flux, $\Phi_B = \int \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}}$, between the conductors. The lines of $\vec{\mathbf{B}}$ are circles surrounding the inner conductor (only one is shown in Fig. 30–5a). From Ampère's law, $\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 I$, the magnitude of the field along a circle at a distance $r$ from the center, when the inner conductor carries a current $I$, is (Examples 28–6 and 28–7):

$$B = \frac{\mu_0 I}{2\pi r}.$$

The magnetic flux through a rectangle of width $dr$ and length $\ell$ (along the cable, Fig. 30–5b), a distance $r$ from the center, is

$$d\Phi_B = B\,dA = B(\ell\,dr) = \frac{\mu_0 I}{2\pi r}\ell\,dr.$$

**SOLUTION** The total flux in a length $\ell$ of cable is

$$\Phi_B = \int d\Phi_B = \frac{\mu_0 I \ell}{2\pi}\int_{r_1}^{r_2}\frac{dr}{r} = \frac{\mu_0 I \ell}{2\pi}\ln\frac{r_2}{r_1}.$$

Since the current $I$ all flows in one direction in the inner conductor, and the same current $I$ all flows in the opposite direction in the outer conductor, we have only one turn, so $N = 1$ in Eq. 30–4. Hence the self-inductance for a length $\ell$ is

$$L = \frac{\Phi_B}{I} = \frac{\mu_0 \ell}{2\pi}\ln\frac{r_2}{r_1}.$$

The inductance per unit length is

$$\frac{L}{\ell} = \frac{\mu_0}{2\pi}\ln\frac{r_2}{r_1}.$$

Note that the inductance $L$ depends only on geometric factors and not on the current $I$.

# 30–3 Energy Stored in a Magnetic Field

When an inductor of inductance $L$ is carrying a current $I$ which is changing at a rate $dI/dt$, energy is being supplied to the inductor at a rate

$$P = I\mathscr{E} = LI\frac{dI}{dt}$$

where $P$ stands for power and we used[†] Eq. 30–5. Let us calculate the work needed to increase the current in an inductor from zero to some value $I$. Using this last equation, the work $dW$ done in a time $dt$ is

$$dW = P\,dt = LI\,dI.$$

Then the total work done to increase the current from zero to $I$ is

$$W = \int dW = \int_0^I LI\,dI = \tfrac{1}{2}LI^2.$$

This work done is equal to the energy $U$ stored in the inductor when it is carrying a current $I$ (and we take $U = 0$ when $I = 0$):

$$U = \tfrac{1}{2}LI^2. \qquad \textbf{(30–6)}$$

This can be compared to the energy stored in a capacitor, $C$, when the potential difference across it is $V$ (see Section 24–4):

$$U = \tfrac{1}{2}CV^2.$$

[†]No minus sign here because we are supplying power to oppose the emf of the inductor.

**EXERCISE B** What is the inductance of an inductor if it has a stored energy of 1.5 J when there is a current of 2.5 A in it? (*a*) 0.48 H, (*b*) 1.2 H, (*c*) 2.1 H, (*d*) 4.7 H, (*e*) 19 H.

Just as the energy stored in a capacitor can be considered to reside in the electric field between its plates, so the energy in an inductor can be considered to be stored in its magnetic field. To write the energy in terms of the magnetic field, we use the result of Example 30–3, that the inductance of an ideal solenoid (end effects ignored) is $L = \mu_0 N^2 A/\ell$. The magnetic field $B$ inside a solenoid is related to the current $I$ by $B = \mu_0 NI/\ell$ (Eq. 28–4), so

$$U = \tfrac{1}{2}LI^2 = \frac{1}{2}\left(\frac{\mu_0 N^2 A}{\ell}\right)\left(\frac{B\ell}{\mu_0 N}\right)^2$$
$$= \frac{1}{2}\frac{B^2}{\mu_0}A\ell.$$

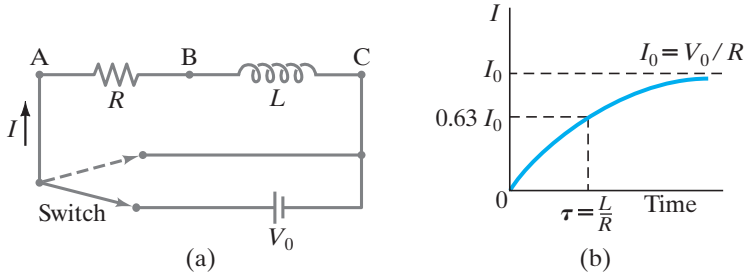
We can think of this energy as residing in the volume enclosed by the windings, which is $A\ell$. Then the energy per unit volume or **energy density** is

$$u = \text{energy density} = \frac{1}{2}\frac{B^2}{\mu_0}. \qquad \textbf{(30–7)}$$

This formula for the energy density in a magnetic field, which was derived for the special case of a solenoid, can be shown to be valid for any region of space where a magnetic field is present. If a ferromagnetic material is present, $\mu_0$ is replaced by $\mu$. This equation is analogous to that for an electric field, $\frac{1}{2}\epsilon_0 E^2$, Eq. 24–6.

## 30–4 *LR* Circuits

Any inductor will have some resistance. We represent an inductor by drawing the inductance $L$ and its resistance $R$ separately, as in Fig. 30–6a. The resistance $R$ could also include any other resistance in the circuit. Now we ask, what happens when a battery of voltage $V_0$ is connected in series to such an $LR$ circuit? At the instant the switch connecting the battery is closed, the current starts to flow. It is opposed by the induced emf in the inductor because of the changing current. As soon as current starts to flow, there is also a voltage drop across the resistance ($V = IR$). Hence, the voltage drop across the inductance is reduced and the current increases less rapidly. The current thus rises gradually, as shown in Fig. 30–6b, and approaches the steady value $I_0 = V_0/R$, where there is no more emf in the inductor ($I$ is no longer changing) so all the voltage drop is across the resistance.



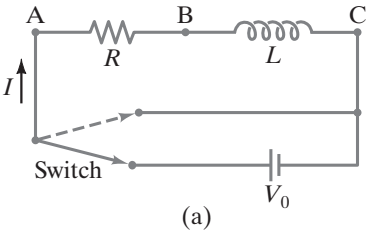


**FIGURE 30–6** (a) *LR* circuit; (b) growth of current when connected to battery.

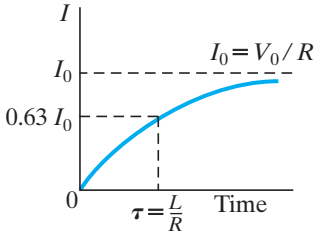
We can show this analytically by applying Kirchhoff's loop rule to the circuit of Fig. 30–6a with the switch closed. The emfs in the circuit are the battery voltage $V_0$ and the emf $\mathcal{E} = -L(dI/dt)$ in the inductor (Eq. 30–5) opposing the increasing current. Hence the sum of the potential changes around the loop is



$$V_0 - IR - L\frac{dI}{dt} = 0,$$

where $I$ is the current in the circuit at any instant. We rearrange this to obtain

$$L\frac{dI}{dt} + RI = V_0. \qquad \textbf{(30–8)}$$

(a)

(b)

**FIGURE 30–6** (Repeated.) (a) *LR* circuit; (b) growth of current when connected to battery.

This Eq. 30-8 we just obtained

$$L\frac{dI}{dt} + RI = V_0 \qquad \textbf{(30–8)}$$

is a linear differential equation and can be integrated in the same way we did in Section 26–5 for an *RC* circuit. We rewrite Eq. 30–8 and then integrate from $t = 0$, when $I = 0$, to a later time $t$ when the current is $I$:

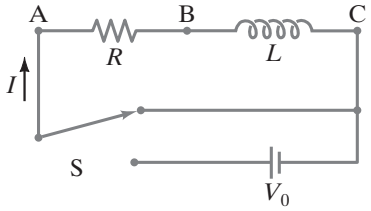
$$\int_{I=0}^{I} \frac{dI}{V_0 - IR} = \int_0^t \frac{dt}{L}.$$

Then

$$-\frac{1}{R}\ln\left(\frac{V_0 - IR}{V_0}\right) = \frac{t}{L} \qquad \text{and} \qquad \frac{V_0 - IR}{V_0} = e^{-\frac{Rt}{L}}$$

so

$$I = \frac{V_0}{R}\left(1 - e^{-t/\tau}\right) \qquad \textbf{(30–9)}$$



where

$$\tau = \frac{L}{R} \qquad \textbf{(30–10)}$$

is the **time constant** of the *LR* circuit. The symbol $\tau$ represents the time required for the current $I$ to reach $(1 - 1/e) = 0.63$ or 63% of its maximum value $(V_0/R)$. Equation 30–9 is plotted in Fig. 30–6b. (Compare to the *RC* circuit, Section 26–5.)

**EXERCISE C** Show that $L/R$ does have dimensions of time. (See Section 1–7.)

**FIGURE 30–7** The switch is flipped quickly so the battery is removed but we still have a circuit. The current at this moment (call it $t = 0$) is $I_0$.

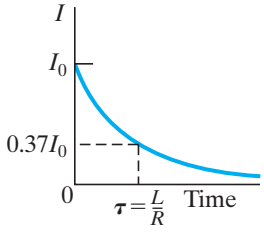
Now let us flip the switch in Fig. 30–6a so that the battery is taken out of the circuit, and points A and C are connected together as shown in Fig. 30–7 at the moment when the switching occurs (call it $t = 0$) and the current is $I_0$. Then the differential equation (Eq. 30–8) becomes (since $V_0 = 0$):

$$L\frac{dI}{dt} + RI = 0.$$

We rearrange this equation and integrate:

$$\int_{I_0}^{I} \frac{dI}{I} = -\int_0^t \frac{R}{L}dt$$

where the current is $I_0$ at $t = 0$, and is $I$ at time $t$.



We integrate this last equation to obtain

$$\ln\frac{I}{I_0} = -\frac{R}{L}t$$

or

$$I = I_0 e^{-t/\tau}. \qquad \textbf{(30–11)}$$

**FIGURE 30–8** Decay of the current in Fig. 30–7 in time after the battery is switched out of the circuit.

The current thus decays exponentially to zero as shown in Fig. 30–8. Again the time constant is $\tau = L/R$, and is the time for the current to decrease to $0.37\,I_0$.

This analysis shows that there is always some "lag time" or "reaction time" when an electromagnet, for example, is turned on or off. We also see that an *LR* circuit has properties similar to an *RC* circuit (Section 26–5). Unlike the capacitor case, however, the time constant here is *inversely* proportional to *R*.

**EXAMPLE 30–6** **An *LR* circuit.** At $t = 0$, a 12.0-V battery is connected in series with a 220-mH inductor and a total resistance of 30 Ω, as shown in Fig. 30–9. (*a*) What is the current at $t = 0$? (*b*) What is the time constant? (*c*) What is the maximum current? (*d*) How long will it take the current to reach half its maximum possible value? (*e*) At this instant, at what rate is energy being delivered by the battery, and (*f*) at what rate is energy being stored in the inductor's magnetic field?

**APPROACH** We have the situation shown in Figs. 30–6a and b, and we can apply the equations we just developed.

**SOLUTION** (*a*) The current cannot instantaneously jump from zero to some other value when the switch is closed because the inductor opposes the change $(\mathcal{E}_L = -L(dI/dt))$. Hence just after the switch is closed, $I$ is still zero at $t = 0$ and then begins to increase.

(*b*) The time constant is, from Eq. 30–10, $\tau = L/R = (0.22\,\text{H})/(30\,\Omega) = 7.3\,\text{ms}$.

(*c*) The current reaches its maximum steady value $I_0$ after a long time (see Fig. 30–6), when $dI/dt = 0$ so $I_0 = V_0/R = 12.0\,\text{V}/30\,\Omega = 0.40\,\text{A}$.

(*d*) We set $I = \frac{1}{2}I_0 = V_0/2R$ in Eq. 30–9, which gives us

$$\tfrac{1}{2} = 1 - e^{-t/\tau}$$

or

$$e^{-t/\tau} = \tfrac{1}{2}.$$

We solve for $t$:

$$t = \tau \ln 2 = (7.3 \times 10^{-3}\,\text{s})(0.693) = 5.1\,\text{ms}.$$

(*e*) At this instant, $I = \frac{1}{2}I_0 = 200\,\text{mA}$, so the power being delivered by the battery is

$$P = IV = (0.20\,\text{A})(12\,\text{V}) = 2.4\,\text{W}.$$

(*f*) From Eq. 30–6, the energy stored in an inductor $L$ at any instant is

$$U = \tfrac{1}{2}LI^2$$

where $I$ is the current in the inductor $(= 0.20\,\text{A})$ at that instant. The *rate* at which the energy changes is

$$\frac{dU}{dt} = LI\frac{dI}{dt}.$$

We can differentiate Eq. 30–9 to obtain $dI/dt$, or use the differential equation, Eq. 30–8, directly:

$$\frac{dU}{dt} = I\left(L\frac{dI}{dt}\right) = I(V_0 - RI)$$
$$= (0.20\,\text{A})[12\,\text{V} - (30\,\Omega)(0.20\,\text{A})] = 1.2\,\text{W}.$$

Since only part of the battery's power is feeding the inductor at this instant, where is the rest going?

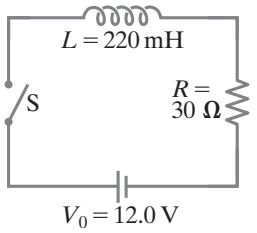


**FIGURE 30–9** Example 30–6.

**EXERCISE D** A resistor in series with an inductor has a time constant of 10 ms. When the same resistor is placed in series with a 5-$\mu$F capacitor, the time constant is $5 \times 10^{-6}$ s. What is the value of the inductor? (*a*) 5 $\mu$H; (*b*) 10 $\mu$H; (*c*) 5 mH; (*d*) 10 mH; (*e*) not enough information to determine it.

**PHYSICS APPLIED**
*Surge protection*

An inductor can act as a **surge protector** for sensitive electronic equipment that can be damaged by high currents. If equipment is plugged into a standard wall plug, a sudden "surge," or increase, in voltage will normally cause a corresponding large change in current and damage the electronics. However, if there is an inductor in series with the voltage to the device, the sudden change in current produces an opposing emf preventing the current from reaching dangerous levels.

## 30–5 *LC* Circuits and Electromagnetic Oscillations

Any electric circuit can contain the three basic components: resistance, capacitance, and inductance, in addition to a source of emf. (There can also be more complex components, such as diodes or transistors.) We have previously discussed both *RC* and *LR* circuits. Now we look at an *LC* circuit, one that contains only a capacitance $C$ and an inductance, $L$, Fig. 30–10. This is an idealized circuit in which we assume there is no resistance; in the next Section we will include resistance.

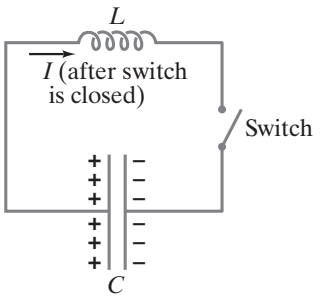

**FIGURE 30–10** An *LC* circuit.

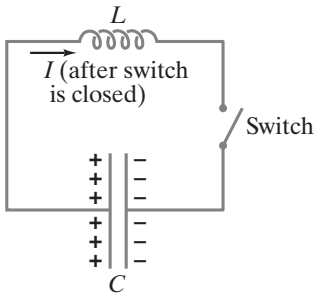

**FIGURE 30–10** (Repeated.) An $LC$ circuit.

Let us suppose the capacitor in Fig. 30–10 is initially charged so that one plate has charge $Q_0$ and the other plate has charge $-Q_0$, and the potential difference across it is $V = Q/C$ (Eq. 24–1). Suppose that at $t = 0$, the switch is closed. The capacitor immediately begins to discharge. As it does so, the current $I$ through the inductor increases. We now apply Kirchhoff's loop rule (sum of potential changes around a loop is zero):

$$-L\frac{dI}{dt} + \frac{Q}{C} = 0.$$

Because charge leaves the positive plate on the capacitor to produce the current $I$ as shown in Fig. 30–10, the charge $Q$ on the (positive) plate of the capacitor is decreasing, so $I = -dQ/dt$. We can then rewrite the above equation as

$$\frac{d^2Q}{dt^2} + \frac{Q}{LC} = 0. \qquad \textbf{(30–12)}$$

This is a familiar differential equation, which has the same form as the equation for simple harmonic motion (Chapter 14, Eq. 14–3). Its solution is *sinusoidal* which we can write like Eq. 14–4 as

$$Q = Q_0 \cos(\omega t + \phi) \qquad \textbf{(30–13)}$$

where $Q_0$ and $\phi$ are constants that depend on the initial conditions and $(\omega t + \phi)$ is in radians. [Note: the amplitude $Q_0$ represents $Q$ at $t = 0$ *only* if the phase angle $\phi$ is 0.] We insert Eq. 30–13 into Eq. 30–12, noting that $d^2Q/dt^2 = -\omega^2 Q_0 \cos(\omega t + \phi)$; thus

$$-\omega^2 Q_0 \cos(\omega t + \phi) + \frac{1}{LC} Q_0 \cos(\omega t + \phi) = 0$$

or

$$\left(-\omega^2 + \frac{1}{LC}\right)\cos(\omega t + \phi) = 0.$$

This relation can be true for all times $t$ only if $(-\omega^2 + 1/LC) = 0$, which tells us that

$$\omega = 2\pi f = \sqrt{\frac{1}{LC}}. \qquad \textbf{(30–14)}$$

Equation 30–13 shows that the charge on the capacitor in an $LC$ circuit oscillates sinusoidally. The current in the inductor is

$$I = -\frac{dQ}{dt} = \omega Q_0 \sin(\omega t + \phi)$$
$$= I_0 \sin(\omega t + \phi); \qquad \textbf{(30–15)}$$

so the current too is sinusoidal. The maximum value of $I$ is $I_0 = \omega Q_0 = Q_0/\sqrt{LC}$. Equations 30–13 and 30–15 for $Q$ and $I$ when $\phi = 0$ are plotted in Fig. 30–11.

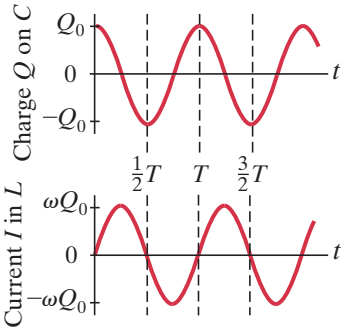

**FIGURE 30–11** Charge $Q$ and current $I$ in an $LC$ circuit. The period $T = \frac{1}{f} = \frac{2\pi}{\omega} = 2\pi\sqrt{LC}$.

Now let us look at $LC$ oscillations from the point of view of energy. The energy stored in the electric field of the capacitor at any time $t$ is (see Eq. 24–5):

$$U_E = \frac{1}{2}\frac{Q^2}{C} = \frac{Q_0^2}{2C}\cos^2(\omega t + \phi).$$

The energy stored in the magnetic field of the inductor at the same instant is (Eq. 30–6)

$$U_B = \frac{1}{2}LI^2 = \frac{L\omega^2 Q_0^2}{2}\sin^2(\omega t + \phi) = \frac{Q_0^2}{2C}\sin^2(\omega t + \phi)$$

where we used Eq. 30–14. If we let $\phi = 0$, then at times $t = 0$, $t = \frac{1}{2}T$, $t = T$, and so on (where $T$ is the period $= 1/f = 2\pi/\omega$), we have $U_E = Q_0^2/2C$ and $U_B = 0$. That is, all the energy is stored in the electric field of the capacitor. But at $t = \frac{1}{4}T$, $\frac{3}{4}T$, and so on, $U_E = 0$ and $U_B = Q_0^2/2C$, and so all the energy is stored in the magnetic field of the inductor. At any time $t$, the total energy is

$$U = U_E + U_B = \frac{1}{2}\frac{Q^2}{C} + \frac{1}{2}LI^2$$
$$= \frac{Q_0^2}{2C}\left[\cos^2(\omega t + \phi) + \sin^2(\omega t + \phi)\right] = \frac{Q_0^2}{2C}. \quad \textbf{(30–16)}$$

Hence the total energy is constant, and energy is conserved.

This $LC$ circuit is an ***LC* oscillator** or **electromagnetic oscillation**. The charge $Q$ oscillates back and forth, from one plate of the capacitor to the other, and repeats this continuously. The current also oscillates back and forth. There are also energy oscillations: when $Q$ is a maximum, the energy is all stored in the electric field of the capacitor; when $Q$ reaches zero, the current $I$ is a maximum and all the energy is stored in the magnetic field of the inductor. Thus the energy in an $LC$ circuit oscillates between the capacitor and the inductor, but the total energy is constant. See Fig. 30–12.

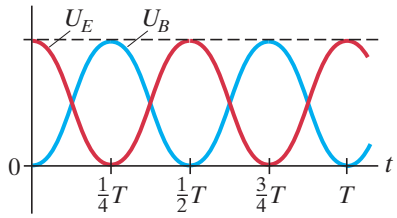

**FIGURE 30–12** Energy $U_E$ (red line) and $U_B$ (blue line) stored in the capacitor and the inductor as a function of time. Note how the energy oscillates between electric and magnetic. The dashed line at the top is the (constant) total energy $U = U_E + U_B$.

**EXERCISE E** Return to the Chapter-Opening Question, page 869, and answer it again now. Try to explain why you may have answered differently the first time.

**EXAMPLE 30–7** ***LC* circuit.** A 1200-pF capacitor is fully charged by a 500-V dc power supply. It is disconnected from the power supply and is connected, at $t = 0$, to a 75-mH inductor. Determine: (*a*) the initial charge on the capacitor; (*b*) the maximum current; (*c*) the frequency $f$ and period $T$ of oscillation; and (*d*) the total energy oscillating in the system.

**APPROACH** We use the analysis above, and the definition of capacitance $Q = CV$ (Chapter 24).

**SOLUTION** (*a*) The 500-V power supply, before being disconnected, charged the capacitor to a charge of

$$Q_0 = CV = (1.2 \times 10^{-9}\,\text{F})(500\,\text{V}) = 6.0 \times 10^{-7}\,\text{C}.$$

(*b*) The maximum current, $I_0$, is (see Eqs. 30–14 and 30–15)

$$I_0 = \omega Q_0 = \frac{Q_0}{\sqrt{LC}} = \frac{(6.0 \times 10^{-7}\,\text{C})}{\sqrt{(0.075\,\text{H})(1.2 \times 10^{-9}\,\text{F})}} = 63\,\text{mA}.$$

(*c*) Equation 30–14 gives us the frequency:

$$f = \frac{\omega}{2\pi} = \frac{1}{(2\pi\sqrt{LC})} = 17\,\text{kHz},$$

and the period $T$ is

$$T = \frac{1}{f} = 6.0 \times 10^{-5}\,\text{s}.$$

(*d*) Finally the total energy (Eq. 30–16) is

$$U = \frac{Q_0^2}{2C} = \frac{(6.0 \times 10^{-7}\,\text{C})^2}{2(1.2 \times 10^{-9}\,\text{F})} = 1.5 \times 10^{-4}\,\text{J}.$$

# 30–6 *LC* Oscillations with Resistance (*LRC* Circuit)

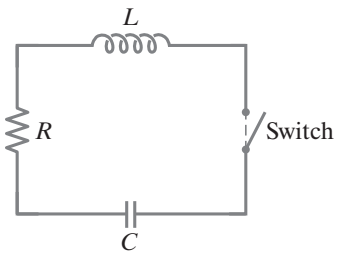

**FIGURE 30–13** An *LRC* circuit.

The *LC* circuit discussed in the previous Section is an idealization. There is always some resistance *R* in any circuit, and so we now discuss such a simple *LRC* circuit, Fig. 30–13.

Suppose again that the capacitor is initially given a charge $Q_0$ and the battery or other source is then removed from the circuit. The switch is closed at $t = 0$. Since there is now a resistance in the circuit, we expect some of the energy to be converted to thermal energy, and so we don't expect undamped oscillations as in a pure *LC* circuit. Indeed, if we use Kirchhoff's loop rule around this circuit, we obtain

$$-L\frac{dI}{dt} - IR + \frac{Q}{C} = 0,$$

which is the same equation we had in Section 30–5 with the addition of the voltage drop *IR* across the resistor. Since $I = -dQ/dt$, as we saw in Section 30–5, this equation becomes

$$L\frac{d^2Q}{dt^2} + R\frac{dQ}{dt} + \frac{1}{C}Q = 0. \qquad \textbf{(30–17)}$$

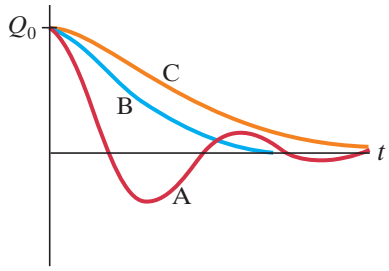
This second-order differential equation in the variable *Q* has precisely the same form as that for a damped harmonic oscillator, Eq. 14–15:

$$m\frac{d^2x}{dt^2} + b\frac{dx}{dt} + kx = 0.$$

Hence we can analyze our *LRC* circuit in the same way as for damped harmonic motion, Section 14–7. Our system may undergo damped oscillations, curve A in Fig. 30–14 (underdamped system), or it may be critically damped (curve B), or overdamped (curve C), depending on the relative values of *R*, *L*, and *C*. Using the results of Section 14–7, with *m* replaced by *L*, *b* by *R*, and *k* by $C^{-1}$, we find that the system will be underdamped when $b^2 < 4mk$ (page 415) or

$$R^2 < \frac{4L}{C}, \qquad \text{[underdamped, oscillating]}$$

and overdamped for $R^2 > 4L/C$. Critical damping (curve B in Fig. 30–14) occurs when $R^2 = 4L/C$. If *R* is smaller than $\sqrt{4L/C}$, the angular frequency, $\omega'$, will be



$$\omega' = \sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}} \qquad \textbf{(30–18)}$$

(compare to Eq. 14–18). And the charge *Q* as a function of time will be

$$Q = Q_0 e^{-\frac{R}{2L}t}\cos(\omega' t + \phi) \qquad \textbf{(30–19)}$$

(compare to Eq. 14–19) where $\phi$ is a phase constant which depends on the initial conditions, and is zero if $Q = Q_0$ at $t = 0$.

**FIGURE 30–14** Charge *Q* on the capacitor in an *LRC* circuit as a function of time: curve A is for underdamped oscillation $(R^2 < 4L/C)$, curve B is for critically damped $(R^2 = 4L/C)$, and curve C is for overdamped $(R^2 > 4L/C)$.

Oscillators are an important element in many electronic devices: radios and television sets use them for tuning stations, and so do cell phones, plus many other electronic devices use oscillators for synchronizing timing. Because some resistance is always present, electrical oscillators generally need a periodic input of power to compensate for the energy converted to thermal energy in the resistance.

**EXAMPLE 30–8** **Damped oscillations.** At $t = 0$, a 40-mH inductor is placed in series with a resistance $R = 3.0\,\Omega$ and a charged capacitor $C = 4.8\,\mu\text{F}$. (*a*) Show that this circuit will oscillate. (*b*) Determine the frequency. (*c*) What is the time required for the charge amplitude to drop to half its starting value? (*d*) What value of $R$ will make the circuit nonoscillating?

**APPROACH** We first check $R^2$ vs. $4L/C$; then use Eqs. 30–18 and 30–19.

**SOLUTION** (*a*) In order to oscillate, the circuit must be underdamped, so we must have $R^2 < 4L/C$. Since $R^2 = 9.0\,\Omega^2$ and $4L/C = 4(0.040\,\text{H})/(4.8 \times 10^{-6}\,\text{F}) = 3.3 \times 10^4\,\Omega^2$, so $R^2$ is a lot less than $4L/C$, and the circuit will oscillate with very small damping.

(*b*) We use Eq. 30–18:

$$f' = \frac{\omega'}{2\pi} = \frac{1}{2\pi}\sqrt{\frac{1}{LC} - \frac{R^2}{4L^2}} = 3.6 \times 10^2\,\text{Hz}.$$

(*c*) From Eq. 30–19, the amplitude will be half when

$$e^{-\frac{R}{2L}t} = \tfrac{1}{2}$$

or

$$t = \frac{2L}{R}\ln 2 = 18\,\text{ms}.$$

(*d*) To make the circuit critically damped or overdamped, we must use the criterion $R^2 \geq 4L/C = 3.3 \times 10^4\,\Omega^2$. Hence we must have $R \geq 180\,\Omega$.

# 30–7 AC Circuits and Reactance

We have previously discussed circuits that contain combinations of resistor, capacitor, and inductor, but only when they are connected to a dc source of emf or to zero voltage. Now we discuss these circuit elements when they are connected to a source of alternating voltage that produces an alternating current (ac).

First we examine, one at a time, how a resistor, a capacitor, and an inductor behave when connected to a source of alternating voltage, represented by the symbol

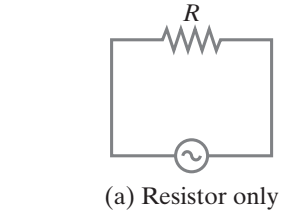
[alternating voltage]

which produces a sinusoidal voltage of frequency $f$. We assume (arbitrarily, for clarity) in each case that the emf gives rise to a current

$$I = I_0 \cos 2\pi f t = I_0 \cos \omega t \qquad \textbf{(30–20)}$$

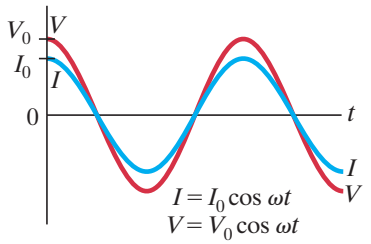
where $t$ is time and $I_0$ is the peak current. Remember (Section 25–7, Eqs. 25–9) that

$$V_{\text{rms}} = V_0/\sqrt{2} \quad \text{and} \quad I_{\text{rms}} = I_0/\sqrt{2}.$$



## Resistor

When an ac source is connected to a resistor as in Fig. 30–15a, the current increases and decreases with the alternating voltage according to Ohm's law



$$V = IR = I_0 R \cos \omega t = V_0 \cos \omega t$$

where $V_0 = I_0 R$ is the peak voltage. Figure 30–15b shows the voltage (red curve) and the current (blue curve) as a function of time. Because the current is zero when the voltage is zero and the current reaches a peak when the voltage does, we say that the current and voltage are **in phase**. Energy is transformed into heat (Section 25–7), at an average rate

$$\overline{P} = \overline{IV} = I_{\text{rms}}^2 R = V_{\text{rms}}^2/R.$$

(a) Resistor only

(b)

**FIGURE 30–15** (a) Resistor connected to an ac source. (b) Current (blue curve) is in phase with the voltage (red) across a resistor.

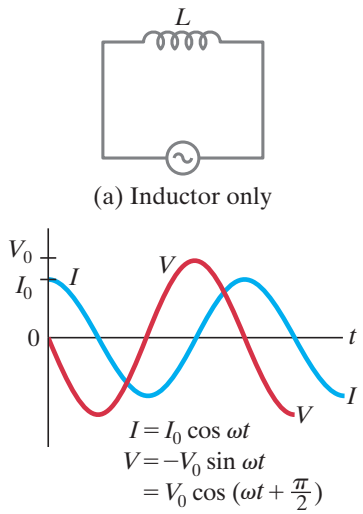


**FIGURE 30–16** (a) Inductor connected to an ac source. (b) Current (blue curve) lags voltage (red curve) by a quarter cycle or $90° = \pi/2$ radians.

## Inductor

In Fig. 30–16a an inductor of inductance $L$ (symbol —ᔓᔓᔓ—) is connected to the ac source. We ignore any resistance it might have (it is usually small). The voltage applied to the inductor will be equal to the "back" emf generated in the inductor by the changing current as given by Eq. 30–5. This is because the sum of the electric potential changes around any closed circuit must add up to zero, according to Kirchhoff's rule. Thus (Eq. 30–5)

$$V - L\frac{dI}{dt} = 0$$

and inserting Eq. 30–20, $I = I_0 \cos \omega t$, we have (recall from Chapter 10 that 360° corresponds to $2\pi$ radians),

$$V = L\frac{dI}{dt} = -\omega L I_0 \sin \omega t. \qquad \textbf{(30–21)}$$

Using the identity $\sin\theta = -\cos(\theta + 90°)$, or in radians, $\sin\theta = -\cos\left(\theta + \frac{\pi}{2}\right)$, we can write

$$V = \omega L I_0 \cos\left(\omega t + \frac{\pi}{2}\right) = V_0 \cos\left(\omega t + \frac{\pi}{2}\right) \qquad \textbf{(30–22a)}$$

where we *must use radians* because $\omega$ has units of rad/s, and

$$V_0 = I_0 \omega L \qquad \textbf{(30–22b)}$$

is the peak voltage. The current $I$ and voltage $V$ as a function of time are graphed in Fig. 30–16b for a "pure" inductor. It is clear from this graph, as well as from Eqs. 30–22, that the current and voltage are out of phase by a quarter cycle, which is equivalent to $\frac{\pi}{2}$ radians or 90°. We see from the graph that

**current lags the voltage by 90° $\left(\frac{\pi}{2}\right.$ radians$\left.\right)$ in an inductor.**

That is, the current in an inductor reaches its peaks a quarter cycle later than the voltage does. Alternatively, we can say that the voltage leads the current by 90°.

Because the current and voltage in an inductor are out of phase by 90° $(\pi/2$ radians$)$, the product $IV$ (= power) is as often positive as it is negative (Fig. 30–16b). So no energy is transformed in an inductor on the average; and no energy is dissipated as thermal energy.

Just as a resistor impedes the flow of charge, so too an inductor impedes the flow of charge in an alternating current due to the back emf produced. For a resistor $R$, the peak current and peak voltage are related by $V_0 = I_0 R$. We can write a similar relation for an inductor:

$$V_0 = I_0 X_L \qquad \left[\begin{array}{c}\text{maximum or rms values,}\\ \text{not at any instant}\end{array}\right] \qquad \textbf{(30–23a)}$$

where, from Eq. 30–22b (and using $\omega = 2\pi f$ where $f$ is the frequency of the ac),

$$X_L = \omega L = 2\pi f L. \qquad \textbf{(30–23b)}$$

The term $X_L$ is called the **inductive reactance** of the inductor, and has units of ohms. $X_L$ is larger for higher frequencies $f$ and larger inductance $L$. The greater $X_L$ is, the more it impedes the flow of charge and the smaller the current. (Reactance and resistance are referred to collectively as *impedance*, as we discuss shortly.)

Equation 30–23a is valid for peak values $I_0$ and $V_0$; it is also valid for rms values, $V_{\text{rms}} = I_{\text{rms}} X_L$. Because the peak values of current and voltage are not reached at the same time, Eq. 30–23a is *not valid at a particular instant*, as is the case for a resistor $(V = IR)$. It simply is an equation that relates the maximum (or rms) values of $V$ and $I$.

**⚠ CAUTION**

*$V_0 = I_0 X_L$ is not valid at any moment in time*

**EXAMPLE 30–9** **Reactance of a coil.** A coil has a resistance $R = 1.00\ \Omega$ and an inductance of 0.300 H. Determine the current in the coil if (*a*) 120-V dc is applied to it, (*b*) 120-V ac (rms) at 60.0 Hz is applied.

**APPROACH** When the voltage is dc, there is no inductive reactance $(X_L = 2\pi f L = 0$ since $f = 0)$, so we apply Ohm's law for the resistance. When the voltage is ac, we calculate the reactance $X_L$ and then use Eq. 30–23a.

**SOLUTION** (*a*) With dc, we have no $X_L$ so we simply apply Ohm's law:

$$I = \frac{V}{R} = \frac{120\text{ V}}{1.00\ \Omega} = 120\text{ A}.$$

(*b*) The inductive reactance is

$$X_L = 2\pi f L = (6.283)\left(60.0\text{ s}^{-1}\right)(0.300\text{ H}) = 113\ \Omega.$$

A useful result here is that for normal U.S. 60-Hz electricity, $\omega = 2\pi f = 377$ rad/s. In comparison to this, the 1.0-Ω resistance can be ignored. Thus,

$$I_{\text{rms}} = \frac{V_{\text{rms}}}{X_L} = \frac{120\text{ V}}{113\ \Omega} = 1.06\text{ A}.$$

**NOTE** It might be tempting to say that the total impedance is 113 Ω + 1 Ω = 114 Ω. This might imply that about 1% of the voltage drop is across the resistor, or about 1 V; and that across the inductance is 119 V. Although the 1 V across the resistor is correct, the other statements are not true because of the phase difference in an inductor. This will be discussed in the next Section.

## Capacitor

When a capacitor is connected to a battery, the capacitor plates quickly acquire equal and opposite charges; but no steady current flows in the circuit. A capacitor prevents the flow of a dc current. But if a capacitor is connected to an alternating source of voltage, as in Fig. 30–17a, an alternating current will flow continuously. This can happen because when the ac voltage is first turned on, charge begins to flow and one plate acquires a negative charge and the other a positive charge. But when the voltage reverses itself, the charges flow in the opposite direction. Thus, for an alternating applied voltage, an ac current is present in the circuit continuously.

Let us look at this in more detail. By Kirchhoff's loop rule, the applied source voltage must equal the voltage $V$ across the capacitor (Eq. 24–1, $Q = CV$) at any moment:

$$V = \frac{Q}{C}$$

where $C$ is the capacitance and $Q$ is the charge on the capacitor plates. The current $I$ at any instant (given as $I = I_0 \cos\omega t$, Eq. 30–20) is

$$I = \frac{dQ}{dt} = I_0 \cos\omega t.$$

Hence the charge $Q$ on the plates at any instant $t$ is given by

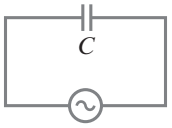
$$Q = \int_0^t dQ = \int_0^t I_0 \cos\omega t\, dt = \frac{I_0}{\omega}\sin\omega t.$$

Then the voltage across the capacitor is

$$V = \frac{Q}{C} = I_0\left(\frac{1}{\omega C}\right)\sin\omega t.$$

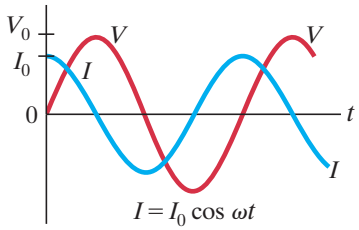
Using the trigonometric identity $\sin\theta = \cos(90° - \theta) = \cos(\theta - 90°)$, we can rewrite this as (changing 90° to $\frac{\pi}{2}$ radians which must be used in calculations)

$$V = I_0\left(\frac{1}{\omega C}\right)\cos\left(\omega t - \frac{\pi}{2}\right) = V_0 \cos\left(\omega t - \frac{\pi}{2}\right) \qquad \textbf{(30–24a)}$$



where

$$V_0 = I_0\left(\frac{1}{\omega C}\right) \qquad \textbf{(30–24b)}$$



is the peak voltage. The current $I\ (= I_0 \cos\omega t)$ and voltage $V$ (Eq. 30–24a) across the capacitor are graphed in Fig. 30–17b. It is clear from this graph, as well as a comparison of Eq. 30–24a with Eq. 30–20, that the current and voltage are out of phase by a quarter cycle or 90°, or $\frac{\pi}{2}$ radians:

**current leads the voltage by 90° $\left(\frac{\pi}{2}\text{ rad}\right)$ for a capacitor.**

Alternatively we can say that the voltage lags the current by 90° or $\pi/2$ radians. This is the opposite of what happens for an inductor.

(a) Capacitor only

$I = I_0 \cos\omega t$
$V = V_0 \sin\omega t$
$= V_0 \cos(\omega t - \frac{\pi}{2})$

(b)

**FIGURE 30–17** (a) Capacitor connected to an ac source. (b) Current leads voltage by a quarter cycle, or 90° = $\pi/2$ radians.

**CAUTION**

*Capacitors and inductors do not dissipate energy, only resistance does*

Because the current and voltage are out of phase by 90° in a capacitor ($\pi/2$ radians), the average power dissipated is zero, just as for an inductor. Energy from the source is fed to the capacitor, where it is stored in the electric field between its plates. As the field decreases, the energy returns to the source. Thus *only a resistance will dissipate energy* as thermal energy in an ac circuit.

A relationship between the applied voltage and the current in a capacitor can be written just as for an inductance:

$$V_0 = I_0 X_C \qquad \left[\begin{array}{c}\text{maximum or rms values,}\\ \text{not at any instant}\end{array}\right] \qquad \textbf{(30–25a)}$$

where $X_C$ is the **capacitive reactance** of the capacitor, and has units of ohms; $X_C$ is given by (see Eq. 30–24b):

$$X_C = \frac{1}{\omega C} = \frac{1}{2\pi f C}. \qquad \textbf{(30–25b)}$$

When frequency $f$ and/or capacitance $C$ are smaller, $X_C$ is larger and thus impedes the flow of charge more. That is, when $X_C$ is larger, the current is smaller (Eq. 30–25a). In the next Section we use the term **impedance** to represent reactances and resistance.

Equation 30–25a relates the *peak* values of $V$ and $I$, or the *rms* values ($V_{\text{rms}} = I_{\text{rms}} X_C$). But it is *not* valid at a particular instant because $I$ and $V$ are not in phase.

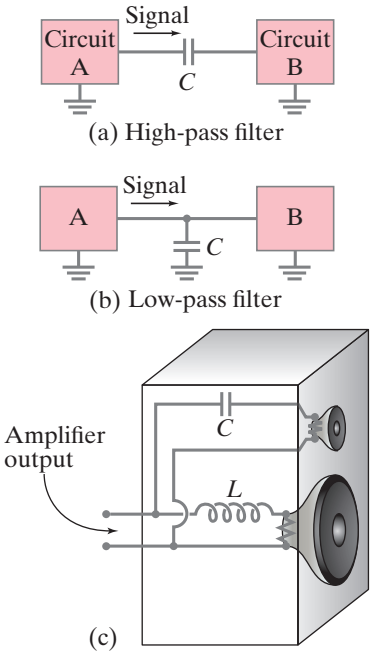
Note from Eq. 30–25b that for dc conditions, $\omega = 2\pi f = 0$ and $X_C$ becomes infinite. This is as it should be, since a capacitor does not pass dc current. Also, note that the reactance of an inductor increases with frequency, but the reactance of a capacitor decreases with frequency.

**EXAMPLE 30–10** **Capacitor reactance.** What is the rms current in the simple capacitor circuit of Fig. 30–17a (previous page) if $C = 1.00\,\mu\text{F}$ and $V_{\text{rms}} = 120\,\text{V}$? Calculate (*a*) for $f = 60.0\,\text{Hz}$, and then (*b*) for $f = 6.00 \times 10^5\,\text{Hz}$.

**APPROACH** We find the reactance using Eq. 30–25b, and solve for current in the equivalent form of Ohm's law, Eq. 30–25a.

**SOLUTION** (*a*) We have

$$X_C = \frac{1}{2\pi f C} = \frac{1}{(6.28)\left(60.0\,\text{s}^{-1}\right)\left(1.00 \times 10^{-6}\,\text{F}\right)} = 2.65\,k\Omega.$$



The rms current is (Eq. 30–25a):

$$I_{\text{rms}} = \frac{V_{\text{rms}}}{X_C} = \frac{120\,\text{V}}{2.65 \times 10^3\,\Omega} = 45.2\,\text{mA}.$$

(*b*) For $f = 6.00 \times 10^5\,\text{Hz}$, $X_C$ will be $0.265\,\Omega$ and $I_{\text{rms}} = 452\,\text{A}$, vastly larger!

**NOTE** The dependence of $X_L$ on $f$ is dramatic. For high frequencies, the capacitive reactance is very small.

**FIGURE 30–18** (a) and (b) Two common uses for a capacitor as a filter. (c) Simple loudspeaker cross-over.

**PHYSICS APPLIED**

*Capacitors as filters*

Two common applications of capacitors are illustrated in Fig. 30–18a and b. In Fig. 30–18a, circuit A is said to be capacitively coupled to circuit B. The purpose of the capacitor is to prevent a dc voltage from passing from A to B but allowing an ac signal to pass relatively unimpeded (if $C$ is sufficiently large, Eq. 30–25b). The capacitor in Fig. 30–18a is called a **high-pass filter** because it allows high-frequency ac to pass easily, but not dc and very little of low-frequency ac.

In Fig. 30–18b, the capacitor passes ac to ground, but not dc. In this case, a dc voltage can be maintained between circuits A and B, but an ac signal leaving A passes to ground instead of into B. Thus the capacitor in Fig. 30–18b acts as a **low-pass filter** when a constant dc voltage is required. Any high-frequency variation in voltage will pass to ground instead of into circuit B. (Very low-frequency ac will also be able to reach circuit B, at least in part.)

**PHYSICS APPLIED**

*Loudspeaker cross-over*

Loudspeakers having separate "woofer" (low-frequency speaker) and "tweeter" (high-frequency speaker) may use a simple "cross-over" that consists of a capacitor in the tweeter circuit to impede low-frequency signals, and an inductor in the woofer circuit to impede high-frequency signals $(X_L = 2\pi f L)$. Hence mainly low-frequency sounds reach and are emitted by the woofer. See Fig. 30–18c.

**EXERCISE F** At what frequency is the reactance of a 1.0-$\mu$F capacitor equal to $500\,\Omega$? (*a*) 320 Hz, (*b*) 500 Hz, (*c*) 640 Hz, (*d*) 2000 Hz, (*e*) 4000 Hz.

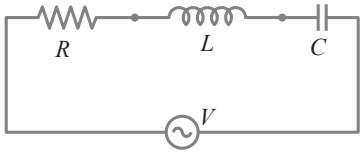


**FIGURE 30–19** An *LRC* circuit.

# 30–8 *LRC* Series AC Circuit; Phasor Diagrams

Let us examine a circuit containing all three elements in series: a resistor $R$, an inductor $L$, and a capacitor $C$, Fig. 30–19. If a given circuit contains only two of these elements, we can still use the results of this Section by setting $R = 0$, $X_L = 0$, or $X_C = 0$, as needed. We let $V_R$, $V_L$, and $V_C$ represent the voltage across each element at a *given instant* in time; and $V_{R0}$, $V_{L0}$, and $V_{C0}$ represent the *maximum* (peak) values of these voltages. The voltage across each of the elements will follow the phase relations we discussed in the previous Section. At any instant the voltage $V$ supplied by the source will be, by Kirchhoff's loop rule,

$$V = V_R + V_L + V_C. \qquad \textbf{(30–26a)}$$

Because the various voltages are not in phase, they do not reach their peak values at the same time, so the peak voltage of the source $V_0$ will *not* equal $V_{R0} + V_{L0} + V_{C0}$. The current in an *LRC* circuit at any instant is the same at all points in the circuit (charge does not pile up in the wires). Thus the currents in each element are in phase with each other, even though the voltages are not. We choose our origin in time $(t = 0)$ so that the current $I$ at any time $t$ is (as in Eq. 30–20)

$$I = I_0 \cos \omega t.$$

AC circuits are complicated to analyze. One approach† is to use a sort of vector device known as a **phasor diagram**. Arrows (treated like vectors) are drawn in an $xy$ coordinate system to represent each voltage. The length of each arrow represents the magnitude of the peak voltage across each element:

$$V_{R0} = I_0 R, \qquad V_{L0} = I_0 X_L, \qquad \text{and} \qquad V_{C0} = I_0 X_C.$$

$V_{R0}$ is in phase with the current and is initially $(t = 0)$ drawn along the positive $x$ axis, as is the current (Fig. 30–20a). $V_{L0}$ leads the current by 90°, so it leads $V_{R0}$ by 90° and is initially drawn along the positive $y$ axis. $V_{C0}$ lags the current by 90°, so $V_{C0}$ is drawn initially along the negative $y$ axis, Fig. 30–20a.

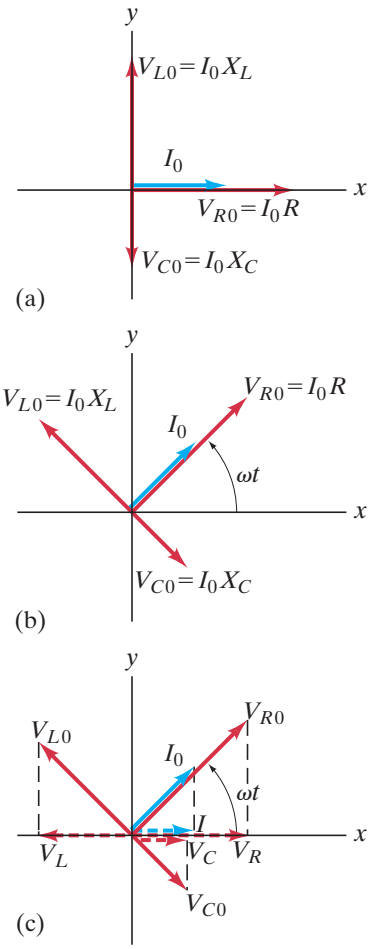
If we let the vector diagram rotate counterclockwise at frequency $f$, we get the diagram shown in Fig. 30–20b; after a time, $t$, each arrow has rotated through an angle $\omega t$. Then the *projections of each arrow onto the x axis represent the voltages across each element at the instant t*, as can be seen in Fig. 30–20c. For example $I = I_0 \cos \omega t$. [Compare Eqs. 30–22a and 30–24a with Fig. 30–20c to confirm the validity of the phasor diagram.]

The sum of the projections of the three voltage vectors represents the *instantaneous* voltage across the whole circuit, $V$, at a given instant. Therefore, the vector sum of these vectors will be the vector that represents the peak source voltage, $V_0$, as shown in Fig. 30–21 where it is seen that $V_0$ makes an angle $\phi$ with $I_0$ and $V_{R0}$. As time passes, $V_0$ rotates with the other vectors, so the instantaneous voltage $V$ (projection of $V_0$ on the $x$ axis) is (see Fig. 30–21)

$$V = V_0 \cos(\omega t + \phi). \qquad \textbf{(30–26b)}$$

The voltage $V$ across the whole circuit must equal the source voltage (Fig. 30–19). Thus the voltage from the source is out of phase with the current by an angle $\phi$. As a check, note in Eq. 30–26b and Fig. 30–21 that if $R = X_C = 0$, then $\phi = \pi/2$, and $V_0$ would lead the current by 90°, as it must for an inductor alone. Similarly, if $R = L = 0$, $\phi = -\pi/2$ and $V_0$ would lag the current by 90°, as it must for a capacitor alone.

†We could instead do our analysis by rewriting Eq. 30–26a as a differential equation (setting $V_C = Q/C$, $V_R = IR = (dQ/dt)R$, and $V_L = L\, dI/dt = Ld^2Q/dt^2$ and trying to solve the differential equation. The differential equation would look like Eq. 14–21 in Section 14–8 (on forced vibrations), and would be solved in the same way. Phasor diagrams are mathematically simpler, and also give us some physical insight.



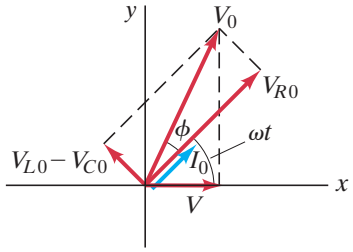


**FIGURE 30–20** Phasor diagram for a series *LRC* circuit (voltages red, current blue). (a) At $t = 0$, (b) a time $t$ later. (c) Projections (dashed) on the $x$ axis which give $I$, $V_R$, $V_C$, and $V_L$ at time $t$.

**FIGURE 30–21** Phasor diagram for a series *LRC* circuit showing the sum vector, $V_0$.

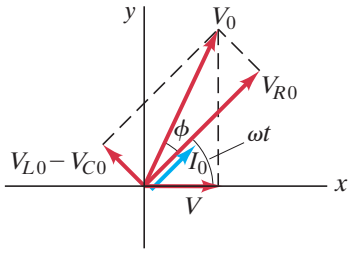

**FIGURE 30–21** (Repeated.) Phasor diagram for a series *LRC* circuit showing the sum vector, $V_0$.

From this analysis we can now determine the total **impedance** $Z$ of the circuit, which is defined in analogy to resistance and reactance as

$$V_{\text{rms}} = I_{\text{rms}} Z, \quad \text{or} \quad V_0 = I_0 Z, \tag{30–27}$$

where as usual $V_{\text{rms}} = V_0/\sqrt{2}$ and $I_{\text{rms}} = I_0/\sqrt{2}$.

From Fig. 30–21 we see, using the Pythagorean theorem ($V_0$ is the hypotenuse of a right triangle), that

$$V_0 = \sqrt{V_{R0}^2 + (V_{L0} - V_{C0})^2}$$
$$= I_0\sqrt{R^2 + (X_L - X_C)^2}.$$

Thus, using Eq. 30–27, the total impedance $Z$ is (see also Eqs. 30–23b and 30–25b)

$$Z = \sqrt{R^2 + (X_L - X_C)^2} \tag{30–28a}$$

$$= \sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}. \tag{30–28b}$$

Also from Fig. 30–21, we can find the phase angle $\phi$ between voltage and current:

$$\tan\phi = \frac{V_{L0} - V_{C0}}{V_{R0}} = \frac{I_0(X_L - X_C)}{I_0 R} = \frac{X_L - X_C}{R}, \tag{30–29a}$$

and

$$\cos\phi = \frac{V_{R0}}{V_0} = \frac{I_0 R}{I_0 Z} = \frac{R}{Z}. \tag{30–29b}$$

Figure 30–21 was drawn for the case $X_L > X_C$, and the current *lags* the source voltage by $\phi$. When the reverse is true, $X_L < X_C$, then $\phi$ in Eqs. 30–29 is less than zero, and the current *leads* the source voltage.

We saw earlier that power is dissipated only by a resistance; none is dissipated by inductance or capacitance. Therefore, the average power $\overline{P} = I_{\text{rms}}^2 R$. But from Eq. 30–29b, $R = Z\cos\phi$. Therefore

$$\overline{P} = I_{\text{rms}}^2 Z\cos\phi = I_{\text{rms}} V_{\text{rms}} \cos\phi. \tag{30–30}$$

The factor $\cos\phi$ is referred to as the **power factor** of the circuit. For a pure resistor, $\cos\phi = 1$ and $\overline{P} = I_{\text{rms}} V_{\text{rms}}$. For a capacitor or inductor alone, $\phi = -\pi/2$ or $+\pi/2$ respectively, so $\cos\phi = 0$ and no power is dissipated.

**EXAMPLE 30–11** ***LRC* series circuit.** Suppose $R = 25.0\,\Omega$, $L = 30.0\,\text{mH}$, and $C = 12.0\,\mu\text{F}$ in a series *LRC* circuit, Fig. 30–19, and they are connected in series to a 90.0-V ac (rms) 500-Hz source. Calculate (*a*) the rms current in the circuit, (*b*) the voltmeter readings (rms) across each element, (*c*) the phase angle $\phi$, and (*d*) the power dissipated in the circuit.

**APPROACH** To obtain the current we need to determine the impedance (Eq. 30–28b), and then use $I_{\text{rms}} = V_{\text{rms}}/Z$. Voltage drops across each element are found using Ohm's law or equivalent for each element: $V_R = IR$, $V_L = IX_L$, and $V_C = IX_C$.

**SOLUTION** (*a*) First, we find the reactance of the inductor and capacitor at $f = 500\,\text{Hz} = 500\,\text{s}^{-1}$:

$$X_L = 2\pi fL = 94.2\,\Omega, \qquad X_C = \frac{1}{2\pi fC} = 26.5\,\Omega.$$

Then the total impedance is

$$Z = \sqrt{R^2 + (X_L - X_C)^2} = \sqrt{(25.0\,\Omega)^2 + (94.2\,\Omega - 26.5\,\Omega)^2} = 72.2\,\Omega.$$

From the impedance version of Ohm's law, Eq. 30–27,

$$I_{\text{rms}} = \frac{V_{\text{rms}}}{Z} = \frac{90.0\,\text{V}}{72.2\,\Omega} = 1.25\,\text{A}.$$

(*b*) The rms voltage across each element is

$$(V_R)_{\text{rms}} = I_{\text{rms}} R = (1.25\,\text{A})(25.0\,\Omega) = 31.2\,\text{V}$$
$$(V_L)_{\text{rms}} = I_{\text{rms}} X_L = (1.25\,\text{A})(94.2\,\Omega) = 118\,\text{V}$$
$$(V_C)_{\text{rms}} = I_{\text{rms}} X_C = (1.25\,\text{A})(26.5\,\Omega) = 33.1\,\text{V}.$$

**NOTE** These voltages do *not* add up to the source voltage, 90.0 V (rms). Indeed, the rms voltage across the inductance (118 V) *exceeds* the source voltage. This can happen because the different voltages are out of phase with each other: so, at any instant the capacitor's voltage might be negative which compensates for a large positive inductor voltage. The rms voltages, however, are always positive by definition. Although the rms voltages need not add up to the source voltage, the instantaneous voltages at any time must add up to the source voltage at that instant.

**CAUTION**
*Individual peak or rms voltages do NOT add up to source voltage (due to phase differences)*

(*c*) The phase angle $\phi$ is given by Eq. 30–29b,

$$\cos\phi = \frac{R}{Z} = \frac{25.0\,\Omega}{72.2\,\Omega} = 0.346,$$

so $\phi = 1.22\,\text{rad} \approx 70°$. Note that $\phi$ is positive because $X_L > X_C$ in this case, so $V_{L0} > V_{C0}$ as in Fig. 30–21.

(*d*) $\overline{P} = I_{\text{rms}} V_{\text{rms}} \cos\phi = (1.25\,\text{A})(90.0\,\text{V})(25.0\,\Omega/72.2\,\Omega) = 39.0\,\text{W}$.

*LRC* circuits with elements in parallel are treated in Problems 89, 91, and 96.

## 30–9 Resonance in AC Circuits

The rms current in an *LRC* series circuit is given by (see Eqs. 30–27 and 30–28b):

$$I_{\text{rms}} = \frac{V_{\text{rms}}}{Z} = \frac{V_{\text{rms}}}{\sqrt{R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2}}. \qquad \textbf{(30–31)}$$

Because the reactance of inductors and capacitors depends on the frequency $f\,(=\omega/2\pi)$ of the source, the current in an *LRC* circuit will depend on frequency. From Eq. 30–31 we can see that the current will be maximum at a frequency that satisfies

$$\left(\omega L - \frac{1}{\omega C}\right) = 0.$$

We solve this for $\omega$ and call the solution $\omega_0$:

$$\omega_0 = \sqrt{\frac{1}{LC}}. \qquad \text{[resonance]} \quad \textbf{(30–32a)}$$

When $\omega = \omega_0$, the circuit is in **resonance**, and

$$f_0 = \omega_0/2\pi = \frac{1}{2\pi\sqrt{LC}} \qquad \textbf{(30–32b)}$$

is the **resonant frequency** of the circuit. At this frequency, $X_C = X_L$, so the impedance is purely resistive (and $\cos\phi = 1$). A graph of $I_{\text{rms}}$ versus $\omega$ is shown in Fig. 30–22 for particular values of $R$, $L$, and $C$. For small $R$ compared to $X_L$ and $X_C$, the resonance peak will be higher and sharper. When $R$ is very small, the circuit approaches the pure *LC* (oscillator) circuit we discussed in Section 30–5. When $R$ is large compared to $X_L$ and $X_C$, the resonance curve is relatively flat—there is little frequency dependence.

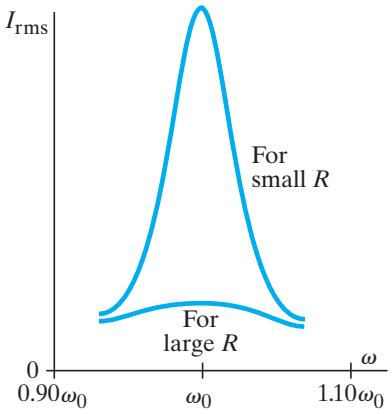

**FIGURE 30–22** Current in *LRC* circuit as a function of angular frequency, $\omega$, showing resonance peak at $\omega = \omega_0 = \sqrt{1/LC}$.

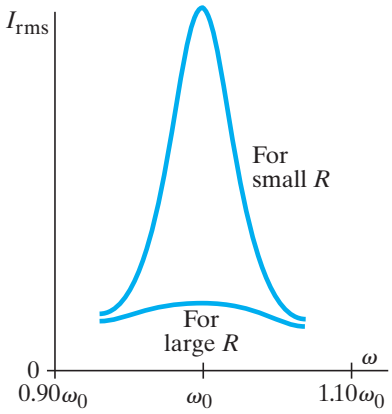

**FIGURE 30–22** (Repeated.) Current in $LRC$ circuit as a function of angular frequency, $\omega$, showing resonance peak at $\omega = \omega_0 = \sqrt{1/LC}$.

This electrical resonance is analogous to mechanical resonance, discussed in Chapter 14. The energy transferred to the system by the source is a maximum at resonance whether it is electrical resonance, the oscillation of a spring, or pushing a child on a swing (Section 14–8). That this is true in the electrical case can be seen from Eq. 30–30; at resonance, $\cos\phi = 1$, and power $\overline{P}$ is a maximum. A graph of power versus frequency peaks like that for the current, Fig. 30–22.

Electric resonance is used in many circuits. Radio and TV sets, for example, use resonant circuits for tuning in a station. Many frequencies reach the circuit from the antenna, but a significant current flows only for those at or near the resonant frequency. Either $L$ or $C$ is variable in the resonant tuning circuit, so that different stations can be tuned in.

## 30–10 Impedance Matching

It is common to connect one electric circuit to a second circuit. For example, a TV antenna is connected to a TV receiver; an amplifier is connected to a loudspeaker; electrodes for an electrocardiogram are connected to a recorder. Maximum power is transferred from one to the other, with a minimum of loss, when the output impedance of the one device matches the input impedance of the second.

To show why, we consider simple circuits that contain only resistance. In Fig. 30–23 the source in circuit 1 could represent the signal from an antenna or a laboratory probe, and $R_1$ represents its resistance including internal resistance of the source. $R_1$ is called the output impedance (or resistance) of circuit 1. The output of circuit 1 is across the terminals a and b which are connected to the input of circuit 2, which may be very complicated. We let $R_2$ be the equivalent "input resistance" of circuit 2.

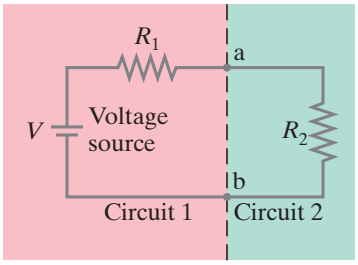

**FIGURE 30–23** Output of the circuit on the left is input to the circuit on the right.

The power delivered to circuit 2 is $P = I^2R_2$ where $I = V/(R_1 + R_2)$ is the current that passes through both circuits. Thus

$$P = I^2R_2 = \frac{V^2R_2}{(R_1 + R_2)^2}.$$

If the resistance of the source is $R_1$, what value should $R_2$ have so that the maximum power is transferred to circuit 2? To determine a maximum, we take the derivative of $P$ with respect to $R_2$ and set it equal to zero, which gives

$$V^2\left[\frac{1}{(R_1 + R_2)^2} - \frac{2R_2}{(R_1 + R_2)^3}\right] = V^2\left[\frac{R_1 + R_2 - 2R_2}{(R_1 + R_2)^3}\right] = 0$$

or

$$R_2 = R_1.$$

Thus, the maximum power is transmitted when the *output impedance* of one device *equals the input impedance* of the second. This is called **impedance matching**.

In an ac circuit that contains capacitors and inductors, the different phases are important and the analysis is more complicated. However, the same result holds: to maximize power transfer it is important to match impedances $(Z_2 = Z_1)$.

In addition, it is possible to seriously distort a signal if impedances do not match closely, and has in some cases led to meaningless or erroneous experimental results.

**⚠ CAUTION**

*Erroneous results can occur if impedances don't match well*

## *30–11 Three-Phase AC

Transmission lines typically consist of four wires, rather than two. One of these wires is the ground; the remaining three are used to transmit three-phase ac power which is a superposition of three ac voltages 120° out of phase with each other:

$$V_1 = V_0 \sin \omega t$$
$$V_2 = V_0 \sin(\omega t + 2\pi/3)$$
$$V_3 = V_0 \sin(\omega t + 4\pi/3).$$

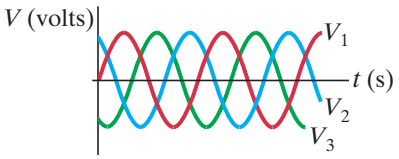

**FIGURE 30–24** The three voltages, (red, green, blue) out of phase by 120° $(= \frac{2}{3}\pi$ radians$)$, in a three-phase power line.

(See Fig. 30–24.) Why is three-phase power used? We saw in Fig. 25–22 that single-phase ac (i.e., the voltage $V_1$ by itself) delivers power to the load in pulses. A much smoother flow of power can be delivered using three-phase power. Suppose that each of the three voltages making up the three-phase source is hooked up to a resistor $R$. Then the power delivered is:

$$P = \frac{1}{R}(V_1^2 + V_2^2 + V_3^2).$$

You can show (Problem 67) that this power is a constant equal to $3V_0^2/2R$, which is three times the rms power delivered by a single-phase source. This smooth flow of power makes electrical equipment run smoothly. Although houses use single-phase ac power, most industrial-grade machinery is wired for three-phase power.

**EXAMPLE 30–12** **Three-phase circuit.** In a three-phase circuit, 266 V (rms) exists between line 1 and ground. What is the rms voltage between lines 2 and 3?

**SOLUTION** We are given $V_{\text{rms}} = V_0/\sqrt{2} = 266\,\text{V}$. Hence $V_0 = 376\,\text{V}$. Now $V_3 - V_2 = V_0[\sin(\omega t + 4\pi/3) - \sin(\omega t + 2\pi/3)] = 2V_0 \sin\frac{1}{2}(\frac{2\pi}{3})\cos\frac{1}{2}(2\omega t)$ where we used the identity: $\sin A - \sin B = 2\left[\sin\frac{1}{2}(A - B)\right]\left[\cos\frac{1}{2}(A + B)\right]$. The rms voltage is

$$(V_3 - V_2)_{\text{rms}} = \frac{1}{\sqrt{2}} 2V_0 \sin\frac{\pi}{3} = \sqrt{2}(376\,\text{V})(0.866) = 460\,\text{V (rms)}.$$

## Summary

A changing current in a coil of wire will induce an emf in a second coil placed nearby. The **mutual inductance**, $M$, is defined as the proportionality constant between the induced emf $\mathcal{E}_2$ in the second coil and the time rate of change of current in the first:

$$\mathcal{E}_2 = -M\, dI_1/dt. \qquad \textbf{(30–3b)}$$

We can also write $M$ as

$$M = \frac{N_2\Phi_{21}}{I_1} \qquad \textbf{(30–1)}$$

where $\Phi_{21}$ is the magnetic flux through coil 2 with $N_2$ loops, produced by the current $I_1$ in another coil (coil 1).

Within a single coil, a changing current induces an opposing emf, $\mathcal{E}$, so a coil has a **self-inductance** $L$ defined by

$$\mathcal{E} = -L\, dI/dt. \qquad \textbf{(30–5)}$$

This induced emf acts as an *impedance* to the flow of an alternating current. We can also write $L$ as

$$L = N\frac{\Phi_B}{I} \qquad \textbf{(30–4)}$$

where $\Phi_B$ is the flux through the inductance when a current $I$ flows in its $N$ loops.

When the current in an inductance $L$ is $I$, the energy stored in the inductance is given by

$$U = \tfrac{1}{2}LI^2. \qquad \textbf{(30–6)}$$

This energy can be thought of as being stored in the magnetic field of the inductor. The energy density $u$ in any magnetic field $B$ is given by

$$u = \frac{1}{2}\frac{B^2}{\mu_0}, \qquad \textbf{(30–7)}$$

where $\mu_0$ is replaced by $\mu$ if a ferromagnetic material is present.

When an inductance $L$ and resistor $R$ are connected in series to a constant dc source of emf, $V_0$, the current rises according to an exponential of the form

$$I = \frac{V_0}{R}(1 - e^{-t/\tau}), \qquad \textbf{(30–9)}$$

where

$$\tau = L/R \qquad \textbf{(30–10)}$$

is the **time constant**. The current eventually levels out at $I = I_0 = V_0/R$. If the battery is suddenly switched out of the ***LR* circuit**, and the circuit remains complete, the current drops exponentially, $I = I_0 e^{-t/\tau}$, with the same time constant $\tau$.

The current in a pure ***LC* circuit** (or charge on the capacitor) would oscillate sinusoidally. The energy too would oscillate back and forth between electric and magnetic, from the capacitor to the inductor, and back again. If such a circuit has resistance (*LRC*), and the capacitor at some instant is charged, it can undergo damped oscillations or exhibit critically damped or overdamped behavior.

Capacitance and inductance offer *impedance* to the flow of alternating current just as resistance does. This impedance is referred to as **reactance**, $X$, and is defined (as for resistors) as the proportionality constant between voltage and current (either the rms or peak values). Across an inductor,

$$V_0 = I_0 X_L, \qquad \textbf{(30–23a)}$$

and across a capacitor,

$$V_0 = I_0 X_C. \qquad \textbf{(30–25a)}$$

The reactance of an inductor increases with frequency:

$$X_L = \omega L. \qquad \textbf{(30–23b)}$$

where $\omega = 2\pi f$ and $f$ is the frequency of the ac. The reactance of a capacitor decreases with frequency:

$$X_C = \frac{1}{\omega C}. \qquad \textbf{(30–25b)}$$

Whereas the current through a resistor is always in phase with the voltage across it, this is not true for inductors and capacitors: in an inductor, the current lags the voltage by 90° or $\pi/2$ radians, and in a capacitor the current leads the voltage by 90° or $\pi/2$ radians.

In an ac ***LRC* series circuit**, the total **impedance** $Z$ is defined by the equivalent of $V = IR$ for resistance: namely $V_0 = I_0 Z$ or $V_{\text{rms}} = I_{\text{rms}} Z$. The impedance $Z$ is related to $R$, $C$, and $L$ by

$$Z = \sqrt{R^2 + (X_L - X_C)^2}. \qquad \textbf{(30–28a)}$$

The current in the circuit lags (or leads) the source voltage by an angle $\phi$ given by $\cos\phi = R/Z$. Only the resistor in an ac *LRC* circuit dissipates energy, and at a rate

$$\overline{P} = I_{\text{rms}}^2 Z \cos\phi \qquad \textbf{(30–30)}$$

where the factor $\cos\phi$ is referred to as the **power factor**.

An *LRC* series circuit **resonates** at a frequency given by

$$\omega_0 = \sqrt{\frac{1}{LC}}. \qquad \textbf{(30–32a)}$$

The rms current in an *LRC* circuit is largest (as is the power transferred) when the applied voltage has a frequency equal to $f_0\ (= \omega_0/2\pi)$. The lower the resistance $R$, the higher and sharper the resonance peak.

# Questions

1. How would you arrange two flat circular coils so that their mutual inductance was (*a*) greatest, (*b*) least (without separating them by a great distance)? Explain.
2. The second coil of $N_2$ turns in Fig. 30–2 is moved so it is near the end of the solenoid. How does this affect the mutual inductance?
3. Would two coils with mutual inductance also have self-inductance? Explain.
4. Is the energy density inside a solenoid greatest near the ends of the solenoid or near its center?
5. If you are given a fixed length of wire, how would you shape it to obtain the greatest self-inductance? The least?
6. Does the emf of the battery in Fig. 30–6a affect the time needed for the *LR* circuit to reach (*a*) a given fraction of its maximum possible current, (*b*) a given value of current? Explain.
7. A circuit with large inductive time constant carries a steady current. If a switch is opened, there can be a very large (and sometimes dangerous) spark or "arcing over." Explain. [*Hint*: Problem 25 may help.]
8. At the instant the battery is connected into the *LR* circuit of Fig. 30–6a, the emf in the inductor has its maximum value even though the current is zero. Explain.
9. What keeps an *LC* circuit oscillating even after the capacitor has discharged completely?
10. In an *LRC* circuit, can the rms voltage across (*a*) an inductor, (*b*) a capacitor, be greater than the rms voltage of the ac source? Explain.
11. When an ac generator is connected to an *LRC* circuit, where does the energy come from ultimately? Where does it go? How do the values of $L$, $C$, and $R$ affect the energy supplied by the generator?
12. In an ac *LRC* circuit, if $X_L > X_C$, the circuit is said to be predominantly "inductive." And if $X_C > X_L$, the circuit is said to be predominantly "capacitive." Discuss the reasons for these terms. In particular, do they say anything about the relative values of $L$ and $C$ at a given frequency?
13. Do the results of Section 30–8 approach the proper expected results when $\omega$ approaches zero? What are the expected results?
14. Under what conditions is the impedance in an *LRC* circuit a minimum?
15. Is it possible for the instantaneous power output of an ac generator connected to an *LRC* circuit ever to be negative? Explain.
16. In an ac *LRC* circuit, does the power factor, $\cos\phi$, depend on frequency? Does the power dissipated depend on frequency?
17. Describe briefly how the frequency of the source emf affects the impedance of (*a*) a pure resistance, (*b*) a pure capacitance, (*c*) a pure inductance, (*d*) an *LRC* circuit near resonance ($R$ small), (*e*) an *LRC* circuit far from resonance ($R$ small).
18. Discuss the response of an *LRC* circuit as $R \to 0$ when the frequency is (*a*) at resonance, (*b*) near resonance, (*c*) far from resonance. Is there energy dissipation in each case? Discuss the transformations of energy that occur in each case.
19. An *LRC* resonant circuit with low resistance is often called an *oscillator* circuit. What is it that oscillates?
20. Compare the oscillations of an *LRC* circuit to the vibration of a mass $m$ on a spring. What do $L$ and $C$ correspond to in the mechanical system?
21. Describe how to make the impedance in an *LRC* circuit a minimum.

# MisConceptual Questions

**1.** How would you orient two flat circular coils so that their mutual inductance was greatest?
(*a*) Have their "faces" be parallel to each other.
(*b*) Have their "faces" be at 45° relative to each other.
(*c*) Have their "faces" be perpendicular to each other.
(*d*) The orientation of the faces does not affect their mutual inductance.

**2.** If you have 1.0 m of wire, how would you shape it to obtain the greatest self-inductance?
(*a*) Leave it straight.
(*b*) Make one single loop.
(*c*) Make two loops.
(*d*) Make many tiny loops.
(*e*) It won't matter.

**3.** A circuit with a large inductive time constant carries a steady current. When a switch is opened, causing the current to be interrupted, what happens?
(*a*) The current drops to zero in a very short time with no other effects.
(*b*) A current in the opposite direction of the original current is induced in the circuit.
(*c*) A (possibly large) emf is induced which can lead to a spark or "arcing over."
(*d*) The inductive reactance increases due to the sudden current decrease.
[*Hint*: Problem 25 may be helpful.]

**4.** What would increase the period of an oscillating $LC$ circuit the most?
(*a*) Double the inductance.
(*b*) Double the capacitance.
(*c*) Double both the inductance and the capacitance.
(*d*) Double the maximum charge on the capacitor.
(*e*) Double the maximum current through the inductor.

**5.** How does the resistance affect the period of an oscillating $LC$ circuit with low resistance?
(*a*) The smaller the resistance, the larger the period.
(*b*) The smaller the resistance, the smaller the period.
(*c*) The resistance does not affect the period.
(*d*) There is a specific non-zero resistance at which the period is minimized.
(*e*) There is a specific non-zero resistance at which the period is maximized.

**6.** Which of the following actions will *always* increase the rms current in an $LRC$ series ac circuit?
(*a*) Increase the source voltage.
(*b*) Increase the source frequency.
(*c*) Increase the resistance in the circuit.
(*d*) Increase the capacitance in the circuit.
(*e*) Increase the inductance in the circuit.
(*f*) None of the above.

**7.** In an oscillating $LC$ circuit, what oscillates?
(*a*) The amount of charge on the capacitor.
(*b*) The current in the inductor.
(*c*) The voltage across the capacitor.
(*d*) The voltage across the inductor.
(*e*) All of the above quantities.

**8.** Is the ac current in the inductor always the same as the current in the resistor of the $LRC$ circuit of Fig. 30–19?
(*a*) No.
(*b*) Yes, but only when $X_C = X_L$.
(*c*) Yes, but only if $R = 0$.
(*d*) Yes, always.
(*e*) It depends.

**9.** A series $LRC$ circuit has been connected to an ac source for a long time. The average power is given by Eq. 30–30. The average power
(*a*) is transformed into heat by the resistor.
(*b*) goes into energy stored by the magnetic field in the inductor.
(*c*) goes into energy stored by the electric field in the capacitor.
(*d*) (*a*), (*b*), and (*c*) are all true.
(*e*) Only (*b*) and (*c*) are true.

**10.** In an $LRC$ circuit, what must be in phase with the input voltage?
(*a*) The voltage across the resistor.
(*b*) The voltage across the inductor.
(*c*) The voltage across the capacitor.
(*d*) The current through the resistor.
(*e*) All of the above.
(*f*) None of the above.

**11.** Which of the following is true about all series ac circuits?
(*a*) The voltage across any circuit element is a maximum when the current is a maximum in that circuit element.
(*b*) The current at any point in the circuit is always the same as the current at any other point in the circuit.
(*c*) The current in the circuit is a maximum when the source ac voltage is a maximum.
(*d*) Resistors, capacitors, and inductors can all change the phase of the current.

**12.** In an $LRC$ circuit with ac source, the peak source voltage $V_0$ equals
(*a*) $V_{R0} + V_{L0} + V_{C0}$.
(*b*) $V_{R0} + V_{L0} - V_{C0}$.
(*c*) $V_{L0} - V_{C0}$.
(*d*) None of the above.

**13.** Under what circumstance is the impedance in an $LRC$ circuit a minimum?
(*a*) When $C = 0$.
(*b*) When $L = 0$.
(*c*) At resonance.

# Problems

## 30–1 Mutual Inductance

**1.** (II) Determine the mutual inductance per unit length between two long solenoids, one inside the other, whose radii are $r_1$ and $r_2$ $(r_2 < r_1)$ and whose turns per unit length are $n_1$ and $n_2$.

**2.** (II) A small thin coil with $N_2$ loops, each of area $A_2$, is placed inside a long solenoid, near its center. The solenoid has $N_1$ loops in its length $\ell$ and has area $A_1$. Determine the mutual inductance as a function of $\theta$, the angle between the plane of the small coil and the axis of the solenoid.

**3.** (II) A 2.44-m-long coil containing 265 loops is wound on an iron core (average $\mu = 1850\mu_0$) along with a second coil of 115 loops. The loops of each coil have a radius of 2.00 cm. (*a*) Determine the mutual inductance $M$. (*b*) If the current in the first coil drops uniformly from 12.0 A to zero in 98.0 ms, determine the emf induced in the second coil.

**4.** (III) A long straight wire and a small rectangular wire loop lie in the same plane, Fig. 30–25. Determine the mutual inductance in terms of $\ell_1, \ell_2$, and $w$. Assume the wire is very long compared to $\ell_1, \ell_2$, and $w$, and that the rest of its circuit is very far away compared to $\ell_1, \ell_2$, and $w$.

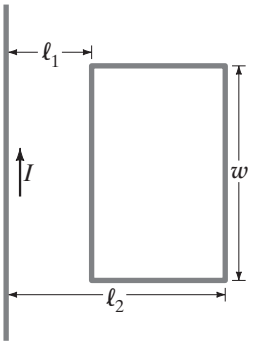

**FIGURE 30–25**
Problem 4.

## 30–2 Self-Inductance; Inductors

**5.** (I) Determine the inductance $L$ of a 0.60-m-long air-filled solenoid 2.9 cm in diameter containing 7500 loops.

**6.** (I) How many turns of wire would be required to make a 130-mH inductor out of a 33.0-cm-long air-filled coil solenoid with a diameter of 4.2 cm?

**7.** (I) What is the inductance of a coil if the coil produces an emf of 2.20 V when the current in it changes from −28.0 mA to +25.0 mA in 12.0 ms?

**8.** (II) An air-filled cylindrical inductor has 3200 turns, and it is 2.5 cm in diameter and 28.2 cm long. (*a*) What is its inductance? (*b*) How many turns would you need to generate the same inductance if the core were iron-filled instead? Assume the magnetic permeability of iron is about 1200 times that of free space.

**9.** (II) A coil has 3.25-Ω resistance and 440-mH inductance. If the current is 3.00 A and is increasing at a rate of 3.15 A/s, what is the potential difference across the coil at this moment?

**10.** (II) If the outer conductor of a coaxial cable has radius 3.0 mm, what should be the radius of the inner conductor so that the inductance per unit length does not exceed 75 nH per meter?

**11.** (II) The wire of a tightly wound solenoid is unwound and used to make another tightly wound solenoid of 2.2 times the diameter. By what factor does the inductance change?

**12.** (II) Ignoring any mutual inductance, what is the equivalent inductance of two inductors connected (*a*) in series, (*b*) in parallel?

**13.** (III) A toroid has a rectangular cross section as shown in Fig. 30–26. Show that the self-inductance is

$$L = \frac{\mu_0 N^2 h}{2\pi} \ln \frac{r_2}{r_1}$$

where $N$ is the total number of turns and $r_1, r_2$, and $h$ are the dimensions shown in Fig. 30–26. [*Hint*: Use Ampère's law to get $B$ as a function of $r$ inside the toroid, and integrate.]

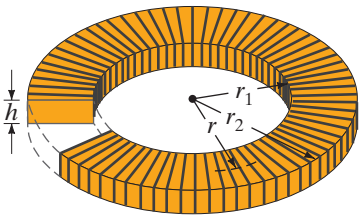

**FIGURE 30–26**
Problems 13 and 18. A toroid of rectangular cross section, with $N$ turns carrying a current $I$.

## 30–3 Magnetic Energy Storage

**14.** (I) The magnetic field inside an air-filled solenoid 38.0 cm long and 2.10 cm in diameter is 0.720 T. Approximately how much energy is stored in this field?

**15.** (I) Typical large values for electric and magnetic fields attained in laboratories are about $1.0 \times 10^4$ V/m and 2.0 T. (*a*) Determine the energy density for each field and calculate the ratio of electric to magnetic energy. (*b*) What magnitude electric field would be needed to produce the same energy density as the 2.0-T magnetic field?

**16.** (II) What is the energy density at the center of a circular loop of wire carrying a 19.0-A current if the radius of the loop is 28.0 cm?

**17.** (II) Calculate the magnetic and electric energy densities at the surface of a 3.0-mm-diameter copper wire carrying an 18-A current. [*Hint*: Do not ignore resistance of the wire.]

**18.** (II) For the toroid of Fig. 30–26, determine the energy density in the magnetic field as a function of $r$ $(r_1 < r < r_2)$ and integrate this over the volume to obtain the total energy stored in the toroid, which carries a current $I$ in each of its $N$ loops.

**19.** (II) Determine the total energy stored per unit length in the magnetic field between the coaxial cylinders of a coaxial cable (Fig. 30–5) by using Eq. 30–7 for the energy density and integrating over the volume.

**20.** (II) A long straight wire of radius $r$ carries current $I$ uniformly distributed across its cross-sectional area. Find the magnetic energy stored per unit length in the interior of this wire.

## 30–4 *LR* Circuits

**21.** (II) It takes 2.85 ms for the current in an $LR$ circuit to increase from zero to 0.75 its maximum value. Determine (*a*) the time constant of the circuit, (*b*) the resistance of the circuit if $L = 31.0$ mH.

**22.** (II) How many time constants does it take for the potential difference across the resistor in an $LR$ circuit like that in Fig. 30–7 to drop to 2.0% of its original value, after the switch is moved to the upper position, removing $V_0$ from the circuit?

23. (II) (*a*) Determine the energy stored in the inductor $L$ as a function of time for the $LR$ circuit of Fig. 30–6a. (*b*) After how many time constants does the stored energy reach 99.9% of its maximum value?

24. (II) In the circuit of Fig. 30–27, determine the current in each resistor ($I_1, I_2, I_3$) at the moment (*a*) the switch is closed, (*b*) a long time after the switch is closed. After the switch has been closed for a long time, and then reopened, what is each current (*c*) just after it is opened, (*d*) after a long time?

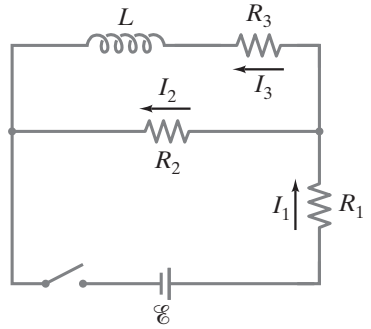

**FIGURE 30–27** Problem 24.

25. (II) (*a*) In Fig. 30–28, assume that the switch has been in position A for sufficient time so that a steady current $I_0 = V_0/R$ flows through the resistor $R$. At time $t = 0$, the switch is quickly switched to position B and the current decays through resistor $R'$ (which is much greater than $R$) according to $I = I_0 e^{-t/\tau'}$. Show that the maximum emf $\mathscr{E}_{\max}$ induced in the inductor during this time period is $(R'/R)V_0$. (*b*) If $R' = 45R$ and $V_0 = 145\,\text{V}$, determine $\mathscr{E}_{\max}$. [When a mechanical switch is opened, a high-resistance air gap is created, which is modeled as $R'$ here. This Problem illustrates why **high-voltage sparking** can occur if a current-carrying inductor is suddenly cut off from its power source. The very high voltage can produce an electric field great enough to ionize atoms of air, which emit light when electrons recombine with the ions.]

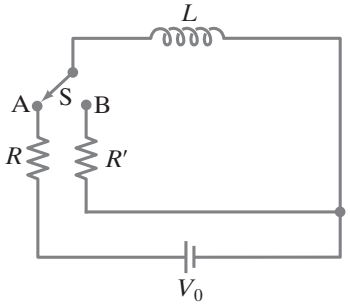

**FIGURE 30–28** Problem 25.

26. (II) For the $LR$ circuit of Fig. 30–6a determine $dI/dt$ at $t = 0$ (when the battery is connected) and show that if $I$ continued to increase at this rate, it would reach its maximum value in one time constant.

27. (III) Two tightly wound solenoids have the same length and circular cross-sectional area. But solenoid 1 uses wire that is 1.5 times as thick as solenoid 2. (*a*) What is the ratio of their inductances? (*b*) What is the ratio of their inductive time constants? (Assume the only resistance in the circuits is that of the wire itself.)

## 30–5 *LC* Circuits and Oscillations

28. (II) (*a*) If the initial conditions of an $LC$ circuit are $I = I_0$ and $Q = 0$ at $t = 0$, write $Q$ as a function of time. (*b*) Practically, how could you set up these initial conditions?

29. (II) A 475-pF capacitor is charged to 135 V and then quickly connected to a 175-mH inductor. Determine (*a*) the frequency of oscillation, (*b*) the peak value of the current, and (*c*) the maximum energy stored in the magnetic field of the inductor.

30. (II) At $t = 0$, let $Q = Q_0$, and $I = 0$ in an $LC$ circuit. (*a*) The first time when the energy becomes shared equally by the inductor and the capacitor, what is the charge on the capacitor? (*b*) How much time has elapsed (in terms of the period $T$)?

## 30–6 *LC* Oscillations with Resistance

31. (II) A damped $LC$ circuit loses 3.5% of its electromagnetic energy per cycle to thermal energy. If $L = 85\,\text{mH}$ and $C = 1.00\,\mu\text{F}$, what is the value of $R$?

32. (II) In an oscillating $LRC$ circuit, how much time does it take for the energy stored in the fields of the capacitor and inductor to fall to 65% of the initial value? (See Fig. 30–13; assume $R \ll \sqrt{4L/C}$.)

33. (III) How much resistance must be added to a pure $LC$ circuit ($L = 350\,\text{mH}$, $C = 1600\,\text{pF}$) to change the oscillator's frequency by 0.25%? Will it be increased or decreased?

## 30–7 AC Circuits; Reactance

34. (I) At what frequency will a 32.0-mH inductor have a reactance of 760 Ω?

35. (I) What is the reactance of an 8.4-$\mu$F capacitor at a frequency of (*a*) 60.0 Hz, (*b*) 1.00 MHz?

36. (I) Calculate the reactance of, and rms current in, a 36.0-mH radio coil connected to a 350-V (rms) 33.3-kHz ac line. Ignore resistance.

37. (II) An inductance coil operates at 240 V (rms) and 60.0 Hz. It draws 10.8 A (rms). What is the coil's inductance?

38. (II) A resistor $R$ is in parallel with a capacitor $C$, and this parallel combination is in series with a resistor $R'$. If connected to an ac voltage source of frequency $\omega$, what is the equivalent impedance of this circuit at the two extremes in frequency (*a*) $\omega = 0$, and (*b*) $\omega = \infty$?

39. (II) What is the inductance $L$ of the primary of a transformer whose input is 110 V rms at 60.0 Hz and the rms current drawn is 3.8 A? Assume no current in the secondary.

40. (II) (*a*) What is the reactance of a well-insulated 0.030-$\mu$F capacitor connected to a 1.6-kV (rms) 720-Hz line? (*b*) What will be the peak value of the current?

41. (II) A capacitor is placed in parallel with some device, B, as in Fig. 30–18b, to filter out stray high-frequency signals, but to allow ordinary 60.0-Hz ac to pass through with little loss. Suppose that circuit B in Fig. 30–18b is a resistance $R = 530\,\Omega$ connected to ground, and that $C = 0.35\,\mu\text{F}$. Calculate the ratio of the capacitor's current amplitude to the incoming current's amplitude if the incoming current has a frequency of (*a*) 60.0 Hz; (*b*) 60.0 kHz.

42. (II) A current $I = 1.80\cos 377t$ ($I$ in amps, $t$ in seconds, and the argument of the cosine is in radians) flows in a series $LR$ circuit in which $L = 3.45\,\text{mH}$ and $R = 1.35\,\text{k}\Omega$. What is the average power dissipation?

## 30–8 *LRC* Series AC Circuit; Phasor Diagrams

**43.** (I) A 10.0-kΩ resistor is in series with a 34.0-mH inductor and an ac source. Calculate the impedance of the circuit if the source frequency is (*a*) 55.0 Hz; (*b*) 55.0 kHz.

**44.** (I) A 75-Ω resistor and a 5.8-μF capacitor are connected in series to an ac source. Calculate the impedance of the circuit if the source frequency is (*a*) 60.0 Hz; (*b*) 6.0 MHz.

**45.** (II) For a 120-V, 60-Hz voltage, a current of 70 mA passing through the body for 1.0 s could be lethal. What must be the impedance of the body for this to occur?

**46.** (II) Determine the resistance of a coil if its impedance is 275 Ω and its reactance is 145 Ω.

**47.** (II) A 1.50-kΩ resistor in series with a 370-mH inductor is driven by an ac power supply. At what frequency is the impedance double that of the impedance at 60.0 Hz?

**48.** (II) An ac voltage source is connected in series with a 2.0-μF capacitor and a 750-Ω resistor. Using a digital ac voltmeter, the voltage source is measured to be 4.0 V rms, and the voltages across the resistor and across the capacitor are found to be 3.0 V rms and 2.7 V rms, respectively. Determine the frequency of the ac voltage source. Why is the voltage measured across the voltage source not equal to the sum of the voltages measured across the resistor and across the capacitor?

**49.** (II) Determine the total impedance, phase angle, and rms current in an *LRC* circuit connected to a 10.0-kHz, 625-V (rms) source if $L = 32.0\,\text{mH}$, $R = 8.70\,\text{k}\Omega$, and $C = 6250\,\text{pF}$.

**50.** (II) (*a*) What is the rms current in a series *LR* circuit when a 60.0-Hz, 120-V rms ac voltage is applied, where $R = 965\,\Omega$ and $L = 255\,\text{mH}$? (*b*) What is the phase angle between voltage and current? (*c*) How much power is dissipated? (*d*) What are the rms voltage readings across *R* and *L*?

**51.** (II) A 35-mH inductor with 2.0-Ω resistance is connected in series to a 21-μF capacitor and a 60.0-Hz, 45-V (rms) source. Calculate (*a*) the rms current, (*b*) the phase angle, and (*c*) the power dissipated in this circuit.

**52.** (II) A 25-mH coil whose resistance is 0.80 Ω is connected to a capacitor *C* and a 420-Hz source voltage. If the current and voltage are to be in phase, what value must *C* have?

**53.** (II) A 75-W incandescent lightbulb is designed to operate with an applied ac voltage of 120 V rms. The bulb is placed in series with an inductor *L*, and this series combination is then connected to a 60.0-Hz 240-V rms voltage source. For the bulb to operate properly, determine the required value for *L*. Assume the bulb has resistance *R* and negligible inductance.

**54.** (II) In the *LRC* circuit of Fig. 30–19, suppose $I = I_0 \sin\omega t$ (not cosine as in the text) and $V = V_0 \sin(\omega t + \phi)$. Determine the instantaneous power dissipated in the circuit from $P = IV$ using these equations and show that on the average, $\overline{P} = \frac{1}{2} V_0 I_0 \cos\phi$, which is in accord with Eq. 30–30.

**55.** (II) An *LRC* series circuit with $R = 120\,\Omega$, $L = 25\,\text{mH}$, and $C = 2.0\,\mu\text{F}$ is powered by an ac voltage source of peak voltage $V_0 = 340\,\text{V}$ and frequency $f = 660\,\text{Hz}$. (*a*) Determine the peak current that flows in this circuit. (*b*) Determine the phase angle of the source voltage relative to the current. (*c*) Determine the peak voltage across *R* and its phase angle relative to the source voltage. (*d*) Determine the peak voltage across *L* and its phase angle relative to the source voltage. (*e*) Determine the peak voltage across *C* and its phase angle relative to the source voltage.

**56.** (II) An *LR* circuit can be used as a "phase shifter." Assume that an "input" source voltage $V = V_0 \sin(2\pi f t + \phi)$ is connected across a series combination of an inductor $L = 55\,\text{mH}$ and resistor *R*. The "output" of this circuit is taken across the resistor. If $V_0 = 24\,\text{V}$ and $f = 225\,\text{Hz}$, determine the value of *R* so that the output voltage $V_R$ lags the input voltage *V* by 25°. Compare (as a ratio) the peak output voltage with $V_0$.

## 30–9 Resonance in AC Circuits

**57.** (I) A 3400-pF capacitor is connected in series to a 26.0-μH coil of resistance 2.00 Ω. What is the resonant frequency of this circuit?

**58.** (I) What is the resonant frequency of the *LRC* circuit of Example 30–11? At what rate is energy taken from the generator, on the average, at this frequency?

**59.** (II) An *LRC* circuit has $L = 4.15\,\text{mH}$ and $R = 3.80\,\text{k}\Omega$. (*a*) What value must *C* have to produce resonance at 38.0 kHz? (*b*) What will be the maximum current at resonance if the peak external voltage is 136 V?

**60.** (II) The frequency of the ac voltage source (peak voltage $V_0$) in an *LRC* circuit is tuned to the circuit's resonant frequency $f_0 = 1/(2\pi\sqrt{LC})$. (*a*) Show that the peak voltage across the capacitor is $V_{C0} = V_0\, T_0/(2\pi\tau)$, where $T_0 (= 1/f_0)$ is the period of the resonant frequency and $\tau = RC$ is the time constant for charging the capacitor *C* through a resistor *R*. (*b*) Define $\beta = T_0/(2\pi\tau)$ so that $V_{C0} = \beta V_0$. Then $\beta$ is the "amplification" of the source voltage across the capacitor. If a particular *LRC* circuit contains a 2.0-nF capacitor and has a resonant frequency of 5.0 kHz, what value of *R* will yield $\beta = 125$?

**61.** (II) Capacitors made from piezoelectric materials are commonly used as sound transducers ("loudspeakers"). They often require a large operating voltage. One method for providing the required voltage is to include the loudspeaker as part of an *LRC* circuit as shown in Fig. 30–29, where the loudspeaker is modeled electrically as the capacitance $C = 1.0\,\text{nF}$. Take $R = 35\,\Omega$ and $L = 55\,\text{mH}$. (*a*) What is the resonant frequency $f_0$ for this circuit? (*b*) If the voltage source has peak amplitude $V_0 = 2.0\,\text{V}$ at frequency $f = f_0$, find the peak voltage $V_{C0}$ across the loudspeaker (i.e., the capacitor *C*). (*c*) Determine the ratio $V_{C0}/V_0$.

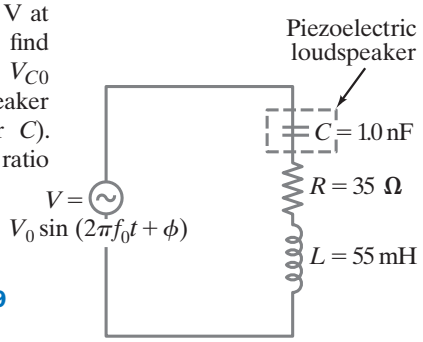

**FIGURE 30–29**
Problem 61.

**62.** (II) (*a*) Show that oscillation of charge *Q* on the capacitor of an *LRC* circuit has amplitude

$$Q_0 = \frac{V_0}{\sqrt{(\omega R)^2 + \left(\omega^2 L - \frac{1}{C}\right)^2}}.$$

(*b*) At what angular frequency, $\omega'$, will $Q_0$ be a maximum? (*c*) Compare to a forced damped harmonic oscillator (Chapter 14), and discuss. What do *L* and *C* correspond to in the mechanical system?

**63.** (II) A resonant circuit using a 220-nF capacitor is to resonate at 35.0 kHz. The air-core inductor is to be a solenoid with closely packed coils made from 12.0 m of insulated wire 1.1 mm in diameter. How many loops should the inductor contain?

**64.** (III) (*a*) Determine a formula for the average power $\overline{P}$ dissipated in an *LRC* circuit in terms of $L$, $R$, $C$, $\omega$, and $V_0$. (*b*) At what frequency is the power a maximum? (*c*) Find an approximate formula for the width of the resonance peak in average power, $\Delta\omega$, which is the difference in the two (angular) frequencies where $\overline{P}$ has half its maximum value. Assume a sharp peak.

### 30–10 Impedance Matching

**65.** (II) The output of an electrocardiogram amplifier has an impedance of 45 kΩ. It is to be connected to an 8.0-Ω loudspeaker through a transformer. What should be the turns ratio of the transformer?

### *30–11 Three-Phase AC

***66.** (II) Show that the power delivered by a three-phase ac source equals a constant $P = 3V_0^2/2R$, by combining the four equations in Section 30–11.

## General Problems

**67.** At $t = 0$, the current through a 60.0-mH inductor is 50.0 mA and is increasing at the rate of 78.0 mA/s. What is the initial energy stored in the inductor, and how long does it take for the energy to increase by a factor of 8.0 from the initial value?

**68.** At time $t = 0$, the switch in the circuit shown in Fig. 30–30 is closed. After a sufficiently long time, steady currents $I_1$, $I_2$, and $I_3$ flow through resistors $R_1$, $R_2$, and $R_3$, respectively. Determine these three currents.

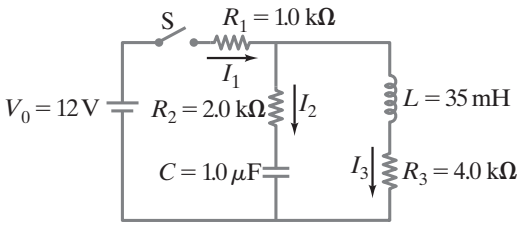

**FIGURE 30–30** Problem 68.

**69.** (*a*) Show that the self-inductance $L$ of a toroid (Fig. 30–31) of radius $r_0$ containing $N$ loops each of diameter $d$ is

$$L \approx \frac{\mu_0 N^2 d^2}{8 r_0}$$

if $r_0 \gg d$. Assume the field is uniform inside the toroid; is this actually true? (*b*) Is this result consistent with $L$ for a solenoid? Should it be? (*c*) Calculate the inductance $L$ of a large toroid if the diameter of the coils is 2.0 cm and the diameter of the whole ring is 66 cm. Assume the field inside the toroid is uniform. There are a total of 660 loops of wire.

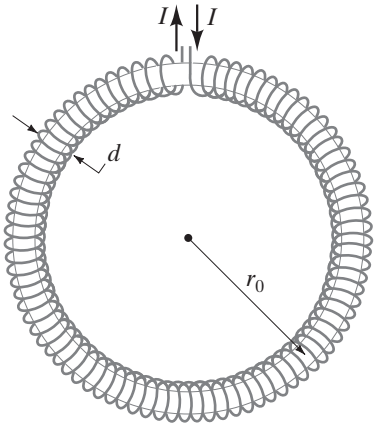

**FIGURE 30–31** A toroid. Problem 69.

**70.** A pair of straight parallel thin wires, such as a lamp cord, each of radius $r$, are a distance $\ell$ apart and carry current to a circuit some distance away. Ignoring the field within each wire, show that the inductance per unit length is $(\mu_0/\pi)\ln[(\ell - r)/r]$.

**71.** Assuming the Earth's magnetic field averages about $0.50 \times 10^{-4}$ T near the surface of the Earth, estimate the total energy stored in this field in the first 5.0 km above the Earth's surface.

**72.** (*a*) For an underdamped *LRC* circuit, determine a formula for the energy $U = U_E + U_B$ stored in the electric and magnetic fields as a function of time. Give answer in terms of the initial charge $Q_0$ on the capacitor. (*b*) Show how $dU/dt$ is related to the rate energy is transformed in the resistor, $I^2R$.

**73.** A physics professor wants to demonstrate the large size of the henry unit. On the outside of a 12-cm-diameter plastic hollow tube, she wants to wind an air-filled solenoid with self-inductance of 1.0 H using copper wire with a 0.81-mm diameter. The solenoid is to be tightly wound with each turn touching its neighbor (the wire has a thin insulating layer on its surface so the neighboring turns are not in electrical contact). How long will the plastic tube need to be and what length of copper wire will be required? What will be the resistance of this solenoid?

**74.** The circuit shown in Fig. 30–32a can integrate (in the calculus sense) the input voltage $V_{\text{in}}$, if the time constant $L/R$ is large compared with the time during which $V_{\text{in}}$ varies. Explain how this *integrator* works and sketch its output for the square wave signal input shown in Fig. 30–32b. [*Hint*: Write Kirchhoff's loop rule for the circuit. Multiply each term in this differential equation (in $I$) by a factor $e^{Rt/L}$ to make it easier to integrate.]

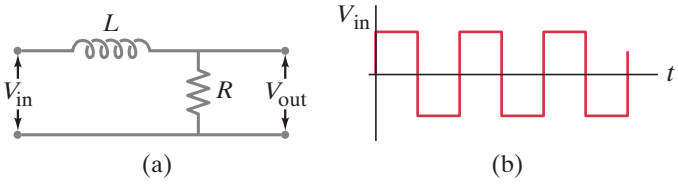

**FIGURE 30–32** Problem 74.

**75.** Suppose circuit B in Fig. 30–18a consists of a resistance $R = 550\ \Omega$. The filter capacitor has capacitance $C = 1.6\ \mu\text{F}$. Will this capacitor act to eliminate 60.0-Hz ac but pass a high-frequency signal of frequency 6.0 kHz? To check this, determine the rms voltage drop across $R$ for a 130-mV rms signal of frequency (*a*) 60.0 Hz; (*b*) 6.0 kHz.

**76.** In a series *LRC* circuit, the inductance is 33 mH, the capacitance is 55 nF, and the resistance is 1.50 kΩ. At what frequencies is the power factor equal to 0.24?

**77.** In our analysis of a series $LRC$ circuit, Fig. 30–19, suppose we chose $V = V_0 \sin \omega t$. (*a*) Construct a phasor diagram, like that of Fig. 30–21, for this case. (*b*) Write a formula for the current $I$, defining all terms.

**78.** An ac voltage source $V = V_0 \sin(\omega t + 90°)$ is connected across an inductor $L$ and current $I = I_0 \sin(\omega t)$ flows in this circuit. Note that the current and source voltage are 90° out of phase. (*a*) Directly calculate the average power delivered by the source over one period $T$ of its sinusoidal cycle via the integral $\overline{P} = \int_0^T VI\, dt/T$. (*b*) Apply the relation $\overline{P} = I_{\text{rms}} V_{\text{rms}} \cos\phi$ to this circuit and show that the answer you obtain is consistent with that found in part (*a*). Comment on your results.

**79.** A circuit contains two elements, but it is not known if they are $L$, $R$, or $C$. The current in this circuit when connected to a 120-V rms 60.0-Hz source is 5.6 A and lags the voltage by 55°. What are the two elements and what are their values?

**80.** (*a*) What is the rms current in an $RC$ circuit if $R = 6.40\,\text{k}\Omega$, $C = 1.80\,\mu\text{F}$, and the rms applied voltage is 120 V at 60.0 Hz? (*b*) What is the phase angle between voltage and current? (*c*) What is the power dissipated by the circuit? (*d*) What are the voltmeter readings across $R$ and $C$?

**81.** An inductance coil draws 2.2 A dc when connected to a 45-V battery. When connected to a 60.0-Hz 120-V (rms) source, the current drawn is 3.8 A (rms). Determine the inductance and resistance of the coil.

**82.** The ***Q*-value** of a resonance circuit can be defined as the ratio of the voltage across the capacitor (or inductor) to the voltage across the resistor, at resonance. The larger the $Q$ factor, the sharper the resonance curve will be and the sharper the tuning. (*a*) Show that the $Q$ factor is given by the equation $Q = (1/R)\sqrt{L/C}$. (*b*) At a resonant frequency $f_0 = 1.0\,\text{MHz}$, what must be the value of $L$ and $R$ to produce a $Q$ factor of 550? Assume that $C = 0.010\,\mu\text{F}$.

**83.** Show that the fraction of electromagnetic energy lost (to thermal energy) per cycle in a lightly damped $(R^2 \ll 4L/C)$ $LRC$ circuit is approximately

$$\frac{\Delta U}{U} = \frac{2\pi R}{L\omega} = \frac{2\pi}{Q}.$$

The quantity $Q$ can be defined as $Q = L\omega/R$, and is called the *Q-value*, or *quality factor*, of the circuit and is a measure of the damping present. A high $Q$-value means smaller damping and less energy input required to maintain oscillations.

**84.** In some experiments, very *tiny distances* or spaces ($\approx$ nm) can be measured by using capacitance. Consider forming an $LC$ circuit using a parallel-plate capacitor with plate area $A$, and a known inductance $L$. (*a*) If charge is found to oscillate in this circuit at frequency $f = \omega/2\pi$ when the capacitor plates are separated by distance $x$, show that $x = 4\pi^2 A\epsilon_0 f^2 L$. (*b*) When the plate separation is changed by $\Delta x$, the circuit's oscillation frequency will change by $\Delta f$. Show that $\Delta x/x \approx 2(\Delta f/f)$. (*c*) If $f$ is on the order of 1 MHz and can be measured to a precision of $\Delta f = 1$ Hz, with what percent accuracy can $x$ be determined? Assume fringing effects at the capacitor's edges can be neglected.

**85.** An electronic device needs to be protected against sudden surges in current. In particular, after the power is turned on the current should rise to no more than 7.5 mA in the first 75 $\mu$s. The device has resistance 120 Ω and is designed to operate at 33 mA. How would you protect this device?

**86.** A voltage $V = 0.95 \sin 688t$ is applied to an $LRC$ circuit ($V$ is in volts, $t$ is in seconds, and the argument of the sine is in radians) which has $L = 22.0\,\text{mH}$, $R = 23.2\,\text{k}\Omega$, and $C = 0.42\,\mu\text{F}$. (*a*) What is the impedance and phase angle? (*b*) How much power is dissipated in the circuit? (*c*) What is the rms current and voltage across each element?

**87.** **Filter circuit.** Figure 30–33 shows a simple filter circuit designed to pass dc voltages with minimal attenuation and to remove, as much as possible, any ac components (such as 60-Hz line voltage that could cause hum in an audio system, for example). Assume $V_{\text{in}} = V_1 + V_2$ where $V_1$ is dc and $V_2 = V_{20} \sin \omega t$, and that any resistance is very small. (*a*) Determine the current through the capacitor: give amplitude and phase (assume $R = 0$ and $X_L > X_C$). (*b*) Show that the ac component of the output voltage, $V_{2\,\text{out}}$, equals $(Q/C) - V_1$, where $Q$ is the charge on the capacitor at any instant, and determine the amplitude and phase of $V_{2\,\text{out}}$. (*c*) Show that the attenuation of the ac voltage is greatest when $X_C \ll X_L$, and calculate the ratio of the output to input ac voltage in this case. (*d*) Compare the dc output voltage to input voltage.

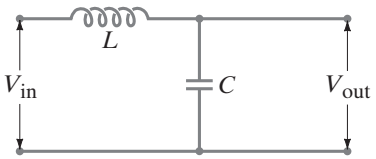

**FIGURE 30–33**
Problems 87 and 88.

**88.** Show that if the inductor $L$ in the filter circuit of Fig. 30–33 (Problem 87) is replaced by a large resistor $R$, there will still be significant attenuation of the ac voltage and little attenuation of the dc voltage if the input dc voltage is high and the current (and power) are low.

**89.** **Parallel *LRC* Circuit.** A resistor $R$, capacitor $C$, and inductor $L$ are connected in parallel across an ac generator as shown in Fig. 30–34. The source emf is $V = V_0 \sin \omega t$. Determine the current as a function of time (including amplitude and phase): (*a*) in the resistor, (*b*) in the inductor, (*c*) in the capacitor. (*d*) What is the total current leaving the source? (Give amplitude $I_0$ and phase.) (*e*) Determine the impedance $Z$ defined as $Z = V_0/I_0$. (*f*) What is the power factor?

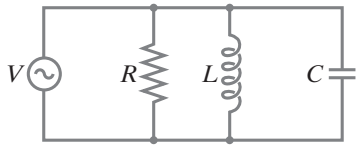

**FIGURE 30–34**
Problem 89.

**90.** Suppose a series $LRC$ circuit has two resistors, $R_1$ and $R_2$, two capacitors, $C_1$ and $C_2$, and two inductors, $L_1$ and $L_2$, all in series. Calculate the total impedance of the circuit.

**91.** For the circuit shown in Fig. 30–35, show that if the condition $R_1 R_2 = L/C$ is satisfied then the potential difference between points a and b is zero for all frequencies.

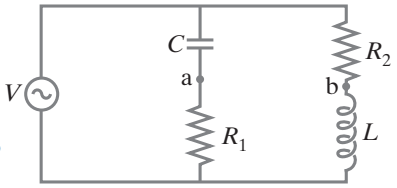

**FIGURE 30–35**
Problem 91.

**92.** In a certain $LRC$ series circuit, when the ac voltage source has a particular frequency $f$, the peak voltage across the inductor is 5.0 times greater than the peak voltage across the capacitor. Determine $f$ in terms of the resonant frequency $f_0$ of this circuit.

**93.** In a *plasma globe*, a hollow glass sphere is filled with low-pressure gas and a small spherical metal electrode is located at its center. Assume an ac voltage source of peak voltage $V_0$ and frequency $f$ is applied between the metal sphere and the ground, and that a person is touching the outer surface of the globe with a fingertip, whose approximate area is $1.0\,\text{cm}^2$. The equivalent circuit for this situation is shown in Fig. 30–36, where $R_G$ and $R_P$ are the resistances of the gas and the person, respectively, and $C$ is the capacitance formed by the gas, glass, and finger. (*a*) Determine $C$ assuming it is a parallel-plate capacitor. The conductive gas and the person's fingertip form the opposing plates of area $A = 1.0\,\text{cm}^2$. The plates are separated by glass (dielectric constant $K = 5.0$) of thickness $d = 2.0\,\text{mm}$. (*b*) In a typical plasma globe, $f = 12\,\text{kHz}$. Determine the reactance $X_C$ of $C$ at this frequency in MΩ. (*c*) The voltage may be $V_0 = 2500\,\text{V}$. With this high voltage, the dielectric strength of the gas is exceeded and the gas becomes ionized. In this "plasma" state, the gas emits light ("sparks") and is highly conductive so that $R_G \ll X_C$. Assuming also that $R_P \ll X_C$, estimate the peak current that flows in the given circuit. Is this level of current dangerous? (*d*) If the plasma globe operated at $f = 1.0\,\text{MHz}$, estimate the peak current that would flow in the given circuit. Is this level of current dangerous?

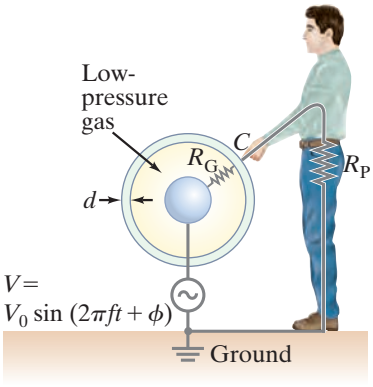

**FIGURE 30–36**
Problem 93.

**94.** You have a small electromagnet that consumes 350 W from a residential circuit operating at 120 V rms at 60.0 Hz. Using your ac multimeter, you determine that the unit draws 5.0 A rms. What are the values of the inductance and the internal resistance?

**95.** An inductor $L$ in series with a resistor $R$, driven by a sinusoidal voltage source, responds as described by the following differential equation:

$$V_0 \sin\omega t = L\frac{dI}{dt} + RI.$$

Show that a current of the form $I = I_0 \sin(\omega t - \phi)$ flows through the circuit by direct substitution into the differential equation. Determine the amplitude of the current $(I_0)$ and the phase difference $\phi$ between the current and the voltage source.

**96. Series and parallel *LRC*.** For the circuit shown in Fig. 30–37, $V = V_0 \sin\omega t$. Determine an equation for the current in each element of the circuit, as well as the total impedance. [*Hint*: Try a trial solution of the form $I = I_0 \sin(\omega t + \phi)$ for the current leaving the source.]

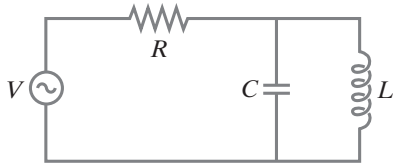

**FIGURE 30–37**
Problem 96.

**97.** The *RC* circuit shown in Fig. 30–38 is a **high-pass filter** because it passes high-frequency ac signals with less attenuation than low-frequency ac signals. (*a*) Show that the voltage gain is $A = V_{\text{out}}/V_{\text{in}} = 2\pi fRC/(4\pi^2 f^2 R^2 C^2 + 1)^{\frac{1}{2}}$. (*b*) Discuss the behavior of the gain $A$ for $f \to 0$ and $f \to \infty$.

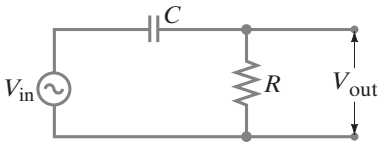

**FIGURE 30–38**
Problem 97.

**98.** The *RC* circuit shown in Fig. 30–39 is a **low-pass filter** because it passes low-frequency ac signals with less attenuation than high-frequency ac signals. (*a*) Show that the voltage gain is $A = V_{\text{out}}/V_{\text{in}} = 1/(4\pi^2 f^2 R^2 C^2 + 1)^{\frac{1}{2}}$. (*b*) Discuss the behavior of the gain $A$ for $f \to 0$ and $f \to \infty$.

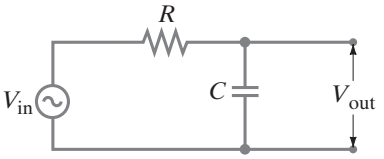

**FIGURE 30–39**
Problem 98.

**99.** To detect vehicles at traffic lights, wire loops with dimensions on the order of 2 m are often buried horizontally under roadways. Assume the self-inductance of such a coil is $L = 5.0\,\text{mH}$ and that it is part of an *LRC* circuit as shown in Fig. 30–40 with $C = 0.10\,\mu\text{F}$ and $R = 38\,\Omega$. The ac voltage has frequency $f$ and rms voltage $V_{\text{rms}}$. (*a*) The frequency $f$ is chosen to match the resonant frequency $f_0$ of the circuit. Find $f_0$ and determine what the rms voltage $(V_R)_{\text{rms}}$ across the resistor will be when $f = f_0$. (*b*) Assume that $f$, $C$, and $R$ never change, but that, when a car is located above the buried coil, the coil's self-inductance decreases by 10% (due to induced eddy currents in the car's metal parts). Determine by what factor the voltage $(V_R)_{\text{rms}}$ decreases in the presence of a car in comparison to no car above the loop and thus how it detects the presence of a car. (*c*) Describe how the eddy currents induced in the car reduce $L$. [*Hint*: Recall Eq. 30–4, the definition of inductance.]

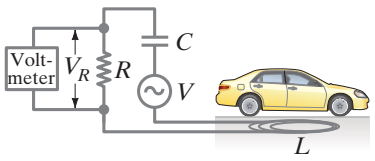

**FIGURE 30–40**
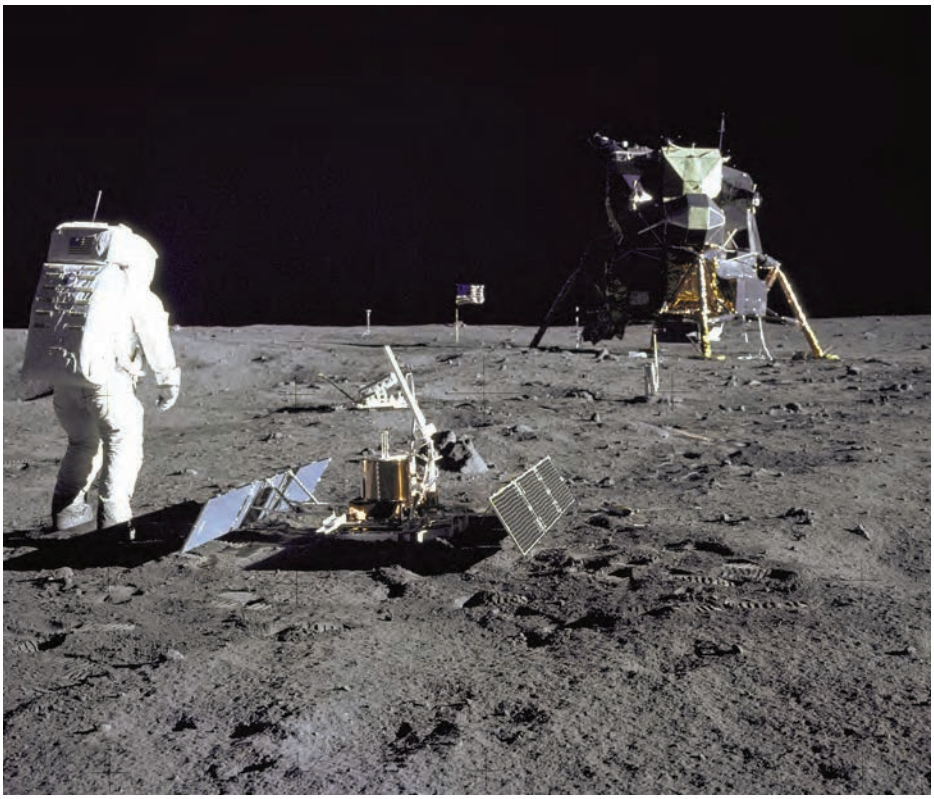
Problem 99.



## ANSWERS TO EXERCISES

**A:** (*b*).
**B:** (*a*).
**C:** From Eq. 30–5, $L$ has dimensions $VT/A$ so $(L/R)$ has dimensions $(VT/A)/(V/A) = T$.
**D:** (*d*).
**E:** (*c*).
**F:** (*a*).

Wireless technology is all around us: radio and television, cell phones, wi-fi, Bluetooth, and all wireless communication. These devices communicate by electromagnetic waves traveling through space. Wireless devices are applications of Marconi's development of long-distance transmission of information more than a century ago.

In this photo we see the first humans to land on the Moon. In the background is a television camera that sent live moving images through empty space to Earth where it was shown live.

We will see in this Chapter that Maxwell predicted the existence of EM waves from his famous equations. Maxwell's equations themselves are a magnificent summary of electromagnetism. We will also see that EM waves carry energy and momentum, and that light itself is an electromagnetic wave.

CHAPTER 31

# Maxwell's Equations and Electromagnetic Waves

## CONTENTS

31 – 8 Energy in EM Waves; the Poynting Vector
31 – 9 Radiation Pressure
31–10 Radio and Television; Wireless Communication

## CHAPTER-OPENING QUESTION—Guess now!

Which of the following best describes the difference between radio waves and X-rays?

**(a)** X-rays are radiation whereas radio waves are electromagnetic waves.
**(b)** Both can be thought of as electromagnetic waves. They differ only in wavelength and frequency.
**(c)** X-rays are pure energy. Radio waves are made of fields, not energy.
**(d)** Radio waves come from electric currents in an antenna. X-rays are not related to electric charge.
**(e)** X-rays are made up of particles called photons whereas radio waves are oscillations in space.

The culmination of electromagnetic theory in the nineteenth century was the prediction, and the experimental verification, that waves of electromagnetic fields could travel through space. This achievement opened a whole new world of communication: first the wireless telegraph, then radio, television, and radar, and more recently cell phones, remote-control devices, wi-fi, GPS, Bluetooth, and all satellite communication. Most important was the spectacular prediction that light is an electromagnetic wave.

The theoretical prediction of electromagnetic waves was the work of the Scottish physicist James Clerk Maxwell (1831–1879; Fig. 31–1), who unified, in one magnificent theory, all the phenomena of electricity and magnetism.

The development of electromagnetic theory in the early part of the nineteenth century by Oersted, Ampère, and others was not actually done in terms of electric and magnetic fields. The idea of the field was introduced somewhat later by Faraday, and was not generally used until Maxwell showed that all electric and magnetic phenomena could be described using only four equations involving electric and magnetic fields. These equations, known as **Maxwell's equations**, are the basic equations for all electromagnetism. They are fundamental in the same sense that Newton's three laws of motion and the law of universal gravitation are for mechanics. In a sense, they are even more fundamental, because they are consistent with the theory of relativity (Chapter 36), whereas Newton's laws are not. Because all of electromagnetism is contained in this set of four equations, Maxwell's equations are considered one of the great triumphs of human intellect.

Before discussing Maxwell's equations and electromagnetic waves, we need to discuss a major prediction of Maxwell's (Section 31–1), and also Gauss's law for magnetism (Section 31–2).

**FIGURE 31–1** James Clerk Maxwell (1831–1879).

# 31–1 Changing Electric Fields Produce Magnetic Fields; Displacement Current

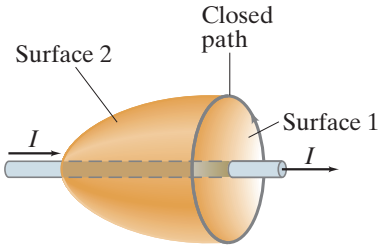
## Ampère's Law

Recall from Chapters 27 and 28 that a magnetic field is produced by an electric current, as was discovered by Oersted, and the mathematic relation is given by Ampère's law (Eq. 28–3):

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 I_{\text{encl}}.$$

Is it possible that magnetic fields could be produced in another way as well? Maxwell argued that if a changing magnetic field produces an electric field, as given by Faraday's law (Section 29–7), then the reverse might be true as well: **a changing electric field will produce a magnetic field**. This was an *hypothesis* by Maxwell, and it turned out to be correct. It is based on the idea of *symmetry* in nature. Indeed, the size of the effect in most cases is so small that Maxwell recognized it would be difficult to detect it experimentally.

To back up the idea that a changing electric field might produce a magnetic field, we use an indirect argument that goes something like this. According to Ampère's law (Section 28–4), we divide any closed path you choose into short segments $d\vec{\boldsymbol{\ell}}$, take the dot product of each $d\vec{\boldsymbol{\ell}}$ with the magnetic field $\vec{\mathbf{B}}$ at that segment, and sum (integrate) all these products over the complete closed path. That sum will then equal $\mu_0$ times the total current $I$ that passes through a surface bounded by the path of the line integral. When we applied Ampère's law to the field around a straight wire (Section 28–4), we imagined the current as passing through the flat circular area enclosed by our circular loop. That area is the surface 1 shown in Fig. 31–2. However, we could just as well imagine using the sack-shaped surface 2 in Fig. 31–2 as the surface for Ampère's law because the same current $I$ passes through it.



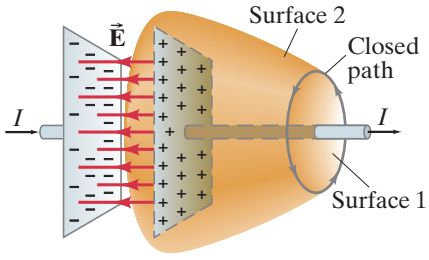


**FIGURE 31–2** Ampère's law applied to two different surfaces bounded by the same closed path.

Now consider the closed circular path for the situation of Fig. 31–3, where a capacitor is being discharged, and two imaginary surfaces are shown. Ampère's law works for surface 1 (current $I$ passes through surface 1), but it does not work for surface 2 because no current passes through surface 2. There is a magnetic field around the wire, so the left side of Ampère's law, $\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}}$, is not zero around the circular closed path; yet no current flows through surface 2, so the right side of Ampère's law *is* zero for surface 2. We seem to have a contradiction of Ampère's law.

There is a magnetic field present in Fig. 31–3, however, only if charge is flowing to or away from the capacitor plates. The changing charge on the plates means that the electric field between the plates is changing in time.

**FIGURE 31–3** A capacitor discharging. A conduction current passes through surface 1, but no conduction current passes through the sack-like surface 2. An extra term is needed in Ampère's law.

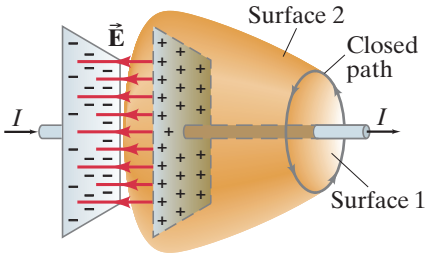

**FIGURE 31–3** (Repeated.)
A capacitor discharging. A conduction current passes through surface 1, but no conduction current passes through the sack-like surface 2. An extra term is needed in Ampère's law.

Maxwell resolved the problem of no current through surface 2 in Fig. 31–3 by proposing that the changing electric field between the plates is *equivalent to* an electric current. He called it **displacement current** $I_D$. (An ordinary current $I$ is then called a **conduction current**.)

Let us see what this displacement current term should be by determining it for the changing electric field between the capacitor plates in Fig. 31–3. The charge $Q$ on a capacitor of capacitance $C$ is $Q = CV$ where $V$ is the potential difference between the plates (Eq. 24–1). Also recall that $V = Ed$ (Eq. 23–4) where $d$ is the (small) separation of the plates and $E$ is the (uniform) electric field magnitude between them, if we ignore any fringing of the field. Also, for a parallel-plate capacitor, $C = \epsilon_0 A/d$, where $A$ is the area of each plate (Eq. 24–2). We combine these to obtain:

$$Q = CV = \left(\epsilon_0 \frac{A}{d}\right)(Ed) = \epsilon_0 AE.$$

If the charge on each plate changes at a rate $dQ/dt$, the electric field changes at a proportional rate. That is, by differentiating this expression for $Q$, we have:

$$\frac{dQ}{dt} = \epsilon_0 A \frac{dE}{dt}.$$

But $dQ/dt$ is also the current $I$ flowing into or out of the capacitor, so

$$I = \frac{dQ}{dt} = \epsilon_0 A \frac{dE}{dt} = \epsilon_0 \frac{d\Phi_E}{dt}$$

where $\Phi_E = EA$ is the **electric flux** through a surface enclosed by the integration path, which we now take as surface 2 in Fig. 31–3. In order to make Ampère's law work for surface 2 in Fig. 31–3, as well as for surface 1 (where current $I$ flows), we therefore write:

*AMPÈRE'S LAW (general form)*

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 I_{\text{encl}} + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \qquad \textbf{(31–1)}$$

This equation is the general form of **Ampère's law**,[†] and embodies Maxwell's idea that a magnetic field can be caused not only by an ordinary electric current, but also by a changing electric field or changing electric flux. Although we arrived at it for a special case, Eq. 31–1 has proved valid in general. The last term on the right in Eq. 31–1 is usually very small, and not easy to measure experimentally.

**EXAMPLE 31–1** **Maxwell's extra term: charging capacitor.** A 30-pF air-gap capacitor has circular plates of area $A = 100\ \text{cm}^2$. It is charged by a 70-V battery through a 2.0-Ω resistor. At the instant the battery is connected, $t = 0$, the electric field between the plates is changing most rapidly. At this instant, calculate (*a*) the current in this RC circuit, and (*b*) the rate of change of electric field between the plates. (*c*) Determine the magnetic field induced between the plates. Assume $\vec{\mathbf{E}}$ is uniform between the plates at any instant and is zero at all points beyond the edges of the plates. (*d*) Determine $\vec{\mathbf{B}}$ beyond the edges of the plates.

**APPROACH** In Section 26–5 we discussed *RC* circuits and saw that the charge on a capacitor being charged, as a function of time, is

$$Q = CV_0\left(1 - e^{-t/RC}\right),$$

where $V_0$ is the voltage of the battery. To find the current at $t = 0$, we need to differentiate this and substitute the values $V_0 = 70\ \text{V}$, $C = 30\ \text{pF}$, $R = 2.0\ \Omega$.

**SOLUTION** (*a*) We take the derivative of $Q$ and evaluate it at $t = 0$:

$$\left.\frac{dQ}{dt}\right|_{t=0} = \left.\frac{CV_0}{RC} e^{-t/RC}\right|_{t=0} = \frac{V_0}{R} = \frac{70\ \text{V}}{2.0\ \Omega} = 35\ \text{A}.$$

This is the rate at which charge accumulates on the capacitor and equals the current flowing in the circuit at $t = 0$.

[†]Actually, there is a third term on the right for the case when a magnetic field is produced by magnetized materials. This can be accounted for by changing $\mu_0$ to $\mu$ but we will mainly be interested in cases where no magnetic material is present. In the presence of a dielectric, $\epsilon_0$ is replaced by $\epsilon = K\epsilon_0$ (see Section 24–5).

(*b*) The electric field between two closely spaced conductors is given by (Eq. 21–8)

$$E = \frac{\sigma}{\epsilon_0} = \frac{Q/A}{\epsilon_0}$$

as we saw in Chapter 21 (see Example 21–14). Hence at $t = 0$

$$\frac{dE}{dt} = \frac{dQ/dt}{\epsilon_0 A} = \frac{35\ \text{A}}{(8.85\times10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2)(1.0\times10^{-2}\ \text{m}^2)}$$
$$= 4.0\times10^{14}\ \text{V/m}\cdot\text{s}.$$

(*c*) Because of *symmetry*, we assume the lines of $\vec{\mathbf{B}}$ are circles perpendicular to $\vec{\mathbf{E}}$, as shown in Fig. 31–4a. This is the same symmetry we saw for the opposite situation of a changing magnetic field producing an electric field (Section 29–7, see Fig. 29–28c). To determine the magnitude of $B$ between the capacitor plates we apply Ampère's law, Eq. 31–1, with the current $I_{\text{encl}} = 0$:

$$\oint \vec{\mathbf{B}}\cdot d\vec{\boldsymbol{\ell}} = \mu_0\epsilon_0\frac{d\Phi_E}{dt}.$$

We choose our path to be a circle of radius $r$, centered at the center of the plate and thus following a magnetic field line such as the one shown in Fig. 31–4. For $r \le r_0$ (the radius of plate) the flux through a circle of radius $r$ is $E(\pi r^2)$ since $E$ is assumed uniform between the plates at any moment. So from Ampère's law we have

$$B(2\pi r) = \mu_0\epsilon_0\frac{d}{dt}(\pi r^2 E)$$
$$= \mu_0\epsilon_0\pi r^2\frac{dE}{dt}.$$

Hence

$$B = \frac{\mu_0\epsilon_0}{2}r\frac{dE}{dt} \qquad [r \le r_0]$$

and increases linearly in $r$ out to the edge, $r = r_0$.

(*d*) We have assumed $\vec{\mathbf{E}} \approx 0$ for $r > r_0$, so essentially all the electric flux is contained within the plates $(\text{area} = 4\pi r_0^2)$ and $\Phi_E = E\pi r_0^2$ is a constant for any $r > r_0$. Ampère's law gives

$$B(2\pi r) = \mu_0\epsilon_0\frac{d}{dt}(\pi r_0^2 E)$$
$$= \mu_0\epsilon_0\pi r_0^2\frac{dE}{dt}$$

or

$$B = \frac{\mu_0\epsilon_0 r_0^2}{2r}\frac{dE}{dt}. \qquad [r \ge r_0]$$

Thus $B$ *decreases* with distance $r$ from the center of the plates. See Fig. 31–4b.

**NOTE** $B$ has its maximum value at $r = r_0$ which, from either relation above (using $r_0 = \sqrt{A/\pi} = 5.6\,\text{cm}$), when evaluated at $t = 0$, is

$$B_{\text{max}} = \frac{\mu_0\epsilon_0 r_0}{2}\frac{dE}{dt}$$
$$= \tfrac{1}{2}(4\pi\times10^{-7}\ \text{T}\cdot\text{m/A})(8.85\times10^{-12}\ \text{C}^2/\text{N}\cdot\text{m}^2)(5.6\times10^{-2}\ \text{m})(4.0\times10^{14}\ \text{V/m}\cdot\text{s})$$
$$= 1.2\times10^{-4}\ \text{T}.$$

This is a small field even at $t = 0$, and decreases very quickly because $dE/dt = (dQ/dt)/\epsilon_0 A = (V_0/R\epsilon_0 A)e^{-t/RC}$ (see part *a* and *b* above) where $RC = 6.0\times10^{-11}\,\text{s}$, so Maxwell's extra term in Ampère's law, which initially is on the order of Earth's magnetic field, is so brief it is not so easy to measure.

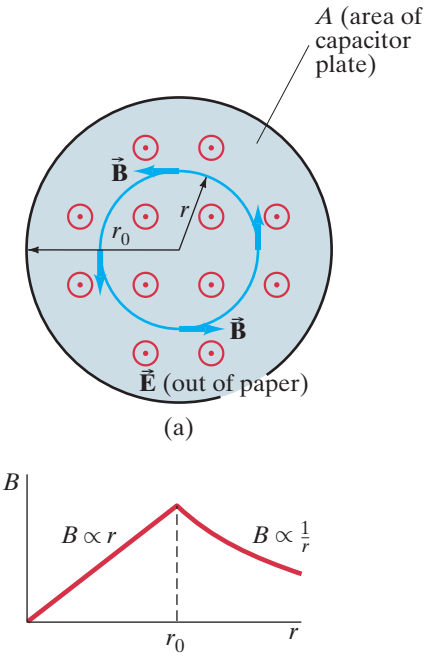

**FIGURE 31–4** (Example 31–1.) (a) A circular plate of a parallel-plate capacitor. $\vec{\mathbf{E}}$ between plates points out toward viewer; lines of $\vec{\mathbf{B}}$ are circles. (b) Graph of $B$ vs. $r$.

We can also consider the magnetic field $B$ outside the capacitor plates of Example 31–1 in terms of the current $I$ in the circuit. The electric field between the plates is $E = \sigma/\epsilon_0 = Q/(\epsilon_0 A)$, as we saw in part *b*, so $dE/dt = I/(\epsilon_0 A)$.

Hence $B$ for $r > r_0$ is, with $A = \pi r_0^2$,

$$B = \frac{\mu_0 \epsilon_0 r_0^2}{2r} \frac{dE}{dt} = \frac{\mu_0 \epsilon_0 r_0^2}{2r} \frac{I}{\epsilon_0 \pi r_0^2} = \frac{\mu_0 I}{2\pi r}.$$

This is the same formula for the field that surrounds a wire (Eq. 28–1). Thus the $B$ field outside the capacitor (Example 31–1) is the same as $B$ outside the wire connected to it carrying current $I$. In other words, the magnetic field produced by the changing electric field between the plates is the same as that produced by the current in the wire.

### Displacement Current

Maxwell interpreted the second term on the right in Eq. 31–1 as being *equivalent* to an electric current. He called it a **displacement current**, $I_D$. An ordinary current $I$ is then called a **conduction current**. Ampère's law can then be written

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 (I + I_D)_{\text{encl}} \tag{31–2}$$

where

*Displacement current*

$$I_D = \epsilon_0 \frac{d\Phi_E}{dt}. \tag{31–3}$$

The term "displacement current" was based on an old discarded theory. Don't let it confuse you: $I_D$ does not represent a flow of electric charge,[†] nor is there a displacement.

## 31–2 Gauss's Law for Magnetism

We are almost in a position to state Maxwell's equations, but first we need to discuss the magnetic equivalent of Gauss's law. As we saw in Chapter 29, for a magnetic field $\vec{\mathbf{B}}$ the *magnetic flux* $\Phi_B$ through a surface is defined as

$$\Phi_B = \int \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}}$$

where the integral is over the area of either an open or a closed surface. The magnetic flux through a closed surface—that is, a surface which completely encloses a volume—is written

$$\Phi_B = \oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}}.$$

In the electric case, we saw in Section 22–2 on Gauss's law that the electric flux $\Phi_E$ through a closed surface is equal to the total net charge $Q$ enclosed by the surface, divided by $\epsilon_0$ (Eq. 22–4):

$$\oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = \frac{Q_{\text{encl}}}{\epsilon_0}.$$

This relation is Gauss's law for electricity.

We can write a similar relation for the magnetic flux. We have seen (Section 27–1) that in spite of intense searches, no isolated magnetic poles (monopoles)—the magnetic equivalent of single electric charges—have ever been observed. Hence, **Gauss's law for magnetism** is

$$\oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = 0. \tag{31–4}$$

In terms of magnetic field lines, this relation tells us that as many lines enter the enclosed volume as leave it. If, indeed, magnetic monopoles do not exist, then there are no "sources" or "sinks" for magnetic field lines to start or stop on, unlike electric field lines that start on positive charges and end on negative charges.

[†]The interpretation of the changing electric field as a current does fit in well with our discussion in Chapter 30 where we saw that an alternating current can be said to pass through a capacitor (although charge doesn't). It also means that Kirchhoff's junction rule will be valid even at a capacitor plate: conduction current flows into the plate, but no conduction current flows out of the plate—instead a "displacement current" flows out of one plate (toward the other plate).

Magnetic field lines must then be continuous. Even for a bar magnet, a magnetic field $\vec{\mathbf{B}}$ exists inside as well as outside the magnetic material, and the lines of $\vec{\mathbf{B}}$ are closed loops as shown in Fig. 31–5.

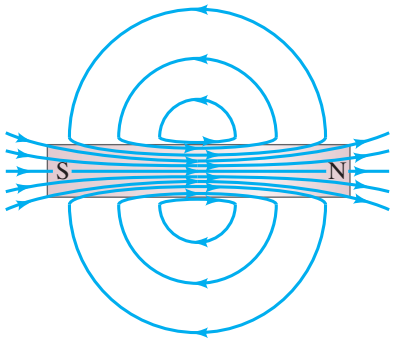

**FIGURE 31–5** Magnetic field lines for a bar magnet. All the lines curve around, as shown for a few, and are continuous.

## 31–3 Maxwell's Equations

With the extension of Ampère's law given by Eq. 31–1, plus Gauss's law for magnetism (Eq. 31–4), we are now ready to state all four of Maxwell's equations. We have seen them all before in the past ten Chapters. In the absence of dielectric or magnetic materials, **Maxwell's equations** are:

*MAXWELL'S EQUATIONS*

$$\oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = \frac{Q}{\epsilon_0} \qquad \textbf{(31–5a)}$$

$$\oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = 0 \qquad \textbf{(31–5b)}$$

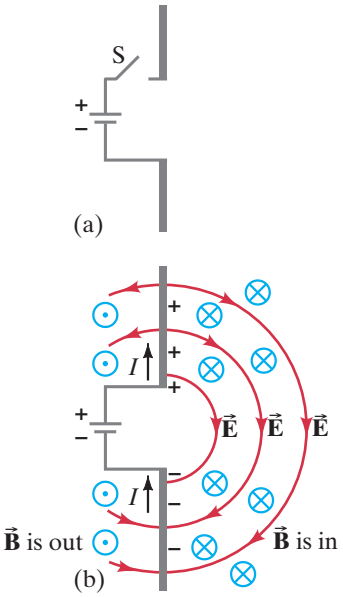
$$\oint \vec{\mathbf{E}} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt} \qquad \textbf{(31–5c)}$$

$$\oint \vec{\mathbf{B}} \cdot d\vec{\ell} = \mu_0 I + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \qquad \textbf{(31–5d)}$$

The first two of Maxwell's equations are the same as Gauss's law for electricity (Chapter 22, Eq. 22–4) and Gauss's law for magnetism (Section 31–2, Eq. 31–4). The third is the general form of Faraday's law (Chapter 29, Eq. 29–8) and the fourth is Ampère's law as modified by Maxwell (Eq. 31–1). The first two equations have integrals over a closed surface on the left, and the second two have line integrals around a closed path. The quantities on the right of each of these equations, $Q$, $I$, and the fluxes, are those enclosed by, or through, a chosen surface (related to the integral on the left). (We drop the subscripts "encl" for simplicity.)

They can be summarized in words: (1) a generalized form of Coulomb's law relating electric field to its sources, electric charges; (2) the same for the magnetic field, except that if there are no magnetic monopoles, magnetic field lines are continuous—they do not begin or end (as electric field lines do on charges); (3) an electric field is produced by a changing magnetic field; (4) a magnetic field is produced by an electric current or by a changing electric field.

Maxwell's equations are the basic equations for all electromagnetism, and are as fundamental as Newton's three laws of motion and the law of universal gravitation. Maxwell's equations can also be written in differential form; see Appendix F.



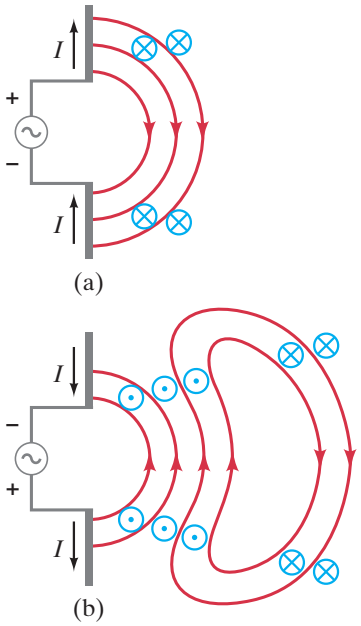
In earlier Chapters, we have seen that we can treat electric and magnetic fields separately if they do not vary in time. But we cannot treat them independently if they change in time because a changing magnetic field produces an electric field; and a changing electric field produces a magnetic field. An important outcome of these relations is the production of electromagnetic waves.

## 31–4 Production of Electromagnetic Waves

According to Maxwell, a magnetic field will be produced in empty space if there is a changing electric field. From this, Maxwell derived another startling conclusion. If a changing magnetic field produces an electric field, that electric field is itself changing. This changing electric field will, in turn, produce a magnetic field, which will be changing, and so it too will produce a changing electric field; and so on. Maxwell found that the net result of these interacting changing fields was a *wave* of electric and magnetic fields that can propagate (travel) through space! We now examine, in a simplified way, how such **electromagnetic waves** can be produced.

Consider two conducting rods that will serve as an "antenna" (Fig. 31–6a). Suppose these two rods are connected by a switch to the opposite terminals of a battery. When the switch is closed, the upper rod quickly becomes positively charged and the lower one negatively charged. Electric field lines are formed as indicated by the red lines in Fig. 31–6b. While the charges are flowing, a current exists whose direction is indicated by the black arrows. A magnetic field is therefore produced near the antenna. The magnetic field lines encircle the rod-like antenna and therefore, in Fig. 31–6b, $\vec{\mathbf{B}}$ points into the page ( $\otimes$ ) on the right and out of the page ( $\odot$ ) on the left.

**FIGURE 31–6** Fields produced by charge flowing into conductors. It takes time for the $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ fields to travel outward to distant points. The fields are shown to the right of the antenna, but they move out in all directions, symmetrically about the (vertical) antenna.



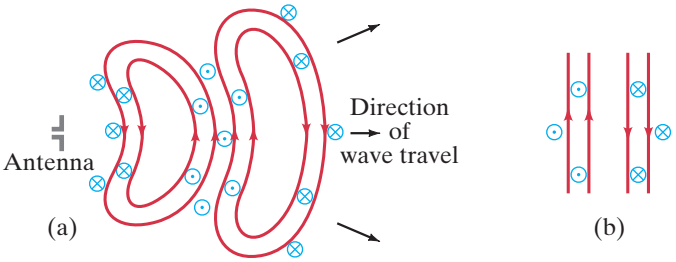


**FIGURE 31–7** Sequence showing electric and magnetic fields that spread outward from oscillating charges on two conductors (the antenna) connected to an ac source (see the text).

Now we ask: how far out do these electric and magnetic fields extend? In the static case, the fields would extend outward indefinitely far. However, when the switch in Fig. 31–6 is closed, the fields quickly appear nearby, but it takes time for them to reach distant points. Both electric and magnetic fields store energy, and this energy cannot be transferred to distant points at infinite speed.

Now we look at the situation of Fig. 31–7 where our antenna is connected to an ac generator. In Fig. 31–7a, the connection has just been completed. Charge starts building up and fields form just as in Fig. 31–6. The + and − signs in Fig. 31–7a indicate the net charge on each rod at a given instant. The black arrows indicate the direction of the current. The electric field is represented by the red lines in the plane of the page; and the magnetic field, according to the right-hand rule, is into ($\otimes$) or out of ($\odot$) the page, in blue. In Fig. 31–7b, the voltage of the ac generator has reversed in direction; the current is reversed and the new magnetic field is in the opposite direction. Because the new fields have changed direction, the old lines fold back to connect up to some of the new lines and form closed loops as shown.[†] The old fields, however, don't suddenly disappear; they are on their way to distant points. Indeed, because a changing magnetic field produces an electric field, and a changing electric field produces a magnetic field, this combination of changing electric and magnetic fields moving outward is self-supporting, no longer depending on the antenna charges.

The fields not far from the antenna, referred to as the *near field*, become quite complicated, but in this book we are not so interested in them. We are instead mainly interested in the fields far from the antenna (they are generally what we detect), which we refer to as the **radiation field**, or *far field*. The electric field lines form loops, as shown in Fig. 31–8, and continue moving outward. The magnetic field lines also form closed loops, but are not shown because they are perpendicular to the page. Although the lines are shown only on the right of the source, fields also travel in other directions. The field strengths are greatest in directions perpendicular to the oscillating charges; and they drop to zero along the direction of oscillation—above and below the antenna in Fig. 31–8.

**FIGURE 31–8** (a) The radiation fields (far from the antenna) produced by a sinusoidal signal on the antenna. The red closed loops represent electric field lines. The magnetic field lines, perpendicular to the page and represented by blue $\otimes$ and $\odot$, also form closed loops. (b) Very far from the antenna the wave fronts (field lines) are essentially flat over a fairly large area, and are referred to as *plane waves*.

The magnitudes of both $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ in the radiation field are found to decrease with distance as $1/r$. (Compare this to the static electric field given by Coulomb's law where $\vec{\mathbf{E}}$ decreases as $1/r^2$.) The energy carried by the electromagnetic wave is proportional (as for any wave, Chapter 15) to the square of the amplitude, $E^2$ or $B^2$, as will be discussed further in Section 31–8. So the intensity of the wave decreases as $1/r^2$. Thus energy carried by EM waves follows the **inverse square law** just as for sound waves (Eqs. 15–8).

Several things about the radiation field can be noted from Fig. 31–8. First, *the electric and magnetic fields at any point are perpendicular to each other, and perpendicular to the direction of wave travel*. Second, we can see that the fields alternate in direction ($\vec{\mathbf{B}}$ is into the page at some points and out of the page at others; $\vec{\mathbf{E}}$ points up at some points and down at others). Thus, the field strengths vary from a maximum

[†]We are considering waves traveling through empty space. There are no charges for lines of $\vec{\mathbf{E}}$ to start or stop on, so they form closed loops. Magnetic field lines always form closed loops.

in one direction, to zero, to a maximum in the other direction. The electric and magnetic fields are "in phase": that is, they each are zero at the same points and reach their maximum at the same points in space. Finally, very far from the antenna (Fig. 31–8b) the field lines are quite flat over a reasonably large area, and the waves are referred to as **plane waves**.

If the source voltage varies sinusoidally, then the electric and magnetic field strengths in the radiation field will also vary sinusoidally. The sinusoidal character of the waves is diagrammed in Fig. 31–9, which displays the field directions and magnitudes plotted as a function of position along the direction of wave travel. Notice that $\vec{\mathbf{B}}$ and $\vec{\mathbf{E}}$ are perpendicular to each other and to the direction of travel (= the direction of the wave velocity $\vec{\mathbf{v}}$). The direction of $\vec{\mathbf{v}}$ can be had from a right-hand rule using $\vec{\mathbf{E}} \times \vec{\mathbf{B}}$: fingers along $\vec{\mathbf{E}}$, then along $\vec{\mathbf{B}}$, gives $\vec{\mathbf{v}}$ along thumb.

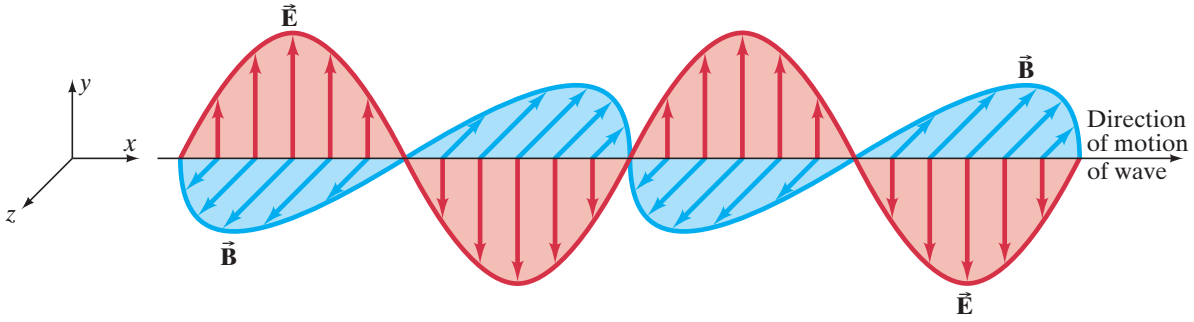

**FIGURE 31–9** Electric and magnetic field strengths in an electromagnetic wave. $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ are at right angles to each other. The entire pattern moves in a direction perpendicular to both $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$.

We call these waves electromagnetic (EM) waves. They are *transverse* waves because the amplitude is perpendicular to the direction of wave travel. However, EM waves are always waves of *fields*, not of matter (like waves on water or a rope). Because they are fields, EM waves can propagate in empty space.

As we have seen, EM waves are produced by electric charges that are oscillating, and hence are undergoing *acceleration*. In fact, we can say in general that

**accelerating electric charges give rise to electromagnetic waves.**

Electromagnetic waves can be produced in other ways as well, requiring description at the atomic and nuclear levels, as we will discuss later.

**EXERCISE A** At a particular instant in time, a wave has its electric field pointing north and its magnetic field pointing vertically up. In which direction is the wave traveling? (*a*) South, (*b*) west, (*c*) east, (*d*) down, (*e*) not enough information.

## 31–5 Electromagnetic Waves, and Their Speed, Derived from Maxwell's Equations

Let us now examine how the existence of EM waves follows from Maxwell's equations. We will see that Maxwell's prediction of the existence of EM waves was startling. Equally startling was the speed at which they were predicted to travel.

We begin by considering a region of free space, where there are *no charges or conduction currents*—that is, far from the source so that the wave fronts (the field lines in Fig. 31–8b) are essentially flat over a reasonable area. We call them **plane waves**, as we saw, because at any instant $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ are uniform over a reasonably large plane perpendicular to the direction of propagation. We choose a coordinate system, so that the wave is traveling in the $x$ direction with velocity $\vec{\mathbf{v}} = v\hat{\mathbf{i}}$, with $\vec{\mathbf{E}}$ parallel to the $y$ axis and $\vec{\mathbf{B}}$ parallel to the $z$ axis, as in Fig. 31–9.

Maxwell's equations in empty space, with $Q = I = 0$, become

$$\oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = 0 \qquad \textbf{(31–6a)}$$

$$\oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = 0 \qquad \textbf{(31–6b)}$$

$$\oint \vec{\mathbf{E}} \cdot d\vec{\boldsymbol{\ell}} = -\frac{d\Phi_B}{dt} \qquad \textbf{(31–6c)}$$

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \qquad \textbf{(31–6d)}$$

Notice the beautiful *symmetry* of these equations. The term on the right in the last equation ("displacement current term") is essential for this symmetry. It is also essential if electromagnetic waves are to be produced, as we will now see.

If the wave is sinusoidal with wavelength $\lambda$ and frequency $f$, then, as we saw in Chapter 15, Section 15–4, such a traveling wave moving to the right along the $x$ axis can be written as

$$\begin{aligned} E &= E_y = E_0 \sin(kx - \omega t) \\ B &= B_z = B_0 \sin(kx - \omega t) \end{aligned} \qquad \textbf{(31–7)}$$

where

$$k = \frac{2\pi}{\lambda}, \qquad \omega = 2\pi f, \qquad \text{and} \qquad f\lambda = \frac{\omega}{k} = v, \qquad \textbf{(31–8)}$$

with $v$ being the speed of the wave. For a wave moving to the left, the minus sign becomes plus, $(kx + \omega t)$, as in Eq. 15–13. Although visualizing the wave as sinusoidal is helpful, we will not have to assume so in most of what follows.

Consider now a small rectangle in the plane of the electric field as shown in Fig. 31–10. This rectangle has a finite height $\Delta y$, and a very thin width which we take to be the infinitesimal distance $dx$. First we show that $\vec{\mathbf{E}}$, $\vec{\mathbf{B}}$, and $\vec{\mathbf{v}}$ are in the orientation shown by applying Lenz's law to this rectangular loop. The changing magnetic flux through this loop is related to the electric field around the loop by Faraday's law (Maxwell's third equation, Eq. 31–6c). For the case shown, $B$ through the loop is decreasing in time as the wave moves to the right. So the electric field must be in a direction to oppose this change. This means $E$ must be greater on the right side of the loop than on the left, as shown (so it could produce a counterclockwise current whose magnetic field would act to oppose the decrease in $\Phi_B$—even though there is no current). This brief argument shows that the orientations of $\vec{\mathbf{E}}$, $\vec{\mathbf{B}}$, and $\vec{\mathbf{v}}$ are in the correct relation as shown. That is, $\vec{\mathbf{v}}$ is in the direction of $\vec{\mathbf{E}} \times \vec{\mathbf{B}}$.

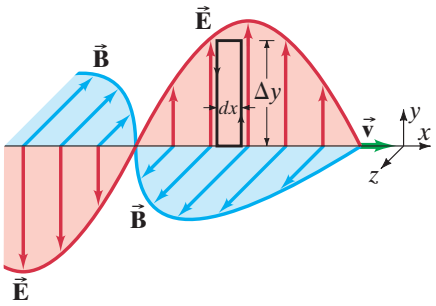

**FIGURE 31–10** Applying Faraday's law to the rectangle $(\Delta y)(dx)$.

Let us again apply Faraday's law, Maxwell's third equation (Eq. 31–6c), in a more detailed way to the same rectangle of height $\Delta y$ and width $dx$ shown in Fig. 31–10. First we consider $\oint \vec{\mathbf{E}} \cdot d\vec{\boldsymbol{\ell}}$ in Eq. 31–6c. Along the short top and bottom sections of length $dx$, $\vec{\mathbf{E}}$ is perpendicular to $d\vec{\boldsymbol{\ell}}$, so $\vec{\mathbf{E}} \cdot d\vec{\boldsymbol{\ell}} = 0$. Along the vertical sides, we let $E$ be the electric field along the left side, and on the right side where it will be slightly larger, it is $E + dE$. Thus, if we take our loop counterclockwise,

$$\oint \vec{\mathbf{E}} \cdot d\vec{\boldsymbol{\ell}} = (E + dE)\,\Delta y - E\,\Delta y = dE\,\Delta y.$$

For the right side of Faraday's law, $-d\Phi_B/dt$, the magnetic flux through the loop changes as

$$\frac{d\Phi_B}{dt} = \frac{dB}{dt} dx\,\Delta y,$$

since the area of the loop, $(dx)(\Delta y)$, is not changing. Thus, Faraday's law gives us

$$dE\,\Delta y = -\frac{dB}{dt} dx\,\Delta y$$

or

$$\frac{dE}{dx} = -\frac{dB}{dt}.$$

Actually, both $E$ and $B$ are functions of position $x$ and time $t$. We should therefore

rewrite this equation using partial derivatives:

$$\frac{\partial E}{\partial x} = -\frac{\partial B}{\partial t} \tag{31–9}$$

where $\partial E/\partial x$ means the derivative of $E$ with respect to $x$ while $t$ is held fixed, and $\partial B/\partial t$ is the derivative of $B$ with respect to $t$ while $x$ is kept fixed.

We can obtain another important relation between $E$ and $B$ in addition to Eq. 31–9. To do so, we consider now a small rectangle in the plane of $\vec{\mathbf{B}}$, whose length and width are $\Delta z$ and $dx$ as shown in Fig. 31–11. To this rectangular loop we apply Maxwell's fourth equation (the extension of Ampère's law) in empty space, Eq. 31–6d:

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}.$$

Along the short sides $(dx)$, the dot product $\vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}}$ is zero since $\vec{\mathbf{B}}$ is perpendicular to $d\vec{\boldsymbol{\ell}}$. Along the longer sides $(\Delta z)$, we let $B$ be the magnetic field along the left side of length $\Delta z$, and $B + dB$ be the (slightly larger) field along the right side. We again integrate counterclockwise, so

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = B\,\Delta z - (B + dB)\,\Delta z = -dB\,\Delta z.$$

The right side of Maxwell's fourth equation, Eq. 31–6d, is

$$\mu_0 \epsilon_0 \frac{d\Phi_E}{dt} = \mu_0 \epsilon_0 \frac{dE}{dt} dx\,\Delta z,$$

where the area $dx\,\Delta y$ is not changing. Equating these last two expressions, we obtain

$$-dB\,\Delta z = \mu_0 \epsilon_0 \frac{dE}{dt} dx\,\Delta z$$

or

$$\frac{\partial B}{\partial x} = -\mu_0 \epsilon_0 \frac{\partial E}{\partial t} \tag{31–10}$$

where we have replaced $dB/dx$ and $dE/dt$ by the proper partial derivatives as before.

We can use Eqs. 31–9 and 31–10 to obtain a relation between the magnitudes of $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$, and the speed $v$. Let $E$ and $B$ be given by Eqs. 31–7 as a function of $x$ and $t$. When we apply Eq. 31–9, taking the derivatives $\partial E/\partial x$ and $\partial B/\partial t$ as given by Eqs. 31–7, we obtain

$$kE_0 \cos(kx - \omega t) = \omega B_0 \cos(kx - \omega t)$$

so

$$\frac{E_0}{B_0} = \frac{\omega}{k} = v,$$

since $v = \omega/k$ (see Eq. 31–8 or 15–12). Since $E$ and $B$ are in phase, we see that $E$ and $B$ are related by

$$\frac{E}{B} = v \tag{31–11}$$

at any point in space, where $v$ is the velocity of the wave.

Now we apply Eq. 31–10 to the sinusoidal fields (Eqs. 31–7), taking partial derivatives, and obtain

$$kB_0 \cos(kx - \omega t) = \mu_0 \epsilon_0 \omega E_0 \cos(kx - \omega t)$$

or

$$\frac{B_0}{E_0} = \frac{\mu_0 \epsilon_0 \omega}{k} = \mu_0 \epsilon_0 v.$$

We just saw that $B_0/E_0 = 1/v$, so

$$\mu_0 \epsilon_0 v = \frac{1}{v}.$$

Solving for $v$ gives us an astonishing result:

$$v = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = c, \tag{31–12}$$

*Speed of light*

where $c$ is the special symbol for the speed of electromagnetic waves in free space.

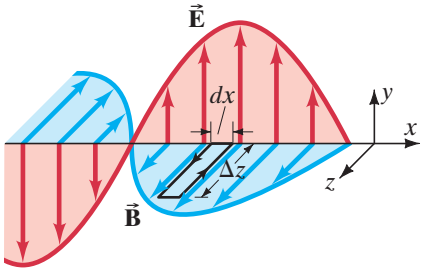

**FIGURE 31–11** Applying Maxwell's fourth equation to the rectangle $(\Delta z)(dx)$.

We see that $c$ is a constant, independent of the wavelength or frequency. If we put in values for $\epsilon_0$ and $\mu_0$ we find

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = \frac{1}{\sqrt{(8.85 \times 10^{-12}\,\mathrm{C^2/N \cdot m^2})(4\pi \times 10^{-7}\,\mathrm{T \cdot m/A})}}$$
$$= 3.00 \times 10^8\,\mathrm{m/s}.$$

This is a remarkable result. For this is precisely equal to the measured speed of light!

**EXAMPLE 31–2 Determining $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ in EM waves.** Assume a 60.0-Hz EM wave is a sinusoidal wave propagating in the $z$ direction with $\vec{\mathbf{E}}$ pointing in the $x$ direction, and $E_0 = 2.00\,\mathrm{V/m}$. Write vector expressions for $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ as functions of position and time.

**APPROACH** We find $\lambda$ from $\lambda f = v = c$. Then we use Fig. 31–9 and Eqs. 31–7 and 31–8 for the mathematical form of traveling electric and magnetic fields of an EM wave.

**SOLUTION** The wavelength is

$$\lambda = \frac{c}{f} = \frac{3.00 \times 10^8\,\mathrm{m/s}}{60.0\,\mathrm{s^{-1}}} = 5.00 \times 10^6\,\mathrm{m}.$$

From Eq. 31–8 we have

$$k = \frac{2\pi}{\lambda} = \frac{2\pi}{5.00 \times 10^6\,\mathrm{m}} = 1.26 \times 10^{-6}\,\mathrm{m^{-1}}$$
$$\omega = 2\pi f = 2\pi(60.0\,\mathrm{Hz}) = 377\,\mathrm{rad/s}.$$

From Eq. 31–11 with $v = c$, we find that

$$B_0 = \frac{E_0}{c} = \frac{2.00\,\mathrm{V/m}}{3.00 \times 10^8\,\mathrm{m/s}} = 6.67 \times 10^{-9}\,\mathrm{T}.$$

The direction of propagation is that of $\vec{\mathbf{E}} \times \vec{\mathbf{B}}$, as in Fig. 31–9. With $\vec{\mathbf{E}}$ pointing in the $x$ direction, and the wave propagating in the $+z$ direction, $\vec{\mathbf{B}}$ must point in the $y$ direction. Using Eqs. 31–7 we find:

$$\vec{\mathbf{E}} = \hat{\mathbf{i}}(2.00\,\mathrm{V/m})\sin\left[(1.26 \times 10^{-6}\,\mathrm{m^{-1}})z - (377\,\mathrm{rad/s})t\right]$$
$$\vec{\mathbf{B}} = \hat{\mathbf{j}}(6.67 \times 10^{-9}\,\mathrm{T})\sin\left[(1.26 \times 10^{-6}\,\mathrm{m^{-1}})z - (377\,\mathrm{rad/s})t\right]$$

## *Derivation of Speed of Light (General)

We can derive the speed of EM waves without having to assume sinusoidal waves by combining Eqs. 31–9 and 31–10 as follows. We take the derivative with respect to $t$ of Eq. 31–10

$$\frac{\partial^2 B}{\partial t\,\partial x} = -\mu_0 \epsilon_0 \frac{\partial^2 E}{\partial t^2}.$$

We next take the derivative of Eq. 31–9 with respect to $x$:

$$\frac{\partial^2 E}{\partial x^2} = -\frac{\partial^2 B}{\partial t\,\partial x}.$$

Since $\partial^2 B/\partial t\,\partial x$ appears in both these relations, we obtain

$$\frac{\partial^2 E}{\partial t^2} = \frac{1}{\mu_0 \epsilon_0}\frac{\partial^2 E}{\partial x^2}. \qquad \textbf{(31–13a)}$$

By taking the derivatives of Eqs. 31–9 (with respect to $t$) and 31–10 (with respect to $x$) we obtain the same relation for $B$:

$$\frac{\partial^2 B}{\partial t^2} = \frac{1}{\mu_0 \epsilon_0}\frac{\partial^2 B}{\partial x^2}. \qquad \textbf{(31–13b)}$$

Both of Eqs. 31–13 have the form of the **wave equation** for a plane wave traveling

in the $x$ direction, as discussed in Section 15–5 (Eq. 15–16):

$$\frac{\partial^2 D}{\partial t^2} = v^2 \frac{\partial^2 D}{\partial x^2},$$

where $D$ stands for any type of displacement. We see that the velocity $v$ for Eqs. 31–13 is given by

$$v^2 = \frac{1}{\mu_0 \epsilon_0}$$

in agreement with Eq. 31–12. Thus we see that a natural outcome of Maxwell's equations is that $E$ and $B$ obey the wave equation for waves traveling with speed $v = 1/\sqrt{\mu_0 \epsilon_0}$. It was on this basis that Maxwell predicted the existence of electromagnetic waves and predicted their speed.

## 31–6 Light as an Electromagnetic Wave and the Electromagnetic Spectrum

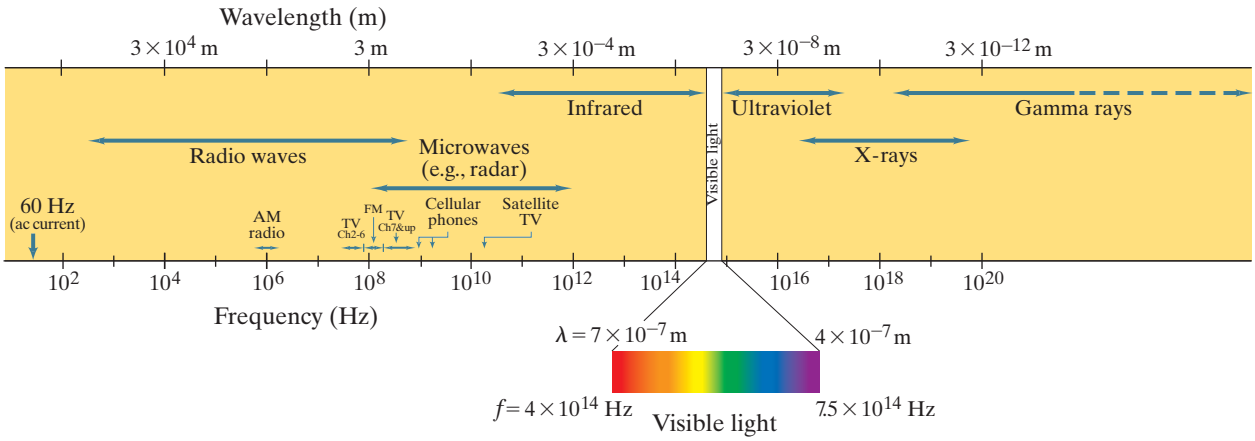
Maxwell's prediction that EM waves should exist was startling. Equally remarkable was the speed at which EM waves were predicted to travel in empty space (Eqs. 31–11 and 31–12),

$$c = \frac{E}{B} = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = 3.00 \times 10^8 \text{ m/s},$$

*Speed of light*

the same as the measured speed of light in vacuum.

Light had been shown some 60 years before Maxwell's work to behave like a wave (we'll discuss this in Chapter 34). But nobody knew what kind of wave it was. What is it that is oscillating in a light wave? Maxwell, on the basis of the calculated speed of EM waves, argued that light must be an electromagnetic wave. This idea soon came to be generally accepted by scientists, but not fully until after EM waves were experimentally detected. EM waves were first generated and detected experimentally by Heinrich Hertz (1857–1894) in 1887, eight years after Maxwell's death. Hertz used a spark-gap apparatus in which charge was made to rush back and forth for a short time, generating waves whose frequency was about $10^9$ Hz. He detected them some distance away using a loop of wire in which an emf was induced when a changing magnetic field passed through. These waves were later shown to travel at the speed of light, $3.00 \times 10^8$ m/s, and to exhibit all the characteristics of light such as reflection, refraction, and interference. The only difference was that their frequencies were not visible to the human eye. Hertz's experiment was a strong confirmation of Maxwell's theory.



The wavelengths of visible light were measured in the first decade of the nineteenth century, long before anyone imagined that light was an electromagnetic wave. The wavelengths were found to lie between $4.0 \times 10^{-7}$ m and $7.5 \times 10^{-7}$ m, or 400 nm to 750 nm $(1 \text{ nm} = 10^{-9} \text{ m})$. The frequencies of visible light can be found using Eq. 15–1 or 31–8, which we rewrite here:

$$c = \lambda f, \qquad \textbf{(31–14)}$$

where $f$ and $\lambda$ are the frequency and wavelength, respectively, of the wave. Here, $c$ is the speed of light, $3.00 \times 10^8$ m/s; it gets the special symbol $c$ because of its universality for all EM waves in "free space" (meaning empty space = a vacuum). Equation 31–14 tells us that the frequencies of visible light are between $4.0 \times 10^{14}$ Hz and $7.5 \times 10^{14}$ Hz. (Recall that 1 Hz = 1 cycle per second = $1 \text{ s}^{-1}$.)

But visible light is only one kind of EM wave. As we have seen, Hertz produced EM waves of much lower frequency, about $10^9$ Hz. These are now called **radio waves**, because frequencies in this range are used to transmit radio and TV signals. Electromagnetic waves, or EM radiation as we sometimes call it, have been produced or detected over a wide range of frequencies. They are usually categorized as shown in Fig. 31–12, which is known as the **electromagnetic spectrum**.

**FIGURE 31–12** Electromagnetic spectrum.

Radio waves and microwaves can be produced in the laboratory using electronic equipment (Fig. 31–7). Higher-frequency waves are very difficult to produce electronically. These and other types of EM waves are produced in natural processes, as emission from atoms, molecules, and nuclei (more on this later). EM waves can be produced by the acceleration of electrons or other charged particles, such as electrons in the antenna of Fig. 31–7. X-rays have very short wavelengths (and very high frequencies), and they are produced (Chapter 35) when fast-moving electrons are rapidly decelerated upon striking a metal target. Even the visible light emitted by an ordinary incandescent bulb is due to electrons undergoing acceleration within the hot filament.

**EXERCISE B** Return to the Chapter-Opening Question, page 898, and answer it again now. Try to explain why you may have answered differently the first time.

We will meet various types of EM waves later. However, it is worth mentioning here that infrared (IR) radiation (EM waves whose frequency is just less than that of visible light) is mainly responsible for the heating effect on Earth due to the Sun. The Sun emits not only visible light but substantial amounts of IR and UV (ultraviolet) as well. The molecules of our skin tend to "resonate" at infrared frequencies, so it is these that are preferentially absorbed and thus warm us up. We humans experience EM waves differently, depending on their wavelengths: Our eyes detect wavelengths between about $4 \times 10^{-7}$ m and $7.5 \times 10^{-7}$ m (visible light), whereas our skin "detects" longer wavelengths (IR). Many EM wavelengths we don't detect directly at all.

**CAUTION**
*Sound and EM waves are different*

Light and other electromagnetic waves travel at a speed of $3 \times 10^8$ m/s. Compare this to sound, which travels (see Chapter 16) at a speed of about 300 m/s in air, a million times slower; or to typical freeway speeds of a car, 30 m/s (100 km/h, or 60 mi/h), 10 million times slower than light. They differ also in that sound is a longitudinal wave, whereas EM waves are transverse. Finally EM waves differ from sound waves in another big way: sound waves travel in a medium such as air, and involve motion of air molecules; EM waves do not involve any material—only fields, and they can travel in empty space.

**EXAMPLE 31–3** **Wavelengths of EM waves.** Calculate the wavelength ($a$) of a 60-Hz EM wave, ($b$) of a 93.3-MHz FM radio wave, and ($c$) of a beam of visible red light from a laser at frequency $4.74 \times 10^{14}$ Hz.

**APPROACH** All of these waves are electromagnetic waves, so their speed is $c = 3.00 \times 10^8$ m/s. We solve for $\lambda$ in Eq. 31–14: $\lambda = c/f$.

**SOLUTION** ($a$) $$\lambda = \frac{c}{f} = \frac{3.00 \times 10^8 \text{ m/s}}{60 \text{ s}^{-1}} = 5.0 \times 10^6 \text{ m},$$

or 5000 km. 60 Hz is the frequency of ac current in the United States, and, as we see here, one wavelength stretches all the way across the continental USA.

($b$) $$\lambda = \frac{3.00 \times 10^8 \text{ m/s}}{93.3 \times 10^6 \text{ s}^{-1}} = 3.22 \text{ m}.$$

The length of an effective FM radio antenna is often about half this $\left(\frac{1}{2}\lambda\right)$, or $1\frac{1}{2}$ m.

($c$) $$\lambda = \frac{3.00 \times 10^8 \text{ m/s}}{4.74 \times 10^{14} \text{ s}^{-1}} = 6.33 \times 10^{-7} \text{ m} \ (= 633 \text{ nm}).$$

**EXERCISE C** What are the frequencies of ($a$) an 80-m-wavelength radio wave, and ($b$) an X-ray of wavelength $5.5 \times 10^{-11}$ m?

**EXAMPLE 31–4** **ESTIMATE** **Cell phone antenna.** The antenna of a cell phone is often $\frac{1}{4}$ wavelength long. A particular cell phone has an 8.5-cm-long straight rod for its antenna. Estimate the operating frequency of this phone.

**APPROACH** The basic equation relating wave speed, wavelength, and frequency is $c = \lambda f$. The wavelength $\lambda$ equals four times the antenna's length.

**SOLUTION** The antenna is $\frac{1}{4}\lambda$ long, so $\lambda = 4(8.5 \text{ cm}) = 34 \text{ cm} = 0.34 \text{ m}$. Then $f = c/\lambda = (3.0 \times 10^8 \text{ m/s})/(0.34 \text{ m}) = 8.8 \times 10^8 \text{ Hz} = 880 \text{ MHz}$.

**NOTE** Radio antennas are not always straight conductors. The conductor may be a round loop to save space. See Fig. 31–22b.

**EXERCISE D** How long should a $\frac{1}{4}\lambda$ antenna be for an aircraft radio operating at 165 MHz?

Electromagnetic waves can travel along transmission lines as well as in empty space. When a source of emf is connected to a transmission line—be it two parallel wires or a coaxial cable (Figs. 31–13 and 28–12)—the electric field within the wire is not set up immediately at all points along the wires. This is based on the same argument we used in Section 31–4 with reference to Fig. 31–7. Indeed, it can be shown that if the wires are separated by empty space or air, the electrical signal travels along the wires at the speed $c = 3.0 \times 10^8$ m/s. For example, when you flip a light switch, the light actually goes on a tiny fraction of a second later. If the wires are in a medium whose electric permittivity is $\epsilon$ and magnetic permeability is $\mu$ (Sections 24–5 and 28–10, respectively), the speed is not given by Eq. 31–12, but by

$$v = \frac{1}{\sqrt{\epsilon\mu}}$$

instead.

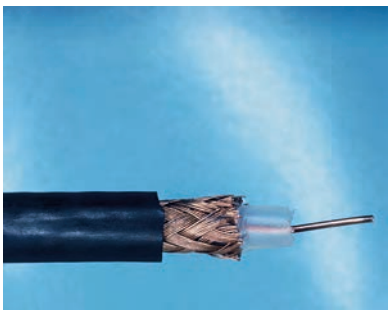


**FIGURE 31–13**
Coaxial cable.

**EXAMPLE 31–5** **ESTIMATE** **Phone call time lag.** You make a telephone call from New York to a friend in London. Estimate how long it will take the electrical signal generated by your voice to reach London, assuming the signal is (*a*) carried on a telephone cable under the Atlantic Ocean, and (*b*) sent via satellite 36,000 km above the ocean. Would there be a noticeable delay in either case?

**APPROACH** The signal is carried (*a*) on a telephone cable [wire or optical fiber (Section 32–7)], or (*b*) in the air via satellite. In either case it is an electromagnetic wave. Electronics as well as the cable slow things down, but as a rough estimate we take the speed to be $c = 3.0 \times 10^8\,\text{m/s}$.

**SOLUTION** The distance from New York to London is about 5000 km.

(*a*) The time delay via the cable is $t = d/c \approx (5 \times 10^6\,\text{m})/(3.0 \times 10^8\,\text{m/s}) = 0.017\,\text{s}$.

(*b*) Via satellite the time would be longer because communications satellites, which are usually geosynchronous (Example 6–6), move at a height of 36,000 km. The signal would have to go up to the satellite and back down, or 72,000 km, but the actual distance the signal would travel would be a little more than this as the signal would go up and down on a diagonal (5000 km New York to London, small compared to the distance up to the satellite). Thus $t = d/c \approx (7.2 \times 10^7\,\text{m})/(3 \times 10^8\,\text{m/s}) \approx 0.24\,\text{s}$, one way. Both directions $\approx \frac{1}{2}\,\text{s}$.

**NOTE** When the signal travels via underwater cable, which nearly all intercontinental calls are today, there is barely a hint of a delay and conversations are normal. If the phone call is sent via satellite, the delay would be noticeable. The length of time between the end of when you speak and your friend receives it and replies, and then you hear the reply, would be about a half second beyond the normal time in a conversation, as we just calculated. This would be enough to be noticeable, and you would have to adjust for it so you don't start talking again while your friend's reply is on the way back to you.

**EXERCISE E** If you are on the phone via satellite to someone only 100 km away, would you notice the same effect discussed in the NOTE above?

**EXERCISE F** If your voice traveled as a sound wave, how long would it take to go from New York to London?

## 31–7 Measuring the Speed of Light

Galileo attempted to measure the speed of light by trying to measure the time required for light to travel a known distance between two hilltops. He stationed an assistant on one hilltop and himself on another, and ordered the assistant to lift the cover from a lamp the instant he saw a flash from Galileo's lamp. Galileo measured the time between the flash of his lamp and when he received the light from his assistant's lamp. The time was so short that Galileo concluded it merely represented human reaction time, and that the speed of light must be extremely high.

The first successful determination that the speed of light is finite was made by the Danish astronomer Ole Roemer (1644–1710). Roemer had noted that the carefully measured orbital period of Io, a moon of Jupiter with an average period of 42.5 h, varied slightly, depending on the relative position of Earth and Jupiter. He attributed this variation in the apparent period to the change in distance between the Earth and Jupiter during one of Io's periods, and the time it took light to travel the extra distance. Roemer concluded that the speed of light—though great—is finite.

Since then a number of techniques have been used to measure the speed of light. Among the most important were those carried out by the American Albert A. Michelson (1852–1931).

Michelson used the rotating mirror apparatus diagrammed in Fig. 31–14 for a series of high-precision experiments carried out from 1880 to the 1920s. Light from a source would hit one face of a rotating eight-sided mirror. The reflected light traveled to a stationary mirror a large distance away and back again as shown. If the rotating mirror was turning at just the right rate, the returning beam of light would reflect from the face of one of the mirrors into a small telescope through which the observer looked. If the speed of rotation was only slightly different, the beam would be deflected to one side and would not be seen by the observer. From the required speed of the rotating mirror and the carefully measured distance to the stationary mirror, the speed of light could be calculated. In the 1920s, Michelson set up the rotating mirror on the top of Mt. Wilson in southern California and the stationary mirror on Mt. San Antonio (Mt. Baldy) 35 km away. He later measured the speed of light in vacuum using a long evacuated tube.

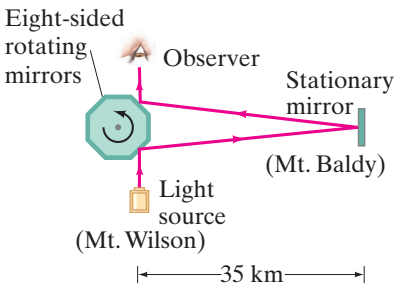

**FIGURE 31–14** Michelson's speed-of-light apparatus (not to scale).

The most recent measurements of the speed of light, $c$, in vacuum yielded

$$c = 2.99792458 \times 10^8 \text{ m/s}.$$

In 1983, international organizations decided to *define* this value as the speed of light. (See Section 1–4, where we also saw that as a consequence, the length of the standard meter became more precise.) We usually round off $c$ to

$$c = 3.00 \times 10^8 \text{ m/s}$$

when extremely precise results are not required. In air, the speed is only slightly less.

## 31–8 Energy in EM Waves; the Poynting Vector

Electromagnetic waves carry energy from one region of space to another. This energy is associated with the moving electric and magnetic fields. In Section 24–4, we saw that the energy density $u_E$ $(\text{J/m}^3)$ stored in an electric field $E$ is $u_E = \frac{1}{2}\epsilon_0 E^2$ (Eq. 24–6). The energy density stored in a magnetic field $B$, as we discussed in Section 30–3, is given by $u_B = \frac{1}{2}B^2/\mu_0$ (Eq. 30–7). Thus, the total energy stored per unit volume in a region of space where there is an electromagnetic wave is

$$u = u_E + u_B = \frac{1}{2}\epsilon_0 E^2 + \frac{1}{2}\frac{B^2}{\mu_0}. \qquad \textbf{(31–15)}$$

In this equation, $E$ and $B$ represent the electric and magnetic field strengths of the wave at any instant in a small region of space. We can write Eq. 31–15 in terms of the $E$ field alone, using Eqs. 31–11 $(B = E/c)$ and 31–12 $\left(c = 1/\sqrt{\epsilon_0\mu_0}\right)$ to obtain

$$u = \frac{1}{2}\epsilon_0 E^2 + \frac{1}{2}\frac{\epsilon_0\mu_0 E^2}{\mu_0} = \epsilon_0 E^2. \qquad \textbf{(31–16a)}$$

Note here that the energy density associated with the $B$ field equals that due to the $E$ field, and each contributes half to the total energy. We can also write the energy density in terms of the $B$ field only (using Eq. 31–11):

$$u = \epsilon_0 E^2 = \epsilon_0 c^2 B^2 = \frac{B^2}{\mu_0}, \qquad \textbf{(31–16b)}$$

or in one term containing both $E$ and $B$,

$$u = \epsilon_0 E^2 = \epsilon_0 EcB = \frac{\epsilon_0 EB}{\sqrt{\epsilon_0\mu_0}}$$

or

$$u = \sqrt{\frac{\epsilon_0}{\mu_0}}\,EB. \qquad \textbf{(31–16c)}$$

Equations 31–16 give the energy density of EM waves in any region of space at any instant.

Now let us determine the energy the wave transports per unit time per unit area. This is given by a vector $\vec{\mathbf{S}}$, which is called the **Poynting vector**.[†] The units of $\vec{\mathbf{S}}$ are $\mathrm{W/m^2}$. The direction of $\vec{\mathbf{S}}$ is the direction in which the energy is transported, which is the direction in which the wave is moving.

Let us imagine the wave is passing through an area $A$ perpendicular to the $x$ axis as shown in Fig. 31–15. In a short time $dt$, the wave moves to the right a distance $dx = c\,dt$ where $c$ is the wave speed. The energy that passes through $A$ in the time $dt$ is the energy that occupies the volume $dV = A\,dx = Ac\,dt$. The energy density $u$ is $u = \epsilon_0 E^2$ where $E$ is the electric field in this volume at the given instant.

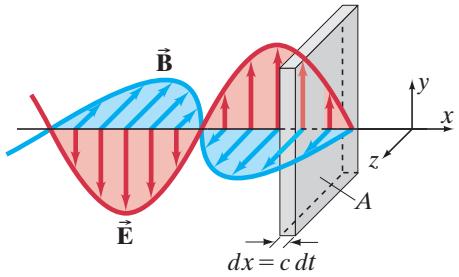

**FIGURE 31–15** Electromagnetic waves carrying energy through area A.

So the total energy $dU$ contained in this volume $dV$ is the energy density $u$ times the volume: $dU = u\,dV = (\epsilon_0 E^2)(Ac\,dt)$. Therefore $S$, the energy crossing the area $A$ per time $dt$, is

$$S = \frac{1}{A}\frac{dU}{dt} = \epsilon_0 cE^2. \qquad \textbf{(31–17)}$$

Since $E = cB$ and $c = 1/\sqrt{\epsilon_0\mu_0}$, this can also be written:

$$S = \epsilon_0 cE^2 = \frac{cB^2}{\mu_0} = \frac{EB}{\mu_0}.$$

The direction of $\vec{\mathbf{S}}$ is along $\vec{\mathbf{v}}$, perpendicular to $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$, so the Poynting vector $\vec{\mathbf{S}}$ can be written

$$\vec{\mathbf{S}} = \frac{1}{\mu_0}(\vec{\mathbf{E}} \times \vec{\mathbf{B}}). \qquad \textbf{(31–18)}$$

Equation 31–17 or 31–18 gives the energy transported per unit area per unit time at any *instant*. We often want to know the *average* over an extended period of time since the frequencies are usually so high we don't detect the rapid time variation. If $E$ and $B$ are sinusoidal, then $\overline{E^2} = E_0^2/2$, just as for electric currents and voltages (Section 25–7), where $E_0$ is the *maximum* value of $E$. Thus we can write for the magnitude of the Poynting vector, on the average,

$$\overline{S} = \frac{1}{2}\epsilon_0 cE_0^2 = \frac{1}{2}\frac{c}{\mu_0}B_0^2 = \frac{E_0 B_0}{2\mu_0}, \qquad \textbf{(31–19a)}$$

where $B_0$ is the maximum value of $B$. This time averaged value of $\vec{\mathbf{S}}$ is the **intensity**, defined as the average power transferred across unit area (Section 15–3). We can also write for the average value of $S$:

$$\overline{S} = \frac{E_{\mathrm{rms}} B_{\mathrm{rms}}}{\mu_0} \qquad \textbf{(31–19b)}$$

where $E_{\mathrm{rms}}$ and $B_{\mathrm{rms}}$ are the rms values $\left(E_{\mathrm{rms}} = \sqrt{\overline{E^2}} = E_0/\sqrt{2}\right.$ and $\left.B_{\mathrm{rms}} = \sqrt{\overline{E^2}} = B_0/\sqrt{2}\right)$.

**EXAMPLE 31–6** ***E* and *B* from the Sun.** Radiation from the Sun reaches the Earth (above the atmosphere) with an intensity of about $1350\ \mathrm{J/s \cdot m^2} = 1350\ \mathrm{W/m^2}$. Assume that this is a single EM wave, and calculate the maximum values of $E$ and $B$.

**APPROACH** We solve Eq. 31–19a $\left(\overline{S} = \frac{1}{2}\epsilon_0 cE_0^2\right)$ for $E_0$ in terms of $\overline{S}$ and use $\overline{S} = 1350\ \mathrm{J/s \cdot m^2}$.

[†]After J. H. Poynting (1852–1914).

**SOLUTION** $E_0 = \sqrt{\frac{2\bar{S}}{\epsilon_0 c}} = \sqrt{\frac{2(1350\,\text{J/s}\cdot\text{m}^2)}{(8.85\times10^{-12}\,\text{C}^2/\text{N}\cdot\text{m}^2)(3.00\times10^8\,\text{m/s})}}$

$= 1.01\times10^3\,\text{V/m}.$

From Eq. 31–11, $B = E/c$, so

$$B_0 = \frac{E_0}{c} = \frac{1.01\times10^3\,\text{V/m}}{3.00\times10^8\,\text{m/s}} = 3.37\times10^{-6}\,\text{T}.$$

**NOTE** Although $B$ has a small numerical value compared to $E$ (because of the way the different units for $E$ and $B$ are defined), $B$ contributes the same energy to the wave as $E$ does, as we saw earlier (Eqs. 31–15 and 16).

**CAUTION**

*E and B have very different values (due to how units are defined), but E and B contribute* equal *energy*

# 31–9 Radiation Pressure

If electromagnetic waves carry energy, then we would expect them to also carry linear momentum. When an electromagnetic wave encounters the surface of an object, a force will be exerted on the surface as a result of the momentum transfer ($F = dp/dt$), just as when a moving object strikes a surface. The force per unit area exerted by the waves is called **radiation pressure**, and its existence was predicted by Maxwell. He showed that if a beam of EM radiation (light, for example) is completely absorbed by an object, then the momentum transferred is

$$\Delta p = \frac{\Delta U}{c} \qquad \begin{bmatrix}\text{radiation}\\ \text{fully}\\ \text{absorbed}\end{bmatrix} \qquad \textbf{(31–20a)}$$

where $\Delta U$ is the energy absorbed by the object in a time $\Delta t$, and $c$ is the speed of light.† If instead, the radiation is fully reflected (suppose the object is a mirror), then the momentum transferred is twice as great, just as when a ball bounces elastically off a surface:

$$\Delta p = \frac{2\,\Delta U}{c}. \qquad \begin{bmatrix}\text{radiation}\\ \text{fully}\\ \text{reflected}\end{bmatrix} \qquad \textbf{(31–20b)}$$

If a surface absorbs some of the energy, and reflects some of it, then $\Delta p = a\,\Delta U/c$, where $a$ has a value between 1 and 2.

Using Newton's second law we can calculate the force and the pressure $P$ exerted by radiation on an object from the change in momentum $p$. The force $F$ is given by

$$F = \frac{dp}{dt}.$$

The average rate that energy is delivered to the object is related to the Poynting vector by (Eq. 31–17)

$$\frac{dU}{dt} = \bar{S}A,$$

where $A$ is the cross-sectional area of the object which intercepts the radiation. The radiation pressure $P$ (assuming full absorption) is given by (see Eq. 31–20a)

$$P = \frac{F}{A} = \frac{1}{A}\frac{dp}{dt} = \frac{1}{Ac}\frac{dU}{dt} = \frac{\bar{S}}{c}. \qquad \begin{bmatrix}\text{fully}\\ \text{absorbed}\end{bmatrix} \qquad \textbf{(31–21a)}$$

If the light is fully reflected, the pressure is twice as great (Eq. 31–20b):

$$P = \frac{2\bar{S}}{c}. \qquad \begin{bmatrix}\text{fully}\\ \text{reflected}\end{bmatrix} \qquad \textbf{(31–21b)}$$

†Very roughly, if we think of light as particles (and we do—see Chapter 37), the force that would be needed to bring such a particle moving at speed $c$ to "rest" (i.e., absorption) is $F = \Delta p/\Delta t$. But $F$ is also related to energy by Eq. 8–7, $F = \Delta U/\Delta x$, so $\Delta p = F\,\Delta t = \Delta U/(\Delta x/\Delta t) = \Delta U/c$ where we identify $(\Delta x/\Delta t)$ as the speed of light $c$.

**EXAMPLE 31–7** **ESTIMATE** **Solar pressure.** Radiation from the Sun that reaches the Earth's surface (after passing through the atmosphere) transports energy at a rate of about $1000\,\text{W/m}^2$. Estimate the pressure and force exerted by the Sun on your outstretched hand.

**APPROACH** The radiation is partially reflected and partially absorbed, so let us estimate simply $P = \bar{S}/c$.

**SOLUTION** $$P \approx \frac{\bar{S}}{c} = \frac{1000\,\text{W/m}^2}{3\times10^8\,\text{m/s}} \approx 3\times10^{-6}\,\text{N/m}^2.$$

An estimate of the area of your outstretched hand might be about 10 cm by 20 cm, so $A = 0.02\,\text{m}^2$. Then the force is

$$F = PA \approx (3\times10^{-6}\,\text{N/m}^2)(0.02\,\text{m}^2) \approx 6\times10^{-8}\,\text{N}.$$

**NOTE** These numbers are tiny. The force of gravity on your hand, for comparison, is maybe a half pound, or with $m = 0.2\,\text{kg}$, $mg \approx (0.2\,\text{kg})(9.8\,\text{m/s}^2) \approx 2\,\text{N}$. The radiation pressure on your hand is imperceptible compared to gravity.

**EXAMPLE 31–8** **ESTIMATE** **A solar sail.** Proposals have been made to use the radiation pressure from the Sun to help propel spacecraft around the solar system. (*a*) About how much force would be applied on a $1\,\text{km}\times1\,\text{km}$ highly reflective sail when about the same distance from the Sun as the Earth is? (*b*) By how much would this increase the speed of a 5000-kg spacecraft in one year? (*c*) If the spacecraft started from rest, about how far would it travel in a year?

**APPROACH** (*a*) Pressure $P$ is force per unit area, so $F = PA$. We use the estimate of Example 31–7, doubling it for a reflecting surface $P = 2\bar{S}/c$. (*b*) We find the acceleration from Newton's second law, and assume it is constant, and then find the speed from $v = v_0 + at$. (*c*) The distance traveled is given by $x = \frac{1}{2}at^2$.

**SOLUTION** (*a*) Doubling the result of Example 31–7, we get a solar pressure that is about $2\bar{S}/c \approx 10^{-5}\,\text{N/m}^2$, rounding off. Then the force is $F \approx PA = (10^{-5}\,\text{N/m}^2)(10^3\,\text{m})(10^3\,\text{m}) \approx 10\,\text{N}$.

(*b*) The acceleration is $a \approx F/m \approx (10\,\text{N})/(5000\,\text{kg}) \approx 2\times10^{-3}\,\text{m/s}^2$. One year has $(365\,\text{days})(24\,\text{h/day})(3600\,\text{s/h}) \approx 3\times10^7\,\text{s}$. The speed increase is $v - v_0 = at \approx (2\times10^{-3}\,\text{m/s}^2)(3\times10^7\,\text{s}) \approx 6\times10^4\,\text{m/s}$ ($\approx 200{,}000\,\text{km/h!}$).

(*c*) Starting from rest, this acceleration would result in a distance traveled of about $d = \frac{1}{2}at^2 \approx \frac{1}{2}(2\times10^{-3}\,\text{m/s}^2)(3\times10^7\,\text{s})^2 \approx 10^{12}\,\text{m}$ in a year, about seven times the Sun–Earth distance. This result would apply if the spacecraft was far from the Earth so the Earth's gravitational force is small compared to 10 N. Also gravity due to the Sun and planets has been ignored, but in reality would have to be considered.

**NOTE** A large sail providing a small force over a long time could result in a lot of motion.

**PHYSICS APPLIED**
*Optical tweezers (move cell parts, DNA elasticity)*

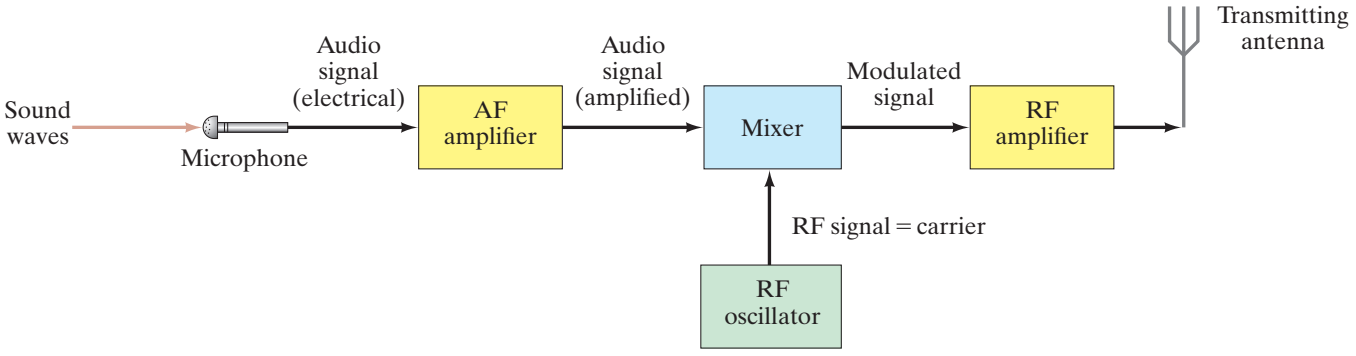
Although you cannot directly feel the effects of radiation pressure, the phenomenon is quite dramatic when applied to atoms irradiated by a finely focused laser beam. An atom has a mass on the order of $10^{-27}\,\text{kg}$, and a laser beam can deliver energy at a rate of $1000\,\text{W/m}^2$. This is the same intensity used in Example 31–7, but here a radiation pressure of $10^{-6}\,\text{N/m}^2$ would be very significant on a molecule whose mass might be $10^{-26}$ to $10^{-23}\,\text{kg}$. It is possible to move atoms and molecules around by steering them with a laser beam, in a device called **optical tweezers**. Optical tweezers have some remarkable applications. They are of great interest to biologists, especially since optical tweezers can manipulate live microorganisms, and components within a cell, without damaging them. Optical tweezers have been used to measure the elastic properties of DNA by pulling each end of the molecule with such a laser "tweezers."

# 31–10 Radio and Television; Wireless Communication

**PHYSICS APPLIED**
*Wireless transmission*

Electromagnetic waves offer the possibility of transmitting information over long distances. Among the first to realize this and put it into practice was Guglielmo Marconi (1874–1937) who, in the 1890s, invented and developed wireless communication. With it, messages could be sent at the speed of light without the use of wires. The first signals were merely long and short pulses that could be translated into words by a code, such as the "dots" and "dashes" of Morse code (Section 23–9): they were digital wireless, believe it or not. In 1895 Marconi sent wireless signals a kilometer or two in Italy. By 1901 he had sent test signals 3000 km across the ocean from Newfoundland, Canada, to Cornwall, England (Fig. 31–16). In 1903 he sent the first practical commercial messages from Cape Cod, Massachusetts, to England: the London *Times* printed news items sent from its New York correspondent. (1903 was also the year of the first powered airplane flight by the Wright brothers. The hallmarks of the modern age—wireless communication and flight—date from the same year. )

Our modern world of wireless communication, including radio, television, cordless phones, cell phones, Bluetooth, wi-fi, and satellite communication, are based on Marconi's pioneering work.



The early twentieth century also saw the development of vacuum tubes. Out of this early work radio and television were born. We now discuss briefly (1) how radio and TV signals are transmitted, and (2) how they are received at home.

The process by which a radio station transmits information (words and music) is outlined in Fig. 31–17. The audio (sound) information is changed into an electrical signal of the same frequencies by, say, a microphone, or an electronic reader (laser for CDs and DVDs). This electrical signal is called an audio frequency (AF) signal, because the frequencies are in the audio range (20 to 20,000 Hz). The signal is amplified electronically and is then mixed with a radio-frequency (RF) signal which is its **carrier frequency**. Each station has its own carrier frequency, and we use it to tune into different stations. AM radio stations have carrier frequencies from about 530 kHz to 1700 kHz. For example, "710 on your dial" means a station whose carrier frequency is 710 kHz. FM radio stations have much higher carrier frequencies, between 88 MHz and 108 MHz. The carrier frequencies for broadcast TV stations in the United States lie between 54 MHz and 72 MHz, between 76 MHz and 88 MHz, between 174 MHz and 216 MHz, and between 470 MHz and 608 MHz.[†] Today's digital broadcasting (see Sections 23–9 and 23–10) uses the same frequencies as the pre-2009 analog transmission.

**FIGURE 31–16** Guglielmo Marconi (1874–1937), on the left, receiving signals in Cornwall, 1901.

**FIGURE 31–17** Block diagram of a radio transmitter.

[†]The band 608-614 MHz is reserved for radio astronomy. All TV stations have a bandwidth of 6 MHz.

**PHYSICS APPLIED**
*AM and FM*

The mixing of the audio and carrier frequencies is done in two ways. In **amplitude modulation** (AM), the amplitude of the high-frequency carrier wave is made to vary in proportion to the amplitude of the audio signal, as shown in Fig. 31–18. It is called "amplitude modulation" because the *amplitude* of the carrier is altered ("modulate" means to change or alter). In **frequency modulation** (FM), the *frequency* of the carrier wave is made to change in proportion to the audio signal's amplitude, as shown in Fig. 31–19. In both cases, the mixed signal is amplified further and sent to the transmitting antenna (Fig. 31–17), where the complex mixture of frequencies is sent out in the form of EM waves. In digital communication, the signal is put into a digital form (Section 23–9) which modulates the carrier.

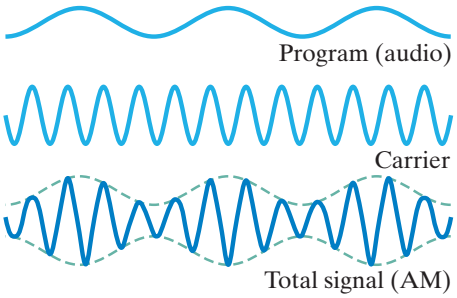


**FIGURE 31–18** In amplitude modulation (AM), the amplitude of the carrier signal is made to vary in proportion to the audio signal's amplitude.

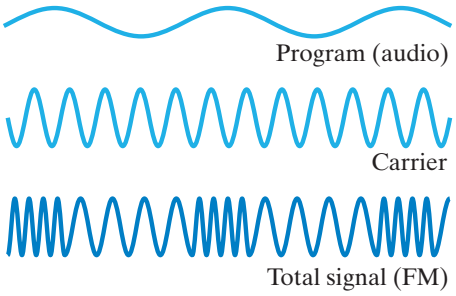

**FIGURE 31–19** In frequency modulation (FM), the frequency of the carrier signal is made to change in proportion to the audio signal's amplitude. This method is used by FM radio and television.

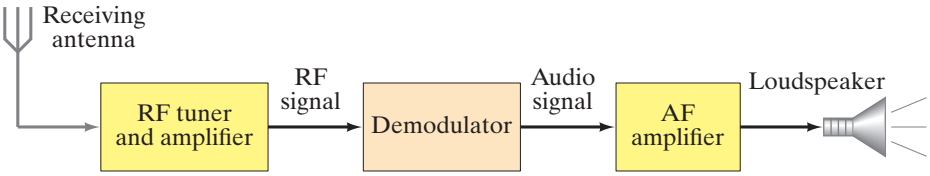
Digital television transmission (Sections 23–9 and 23–10) works in a similar way, usually using a form of AM mixed with carrier frequencies.

**PHYSICS APPLIED**
*Radio and TV receivers*

Now let us look at the other end of the process, the reception of radio and TV programs at home. A simple radio receiver is diagrammed in Fig. 31–20.



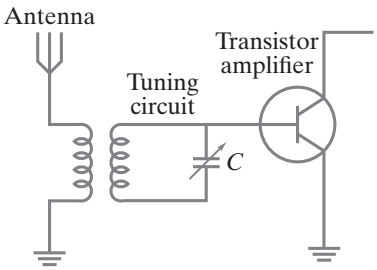


**FIGURE 31–20** Block diagram of a simple radio receiver.

The EM waves sent out by all stations are received by the antenna. The signals the antenna detects and sends to the receiver are very small and contain frequencies from many different stations. The receiver uses a resonant $LC$ circuit (Section 30–9) to select out a particular RF frequency (actually a narrow range of frequencies) corresponding to a particular station. A simple way of tuning a station is shown in Fig. 31–21. A particular station is "tuned in" by adjusting $C$ and/or $L$ so that the resonant frequency of the circuit $f_0 = 1/(2\pi\sqrt{LC})$, Eq. 30–32b, equals that of the station's carrier frequency. The signal, containing both audio and carrier frequencies, next goes to the *demodulator*, or *detector* (Fig. 31–19), where "demodulation" takes place—that is, the audio signal is separated from the RF carrier frequency. The audio signal is amplified and sent to a loudspeaker or headphones.

**FIGURE 31–21** Simple tuning stage of a radio.

Modern receivers have more stages than those shown. Various means are used to increase the sensitivity and selectivity (ability to detect weak signals and distinguish them from other stations), and to minimize distortion of the original signal.[†]

A television receiver does similar things to both the audio and the video signals. The audio signal is amplified and goes to the loudspeaker, and the video signal goes finally to the monitor screen, such as an LCD (Sections 23–10 and 34–8).

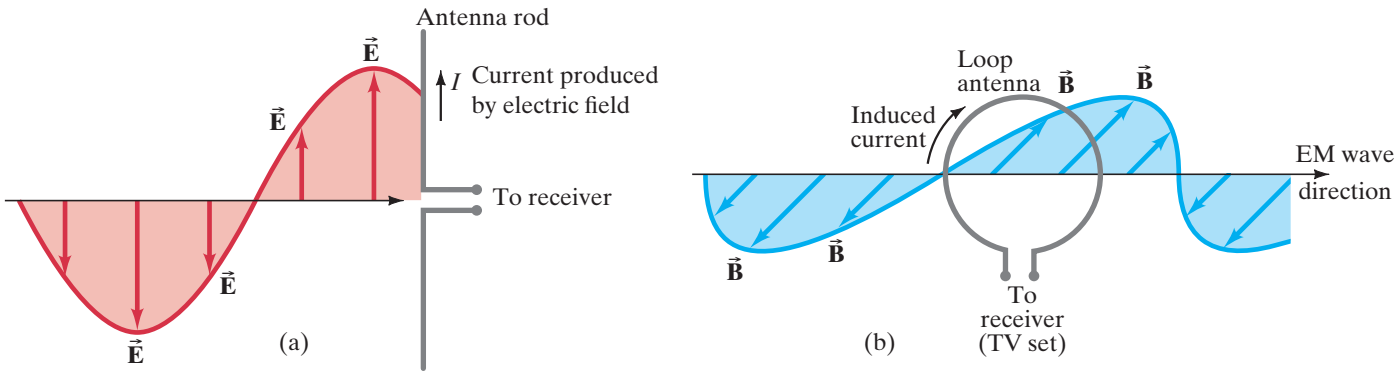

**FIGURE 31–22** Receiving antennas. (a) Electric field of EM wave produces a current in an antenna consisting of straight wire or rods. (b) The moving and changing magnetic field induces an emf and current in a loop antenna.

One kind of receiving **antenna** consists of one or more conducting rods; the electric field in the EM waves exerts a force on the electrons in the conductor, causing them to move back and forth at the frequencies of the waves (Fig. 31–22a). A second type of antenna consists of a coil of wire which detects the magnetic field of the wave: the changing $B$ field induces an emf in the coil (Fig. 31–22b). A satellite dish (Fig. 31–23) consists of a parabolic reflector that focuses the EM waves onto a small antenna (sometimes called a "horn"), similar to a concave mirror telescope.

**FIGURE 31–23** A satellite dish.

**EXAMPLE 31–9** **Tuning a station.** Calculate the transmitting wavelength of an FM radio station that transmits at 100.1 MHz.

**APPROACH** Radio is transmitted as an EM wave, so the speed is $c = 3.0 \times 10^8$ m/s. The wavelength is found from Eq. 31–14, $\lambda = c/f$.

**SOLUTION** The carrier frequency is $f = 100.1\text{ MHz} \approx 1.0 \times 10^8\text{ s}^{-1}$, so

$$\lambda = \frac{c}{f} = \frac{(3.0 \times 10^8\text{ m/s})}{(1.0 \times 10^8\text{ s}^{-1})} = 3.0\text{ m}.$$

**NOTE** The wavelengths of other FM signals (88 MHz to 108 MHz) are close to the 3.0-m wavelength of this station. FM antennas are typically 1.5 m long, or about a half wavelength. This length is chosen so that the antenna reacts in a resonant fashion and thus is more sensitive to FM frequencies. AM radio antennas would have to be very long and impractical to be either $\frac{1}{2}\lambda$ or $\frac{1}{4}\lambda$.

[†]For *FM stereo broadcasting*, two signals are carried by the carrier wave. One signal contains frequencies up to about 15 kHz, which includes most audio frequencies. The other signal includes the same range of frequencies, but 19 kHz is added to it. A stereo receiver subtracts this 19,000-Hz signal and distributes the two signals to the left and right channels. The first signal consists of the sum of left and right channels (L + R), so monophonic radios (one speaker) detect all the sound. The second signal is the difference between left and right (L − R). Hence a stereo receiver must add and subtract the two signals to get pure left and right signals for each channel.

## Other EM Wave Communications

**PHYSICS APPLIED**
*Cell phones, remote controls, cable TV, satellite TV and radio*

The various regions of the radio-wave spectrum are assigned by governmental agencies for various purposes. Besides radio and television, there are "bands" assigned for use by ships, airplanes, police, military, amateurs, satellites and space, and radar. Cell phones (also called mobile phones), for example, are complete radio transmitters and receivers. In the U.S., the first cell phone technology was analog. The first digital service in the U.S. was CDMA, functioning on bands in the vicinity of 800 MHz and 1900 MHz (=1.9 GHz). Later, some U.S. providers followed Europe, Asia, and much of the rest of the world in using an international standard called GSM (Global System for Mobile Communication), mainly on 900-MHz and 1800-MHz bands. GSM phones require a SIM card. A 700-MHz band that used to carry TV broadcast channels (no longer used) is now available for cell phones. More recent technology, like 4G LTE and 5G use a SIM card, and use the same bands plus newly assigned bands around 24 GHz, 28 GHz, 39 GHz, and others, plus in the 600 MHz region where other TV broadcast channels were. Radio-controlled toys (cars, sailboats, robotic animals, etc.) can use various frequencies from 27 MHz to 75 MHz. Automobile remote entry (keyless) may operate around 300 MHz or 400 MHz.

Cable TV channels are carried as electromagnetic waves along a coaxial cable (Figs. 28–12 and 31–13) rather than being broadcast and received through the "air." The channels are in the same part of the EM spectrum, hundreds of MHz, but some are at frequencies not available for TV broadcast. Digital satellite TV and radio are carried in the microwave portion of the spectrum (12 to 18 GHz and 2.3 GHz, respectively).

**FIGURE 31–24** The first person on the Moon, Neil Armstrong, July 20, 1969, pointed out "One small step for a man, one giant leap for mankind."

## Wireless from the Moon

In 1969, astronauts first landed on the Moon. It was shown live on television (Fig. 31–24). The transmitting TV camera can be seen in the Chapter-Opening photo, page 898. At that time, someone pointed out that Columbus and other early navigators could have imagined that humans might one day reach the Moon. But they would never have believed possible that moving images could be sent from the Moon to the Earth through empty space.

# Summary

James Clerk Maxwell synthesized an elegant theory in which all electric and magnetic phenomena could be described using four equations, now called **Maxwell's equations**. They are based on earlier ideas, but Maxwell added one more—that a changing electric field produces a magnetic field. Maxwell's equations are

$$\oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = \frac{Q}{\epsilon_0} \qquad \textbf{(31–5a)}$$

$$\oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = 0 \qquad \textbf{(31–5b)}$$

$$\oint \vec{\mathbf{E}} \cdot d\vec{\ell} = -\frac{d\Phi_B}{dt} \qquad \textbf{(31–5c)}$$

$$\oint \vec{\mathbf{B}} \cdot d\vec{\ell} = \mu_0 I + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}. \qquad \textbf{(31–5d)}$$

The first two are Gauss's laws for electricity and for magnetism; the other two are Faraday's law and Ampère's law (as extended by Maxwell).

Maxwell's theory predicted that transverse **electromagnetic (EM) waves** would be produced by accelerating electric charges, and these waves would propagate (move) through space at the speed of light:

$$c = \frac{1}{\sqrt{\epsilon_0 \mu_0}} = 3.00 \times 10^8 \,\text{m/s}. \qquad \textbf{(31–12)}$$

The wavelength $\lambda$ and frequency $f$ of EM waves are related to their speed $c$ by

$$c = \lambda f, \qquad \textbf{(31–14)}$$

just as for other waves.

The oscillating electric and magnetic fields in an EM wave are perpendicular to each other and to the direction of propagation. These EM waves are waves of fields, not matter, and can propagate in empty space.

After EM waves were experimentally detected it became generally accepted that light is an EM wave. The **electromagnetic spectrum** includes EM waves of a wide variety of wavelengths, from microwaves and radio waves to visible light to X-rays and gamma rays, all of which travel through space at a speed $c = 3.00 \times 10^8$ m/s.

The energy carried by EM waves can be described by the **Poynting vector**

$$\vec{\mathbf{S}} = \frac{1}{\mu_0} \vec{\mathbf{E}} \times \vec{\mathbf{B}} \qquad \textbf{(31–18)}$$

which gives the rate energy is carried across unit area per unit time when the electric and magnetic fields in an EM wave in free space are $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$.

EM waves carry momentum and exert a **radiation pressure** proportional to the intensity $S$ of the wave.

Radio, TV, cell phone, and other wireless signals are transmitted through space in the radio-wave or microwave part of the EM spectrum.

# Questions

1. An electric field $\vec{\mathbf{E}}$ points away from you, and its magnitude is increasing. Will the induced magnetic field be clockwise or counterclockwise? What if $\vec{\mathbf{E}}$ points toward you and is decreasing?
2. What is the direction of the displacement current in Fig. 31–3? (*Note*: The capacitor is discharging.)
3. Why is it that the magnetic field of a displacement current in a capacitor is so much harder to detect than the magnetic field of a conduction current?
4. Are there any good reasons for calling the term $\mu_0 \epsilon_0 d\Phi_E/dt$ in Eq. 31–1 as being due to a "current"? Explain.
5. The electric field in an EM wave traveling north oscillates in an east–west plane. Describe the direction of the magnetic field vector in this wave. Explain.
6. Is sound an electromagnetic wave? If not, what kind of wave is it?
7. Can EM waves travel through a perfect vacuum? Can sound waves?
8. When you flip a light switch on, does the light go on immediately? Explain.
9. Are the wavelengths of radio and television signals longer or shorter than those detectable by the human eye?
10. What does the wavelength calculated in Example 31–2 tell you about the phase of a 60-Hz ac current that starts at a power plant as compared to its phase at a house 200 km away?
11. When you connect two loudspeakers to the output of an audio system, should you be sure the lead-in wires are equal in length to avoid a time lag between speakers? Explain.
12. In the electromagnetic spectrum, what type of EM wave would have a wavelength of $10^3$ km; 1 km; 1 m; 1 cm; 1 mm; 1 $\mu$m?
13. Can radio waves have the same frequencies as sound waves (20 Hz–20,000 Hz)?
14. Discuss how cordless telephones make use of EM waves. What about cell phones?
15. If a radio transmitter has a vertical antenna, should a receiver's antenna (rod type) be vertical or horizontal to obtain best reception?
16. The carrier frequencies of FM broadcasts are much higher than for AM broadcasts. On the basis of what you learned about diffraction in Chapter 15, explain why AM signals can be detected more readily than FM signals behind low hills or buildings.
17. A lost person may signal by switching a flashlight on and off using Morse code. This is actually a modulated EM wave. Is it AM or FM? What is the frequency of the carrier, approximately?

# MisConceptual Questions

1. The radius of an atom is on the order of $10^{-10}$ m. In comparison, the wavelength of visible light is
   (*a*) much smaller.
   (*b*) about the same size.
   (*c*) much larger.
2. Which of the following travel at the same speed as light?
   (*a*) Radio waves.
   (*b*) Microwaves.
   (*c*) Radar.
   (*d*) Ultrasonic waves.
   (*e*) Infrared radiation.
   (*f*) Cell phone signals.
   (*g*) Gamma rays.
   (*h*) X-rays.
3. In empty space, which quantity is always larger for X-ray radiation than for a radio wave?
   (*a*) Amplitude.
   (*b*) Wavelength.
   (*c*) Frequency.
   (*d*) Speed.
4. If electrons in a vertical wire vibrate up and down 1000 times per second, they will create an electromagnetic wave having
   (*a*) a wavelength of 1000 m.
   (*b*) a frequency of 1000 Hz.
   (*c*) a speed of 1000 m/s.
   (*d*) an amplitude of 1000 m.
5. If the Earth–Sun distance were doubled, the intensity of radiation from the Sun that reaches the Earth's surface would
   (*a*) quadruple.
   (*b*) double.
   (*c*) drop to $\frac{1}{2}$.
   (*d*) drop to $\frac{1}{4}$.
6. An electromagnetic wave is traveling vertically downward. At a certain moment the electric field points west. In which direction does the magnetic field point at this instant?
   (*a*) North.
   (*b*) South.
   (*c*) East.
   (*d*) West.
   (*e*) Up.
   (*f*) Down.
   (*g*) Either (*a*) or (*b*).
   (*h*) Either (*c*) or (*d*).
   (*i*) Either (*e*) or (*f*).
7. If the intensity of an electromagnetic wave doubles,
   (*a*) the electric field must also double.
   (*b*) the magnetic field must also double.
   (*c*) both the magnetic field and the electric field must increase by a factor of $\sqrt{2}$.
   (*d*) Any of the above.

8. Maxwell's four equations can be used as a starting point to find
   (*a*) the electric field produced by a stationary point charge.
   (*b*) the electric field produced by a moving point charge.
   (*c*) the gravitational field of a charged object.
   (*d*) electromagnetic waves produced by charges and currents.
   (*e*) the magnetic field produced by a current carrying wire.
9. Which will produce an EM wave?
   (*a*) A steady electric current.
   (*b*) An alternating current.
   (*c*) A proton in uniform circular motion.
   (*d*) None of the above.
10. If all else is the same, for which surface would the radiation pressure from light be the greatest?
   (*a*) A black surface.
   (*b*) A gray surface.
   (*c*) A yellow surface.
   (*d*) A white surface.
   (*e*) All experience the same radiation pressure, because they are exposed to the same light.
11. Starting in 2009, TV stations in the U.S. switched to digital signals. [See Sections 31–10, 23–9, 23–10.] To watch today's digital broadcast TV, could you use a pre-2009 TV antenna meant for analog? Explain.
   (*a*) No; analog antennas do not receive digital signals.
   (*b*) No; digital signals are broadcast at different frequencies, so you need a different antenna.
   (*c*) Yes; digital signals are broadcast with the same carrier frequencies, so your old antenna will be fine.
   (*d*) No; you cannot receive digital signals through an antenna and need to switch to cable or satellite.
12. Which of the following do not produce magnetic fields?
   (*a*) Stationary objects that have electric charge.
   (*b*) Magnets.
   (*c*) Steady electric currents.
   (*d*) Constant electric fields.
   (*e*) Changing electric fields.

# Problems

## 31–1 $\vec{B}$ Produced by Changing $\vec{E}$

1. (I) Determine the rate at which the electric field changes near the center between the round plates of a capacitor, 5.0 cm in diameter, if the plates are spaced 1.1 mm apart and the voltage across them is changing at a rate of 120 V/s.
2. (I) Calculate the displacement current $I_D$ between the square plates, 5.8 cm on a side, of a capacitor if the electric field is changing at a rate of $2.6 \times 10^6\ \text{V/m} \cdot \text{s}$.
3. (II) At a given instant, a 2.4-A current flows in the wires connected to a parallel-plate capacitor. What is the rate at which the electric field is changing between the plates if the square plates are 1.60 cm on a side?
4. (II) A 2200-nF capacitor with circular parallel plates 2.0 cm in diameter is accumulating charge at the rate of 38.0 mC/s at some instant in time. (*a*) What will be the induced magnetic field strength 10.0 cm radially outward from the center of the plates? (*b*) What will be the value of the magnetic field after the capacitor is fully charged?
5. (II) Show that the displacement current through a parallel-plate capacitor can be written $I_D = C\,dV/dt$, where $V$ is the voltage across the capacitor at any instant.
6. (II) Suppose an air-gap capacitor has circular plates of radius $r = 2.5$ cm and separation $d = 1.6$ mm. A 68.0-Hz emf, $\mathscr{E} = \mathscr{E}_0 \cos \omega t$, is applied to the capacitor. The maximum displacement current is 35 $\mu$A. Determine (*a*) the maximum conduction current $I$, (*b*) the value of $\mathscr{E}_0$, (*c*) the maximum value of $d\Phi_E/dt$ between the plates. Neglect fringing.
7. (III) Suppose that a circular parallel-plate capacitor has radius $r_0 = 3.0$ cm and plate separation $d = 5.0$ mm. A sinusoidal potential difference $V = V_0 \sin(2\pi ft)$ is applied across the plates, where $V_0 = 180$ V and $f = 60$ Hz. (*a*) In the region between the plates, show that the magnitude of the induced magnetic field is given by $B = B_0(r) \cos(2\pi ft)$, where $B_0(r)$ is a function of the radial distance $r$ from the capacitor's central axis. (*b*) Determine the expression for the amplitude $B_0(r)$ of this time-dependent (sinusoidal) field when $r \le r_0$, and when $r > r_0$. (*c*) Plot $B_0(r)$ in tesla for the range $0 \le r \le 10$ cm.

## 31–5 EM Waves

8. (I) If the electric field in an EM wave has a peak magnitude of $0.45 \times 10^{-4}$ V/m, what is the peak magnitude of the magnetic field strength?
9. (I) If the magnetic field in a traveling EM wave has a peak magnitude of 16.5 nT, what is the peak magnitude of the electric field?
10. (I) In an EM wave traveling west, the $B$ field oscillates up and down vertically and has a frequency of 85.0 kHz and an rms strength of $7.75 \times 10^{-9}$ T. Determine the frequency and rms strength of the electric field. What is the direction of the electric field oscillations?
11. (I) How long does it take light to reach us from the Sun, $1.50 \times 10^8$ km away?
12. (II) How long should it take the voices of astronauts on the Moon to reach the Earth? Explain in detail.
13. (II) The electric field of a plane EM wave is given by $E_x = E_0 \cos(kz + \omega t)$, $E_y = E_z = 0$. Determine (*a*) the direction of propagation and (*b*) the magnitude and direction of $\vec{\mathbf{B}}$.
14. (III) Consider two possible candidates $E(x, t)$ as solutions of the wave equation for an EM wave's electric field. Let $A$ and $\alpha$ be constants. Show that (*a*) $E(x, t) = Ae^{-\alpha(x-vt)^2}$ satisfies the wave equation, and that (*b*) $E(x, t) = Ae^{-(\alpha x^2 - vt)}$ does not satisfy the wave equation.

## 31–6 Electromagnetic Spectrum

15. (I) (*a*) What is the wavelength of a $35.75 \times 10^9$-Hz radar signal? (*b*) What is the frequency of an X-ray with wavelength 0.12 nm?
16. (I) An EM wave has frequency $2.65 \times 10^{14}$ Hz. What is its wavelength, and how would we classify it?
17. (I) Electromagnetic waves and sound waves can have the same frequency. (*a*) What is the wavelength of a 1.00-kHz electromagnetic wave? (*b*) What is the wavelength of a 1.00-kHz sound wave? (The speed of sound in air is 341 m/s.) (*c*) Can you hear a 1.00-kHz electromagnetic wave?

18. (II) A light-year is a measure of distance (not time). How many meters does light travel in a year?

19. (II) Our nearest star (other than the Sun) is 4.2 light-years away. That is, it takes 4.2 years for the light it emits to reach Earth. How far away is it in meters?

20. (II) How long would it take a message sent as radio waves from Earth to reach Mars when Mars is (*a*) nearest Earth, (*b*) farthest from Earth? Assume that Mars and Earth are in the same plane and that their orbits around the Sun are circles (Mars is $230 \times 10^6$ km from the Sun).

21. (II) Pulsed lasers used for science and medicine produce very brief bursts of electromagnetic energy. If the laser light wavelength is 1062 nm (Neodymium–YAG laser), and the pulse lasts for 32 picoseconds, how many wavelengths are found within the laser pulse? How brief would the pulse need to be to fit only one wavelength?

22. (II) An electromagnetic wave has an electric field given by

$$\vec{\mathbf{E}} = \hat{\mathbf{i}}(275\ \text{V/m})\sin\left[(0.053\ \text{m}^{-1})z - (1.6 \times 10^7\ \text{rad/s})t\right].$$

(*a*) What are the wavelength and frequency of the wave? (*b*) Write down an expression for the magnetic field.

## 31–7 Speed of Light

23. (II) What is the minimum angular speed at which Michelson's eight-sided mirror would have had to rotate to reflect light into an observer's eye by succeeding mirror faces (1/8 of a revolution, Fig. 31–14)?

24. (II) A student wants to scale down Michelson's light-speed experiment to a size that will fit in one room. An eight-sided mirror is available, and the stationary mirror can be mounted 16 m from the rotating mirror. If the arrangement is otherwise as shown in Fig. 31–14, at what minimum rate would the mirror have to rotate? Does this seem feasible?

## 31–8 Energy in EM Waves; Poynting Vector

25. (I) The $\vec{\mathbf{E}}$ field in an EM wave has a peak of 23.5 mV/m. What is the average rate at which this wave carries energy across unit area per unit time?

26. (II) The magnetic field in a traveling EM wave has an rms strength of 22.5 nT. How long does it take to deliver 415 J of energy to 1.00 $\text{cm}^2$ of a wall that it hits perpendicularly?

27. (II) How much energy is transported across a 1.00-$\text{cm}^2$ area per hour by an EM wave whose $E$ field has an rms strength of 25.8 mV/m?

28. (II) A spherically spreading EM wave comes from a 2100-W source. At a distance of 5.0 m, what is the intensity, and what is the rms value of the electric field?

29. (II) If the amplitude of the $B$ field of an EM wave is $1.8 \times 10^{-7}$ T, (*a*) what is the amplitude of the $E$ field? (*b*) What is the average power transported across unit area by the EM wave?

30. (II) What is the average energy contained in a 1.00-$\text{m}^3$ volume near the Earth's surface due to radiant energy from the Sun? See Example 31–6.

31. (II) An 18.5-mW laser puts out a narrow beam 2.40 mm in diameter. What are the rms values of $E$ and $B$ in the beam?

32. (II) Estimate the average power output of the Sun, given that about 1350 $\text{W/m}^2$ reaches the upper atmosphere of the Earth.

33. (II) A high-energy pulsed laser emits a 1.0-ns-long pulse of average power $1.5 \times 10^{11}$ W. The beam is nearly a cylinder $1.8 \times 10^{-3}$ m in radius. Determine (*a*) the energy delivered in each pulse, and (*b*) the rms value of the electric field.

34. (III) (*a*) When a circular parallel-plate capacitor is being charged as in Example 31–1, show that the Poynting vector $\vec{\mathbf{S}}$ points radially inward toward the center of the capacitor, parallel to the plates. (*b*) Integrate $\vec{\mathbf{S}}$ over the cylindrical boundary of the capacitor gap to show that the rate at which energy enters the capacitor is equal to the rate at which electrostatic energy is being stored in the electric field of the capacitor (Section 24–4). Ignore fringing of $\vec{\mathbf{E}}$.

35. (III) The Arecibo radio telescope in Puerto Rico can detect a radio wave with an intensity as low as $1 \times 10^{-23}$ $\text{W/m}^2$. Consider a "best-case" scenario for communication with extraterrestrials: suppose an advanced civilization a distance $x$ away from Earth is able to transform the entire power output of a Sun-like star completely into a radio-wave signal which is transmitted uniformly in all directions. (*a*) In order for Arecibo to detect this radio signal, what is the maximum value for $x$ in light-years ($1\ \text{ly} \approx 10^{16}$ m)? (*b*) How does this maximum value compare with the 100,000-ly size of our Milky Way galaxy? The intensity of sunlight at Earth's orbital distance from the Sun is 1350 $\text{W/m}^2$. [*Hint*: Assume the inverse square law.]

## 31–9 Radiation Pressure

36. (II) Estimate the radiation pressure due to a bulb emitting 5.0 W of EM radiation on a highly absorbing surface at a distance of 8.0 cm from the center of the bulb. Estimate the force exerted on your fingertip if you place it at this point.

37. (II) Laser light can be focused (at best) to a spot with a radius $r$ equal to its wavelength $\lambda$. Suppose a 1.0-W beam of green laser light ($\lambda = 5 \times 10^{-7}$ m) forms such a spot and illuminates a cylindrical object of radius $r$ and length $r$ (Fig. 31–25). Estimate (*a*) the radiation pressure and force on the object, and (*b*) its acceleration, if its density equals that of water and it absorbs all the radiation. [This order-of-magnitude calculation convinced researchers of the feasibility of "optical tweezers," page 916.]

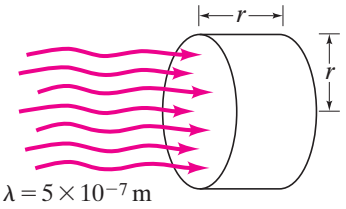

**FIGURE 31–25**
Problem 37.

38. (II) What size should the solar panel on a satellite orbiting Jupiter be if it is to collect the same amount of radiation from the Sun as a 1.0-$\text{m}^2$ solar panel on a satellite orbiting Earth? [*Hint*: Assume the inverse square law.]

39. (II) Suppose you have a car with a 100-hp engine. How large a solar panel would you need to replace the engine with solar power? Assume that the solar panels can utilize 20% of the maximum solar energy that reaches the Earth's surface ($1000\ \text{W/m}^2$). Explain why or why not this is practical.

## 31–10 Radio, TV

40. (I) What is the range of wavelengths for (*a*) FM radio (88 MHz to 108 MHz) and (*b*) AM radio (535 kHz to 1700 kHz)?

41. (I) Estimate the wavelength for a 1.9-GHz cell phone transmitter.

42. (I) Compare 1030 on the AM dial to 103.1 on FM. Which has the longer wavelength, and by what factor is it larger?

43. (I) What are the wavelengths for two TV channels that broadcast at 54.0 MHz (Channel 2) and 692 MHz (Channel 51)?

**44.** (I) The variable capacitor in the tuner of an AM radio has a capacitance of 1800 pF when the radio is tuned to a station at 550 kHz. What must the capacitance be for a station near the other end of the dial, 1610 kHz?

**45.** (I) The oscillator of a 98.3-MHz FM station has an inductance of 2.8 $\mu$H. What value must the capacitance be?

**46.** (II) A certain FM radio tuning circuit has a fixed capacitor $C = 680$ pF. Tuning is done by a variable inductance. What range of values must the inductance have to tune stations from 88 MHz to 108 MHz?

**47.** (II) An amateur radio operator wishes to build a receiver that can tune a range from 14.0 MHz to 15.0 MHz. A variable capacitor has a minimum capacitance of 95 pF. (*a*) What is the required value of the inductance? (*b*) What is the maximum capacitance used on the variable capacitor?

**48.** (II) A satellite beams microwave radiation with a power of 16 kW toward the Earth's surface, 550 km away. When the beam strikes Earth, its circular diameter is about 1500 m. Find the rms electric field strength of the beam.

**49.** (III) A 1.40-m-long FM antenna is oriented parallel to the electric field of an EM wave. How large must the electric field be to produce a 1.00-mV (rms) voltage between the ends of the antenna? What is the rate of energy transport per $m^2$?

# General Problems

**50.** Who will hear the voice of a singer first: a person in the balcony 50.0 m away from the stage (see Fig. 31–26), or a person 1800 km away at home whose ear is next to the radio listening to a live broadcast? Roughly how much sooner? Assume the microphone is a few centimeters from the singer and the temperature is 20°C.

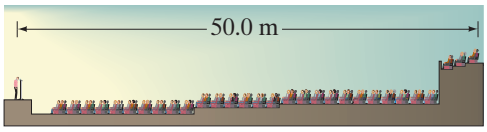

**FIGURE 31–26** Problem 50.

**51.** A global positioning system (GPS) functions by determining the travel times for EM waves from various satellites to a moving GPS receiver on Earth (car or hiker). If the receiver is to detect a change in the receiver's position on the order of 3 m, what is the associated change in travel time (in ns) that must be measured?

**52.** Light is emitted from an incandescent lightbulb filament in wave-train bursts about $10^{-8}$ s in duration. What is the length in space of such wave trains?

**53.** The voice from an astronaut on the Moon (Fig. 31–27) was beamed to an auditorium full of people on Earth. (*a*) If you were standing 32 m from the loudspeaker on Earth, what was the total time lag between when you heard the sound and when the sound originally entered a microphone on the Moon? (*b*) Explain whether the microphone was inside the space helmet, or outside, and why.

**FIGURE 31–27** Problem 53.

**54.** Radio-controlled clocks throughout the United States receive a radio signal from a transmitter in Fort Collins, Colorado, that accurately (within a microsecond) marks the beginning of each minute. A slight amount of time is added by a clock at any location to correct for the signal travel time to the clock from Fort Collins. Assuming Fort Collins is no more than 3000 km from any point in the U.S., what is the longest travel-time delay?

**55.** If the Sun were to disappear or radically change its output, how long would it take for us on Earth to learn about it?

**56.** *Cosmic microwave background* (CMB) radiation fills space with an average energy density of about $4 \times 10^{-14}$ J/$m^3$. (*a*) Find the rms value of the electric field associated with this radiation. (*b*) How far from a 6.8-kW radio transmitter emitting uniformly in all directions would you find a comparable value?

**57.** What are $E_0$ and $B_0$ at a point 2.50 m from a light source whose output is 5.0 W? Assume the bulb emits radiation of a single frequency uniformly in all directions.

**58.** Estimate the rms electric field in the sunlight that hits Mars, knowing that the Earth receives about 1350 W/$m^2$ and that Mars is 1.52 times farther from the Sun (on average) than is the Earth.

**59.** The average intensity of a particular TV station's signal is $1.0 \times 10^{-13}$ W/$m^2$ when it arrives at a 33-cm-diameter satellite TV antenna. (*a*) Calculate the total energy received by the antenna during 3.0 hours of viewing this station's programs. (*b*) Estimate the amplitudes of the $E$ and $B$ fields of the EM wave.

**60.** What length antenna would be appropriate for a portable device that could receive satellite TV?

**61.** A radio station is allowed to broadcast at an average power not to exceed 25 kW. If an electric field amplitude of 0.020 V/m is considered to be acceptable for receiving the radio transmission, estimate how many kilometers away you might be able to detect this station.

**62.** How practical is *solar power* for various devices? Assume that on a sunny day, sunlight has an intensity of 1000 W/$m^2$ at the surface of Earth and that a solar-cell panel can convert 20% of that sunlight into electric power. Calculate the area $A$ of solar panel needed to power (*a*) a calculator that consumes 50 mW, (*b*) a hair dryer that consumes 1875 W, (*c*) a car that would require 120 hp. (*d*) In each case, would the area $A$ be small enough to be mounted on the device itself, or in the case of (*b*) on the roof of a house?

**63.** A point source emits light energy uniformly in all directions at an average rate $P_0$ with a single frequency $f$. Show that the peak electric field in the wave is given by

$$E_0 = \sqrt{\frac{\mu_0 c P_0}{2\pi r^2}}.$$

[*Hint*: The surface area of a sphere is $4\pi r^2$.]

**64.** Estimate how long an AM antenna would have to be if it were (*a*) $\frac{1}{2}\lambda$ or (*b*) $\frac{1}{4}\lambda$. AM radio is roughly 1 MHz (530 kHz to 1.7 MHz).

**65.** A powerful laser portrayed in a movie provides a 3-mm-diameter beam of green light with a power of 3 W. A good agent inside a spacecraft aims the laser beam at an enemy astronaut hovering outside. The mass of the enemy astronaut is 120 kg and the spacecraft 185,000 kg. (*a*) Determine the "radiation-pressure" force exerted on the enemy by the laser beam assuming her suit is perfectly reflecting. (*b*) If the enemy is 30 m from the spacecraft's center of mass, estimate the gravitational force the spacecraft exerts on the enemy. (*c*) Which of the two forces is larger, and by what factor?

**66.** Show that displacement current, $\epsilon_0\,(d\Phi_E/dt)$, has the SI units of amperes.

**67.** When estimating the distance to lightning, you can time how long after the light flash is seen until the thunder is heard. Sound travels 343 m/s, so a good estimate is to allow 3.0 seconds per kilometer. There is actually a small mistake with this method because the time for the light to travel is not accounted for. How big is this mistake (%) for a lightning flash 2.0 km away?

**68.** What is the maximum power level of a radio station so as to avoid electrical breakdown of air at a distance of 0.75 m from the transmitting antenna? Assume the antenna is a point source. Air breaks down in an electric field of about $3 \times 10^6$ V/m.

**69.** In free space ("vacuum"), where the net charge and current flow is zero, the speed of an EM wave is given by $v = 1/\sqrt{\epsilon_0\mu_0}$. If, instead, an EM wave travels in a nonconducting ("dielectric") material with dielectric constant $K$, then $v = 1/\sqrt{K\epsilon_0\mu_0}$. For frequencies corresponding to the visible spectrum (near $5 \times 10^{14}$ Hz), the dielectric constant of water is 1.77. Predict the speed of light in water and compare this value (as a percentage) with the speed of light in a vacuum.

**70.** Why do some **microwave ovens** rotate the food container? Suppose the metal walls form a rectangular cavity of dimensions 37 cm × 37 cm × 20 cm. When 2.45-GHz microwaves are continuously introduced into this cavity, reflection of incident waves from the walls sets up standing waves with nodes at the walls. Along the 37-cm dimension of the oven, how many nodes exist (excluding the nodes at the wall) and what is the distance between adjacent nodes? (No heating occurs at these nodes, so rotating the food container gives more even heating of the food.)

**71.** Imagine that a steady current $I$ flows in a straight cylindrical wire of radius $R_0$ and resistivity $\rho$. (*a*) If the current is then changed at a rate $dI/dt$, show that a displacement current $I_D$ exists in the wire of magnitude $\epsilon_0\rho(dI/dt)$. (*b*) If the current in a copper wire is changed at the rate of 1.0 A/ms, determine the magnitude of $I_D$. (*c*) Determine the magnitude of the magnetic field $B_D$ created by $I_D$ at the surface of a copper wire with $R_0 = 1.0$ mm. Compare (as a ratio) $B_D$ with the field created at the surface of the wire by a steady current of 1.0 A.

**72.** At a given instant in time, a traveling EM wave is noted to have its maximum magnetic field pointing west and its maximum electric field pointing south. In which direction is the wave traveling? If the rate of energy flow is 520 W/m$^2$, what are the maximum values for the two fields?

**73.** The electric and magnetic fields of a certain EM wave in free space are given by $\vec{\mathbf{E}} = E_0 \sin(kx - \omega t)\,\hat{\mathbf{j}} + E_0 \cos(kx - \omega t)\,\hat{\mathbf{k}}$ and $\vec{\mathbf{B}} = B_0 \cos(kx - \omega t)\,\hat{\mathbf{j}} - B_0 \sin(kx - \omega t)\,\hat{\mathbf{k}}$. (*a*) Show that $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ are perpendicular to each other at all times. (*b*) For this wave, $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ are in a plane parallel to the $yz$ plane. Show that the wave moves in a direction perpendicular to both $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$. (*c*) At any arbitrary choice of position $x$ and time $t$, show that the magnitudes of $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ always equal $E_0$ and $B_0$, respectively. (*d*) At $x = 0$, draw the orientation of $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ in the $yz$ plane at $t = 0$. Then qualitatively describe the motion of these vectors in the $yz$ plane as time increases. [Note: The EM wave in this Problem is "circularly polarized."]

**74.** The radiation pressure (Section 31–9) created by electromagnetic waves might someday be used to power spacecraft through the use of a "solar sail," Example 31–8. (*a*) Assuming total reflection, what would be the pressure on a solar sail located at the same distance from the Sun as the Earth (where $I = 1350$ W/m$^2$)? (*b*) Suppose the sail material has a mass density of 1 g/m$^2$. What would be the acceleration of the sail due to solar radiation pressure? (*c*) A realistic solar sail would have a payload. How big a sail would you need to accelerate a 100-kg payload at $1 \times 10^{-3}$ m/s$^2$?

**75.** Suppose a 25-kW radio station emits EM waves uniformly in all directions. (*a*) How much energy per second crosses a 1.0-m$^2$ area 1.0 km from the transmitting antenna? (*b*) What is the rms magnitude of the $\vec{\mathbf{E}}$ field at this point, assuming the station is operating at full power? What is the rms voltage induced in a 1.0-m-long vertical car antenna (*c*) 1.0 km away, (*d*) 50 km away?

**76.** How large an emf (rms) will be generated in an antenna that consists of a circular coil 2.2 cm in diameter having 280 turns of wire, when an EM wave of frequency 810 kHz transporting energy at an average rate of $1.0 \times 10^{-4}$ W/m$^2$ passes through it? [*Hint*: You can use Eq. 29–4 (for a generator) because that equation can be applied to an observer moving *with* the generator's coil as it rotates at $\omega = 2\pi f$ with $f$ the frequency of the magnetic field.]

**77.** 9.0 km from a radio station's transmitting antenna, the amplitude of the electric field is 0.12 V/m. What is the average power output of the radio station?

**78.** Suppose that a right-moving EM wave overlaps with a left-moving EM wave so that, in a certain region of space, the total electric field in the $y$ direction and magnetic field in the $z$ direction are given by $E_y = E_0 \sin(kx - \omega t) + E_0 \sin(kx + \omega t)$ and $B_z = B_0 \sin(kx - \omega t) - B_0 \sin(kx + \omega t)$. (*a*) Find the mathematical expression that represents the standing electric and magnetic waves in the $y$ and $z$ directions, respectively. (*b*) Determine the Poynting vector and find the $x$ locations at which it is zero at all times.

**79.** The electric field of an EM wave pulse traveling along the $x$ axis in free space is given by $E_y = E_0 \exp\left[-\alpha^2x^2 - \beta^2t^2 + 2\alpha\beta xt\right]$, where $E_0$, $\alpha$, and $\beta$ are positive constants. (*a*) Is the pulse moving in the $+x$ or $-x$ direction? (*b*) Express $\beta$ in terms of $\alpha$ and $c$ (speed of light in free space). (*c*) Determine the expression for the magnetic field of this EM wave.

## ANSWERS TO EXERCISES

**A:** (*c*).
**B:** (*b*).
**C:** (*a*) $3.8 \times 10^6$ Hz; (*b*) $5.5 \times 10^{18}$ Hz.
**D:** 45 cm.
**E:** Yes; the signal still travels 72,000 km.
**F:** Over 4 hours.

Reflection from still water, as from a glass mirror, can be analyzed using the ray model of light.

Is this picture right side up? Or upside down? How can you tell? What are the clues? Notice the people and position of the Sun. Ray diagrams, which we will learn to draw in this Chapter, can provide the answer. See Example 32–3.

In this first Chapter on light and optics, we use the ray model of light to understand the formation of images by plane mirrors, and by curved (spherical) mirrors. We also begin our study of refraction—how light rays bend when they go from one medium to another—which prepares us for our study in the next Chapter of lenses, which are the crucial part of so many optical instruments.

CHAPTER 32

# Light: Reflection and Refraction

## CONTENTS

32–1 The Ray Model of Light
32–2 Reflection; Image Formation by a Plane Mirror
32–3 Formation of Images by Spherical Mirrors
32–4 Seeing Yourself in a Magnifying Mirror (Concave)
32–5 Convex (Rearview) Mirrors
32–6 Index of Refraction
32–7 Refraction: Snell's Law
32–8 Visible Spectrum and Dispersion
32–9 Total Internal Reflection; Fiber Optics
*32–10 Refraction at a Spherical Surface

**CHAPTER-OPENING QUESTION—Guess now!**

A 2.0-m-tall person is standing 2.0 m from a flat vertical mirror staring at her image. What minimum height must the mirror itself have if the person is to see her entire body, from the top of her head to her feet?

**(a)** 0.50 m.
**(b)** 1.0 m.
**(c)** 1.5 m.
**(d)** 2.0 m.
**(e)** 2.5 m.

The sense of sight is extremely important to us, for it provides us with a large part of our information about the world. How do we see? What is the something called *light* that enters our eyes and causes the sensation of sight? How does light behave so that we can see everything that we do? We saw in Chapter 31 that light can be considered a form of electromagnetic radiation. We now examine the subject of light in detail in the next four Chapters.

We see an object in one of two ways: (1) the object may be a *source* of light, such as a lightbulb, a flame, or a star, in which case we see the light emitted directly from the source; or, more commonly, (2) we see an object by light *reflected* from it. In the latter case, the light may have originated from the Sun, from artificial lights, or from a campfire. An understanding of how objects *emit* light was not achieved until the 1920s, and will be discussed in Chapter 37. How light is *reflected* from objects was understood much earlier, and will be discussed here, in Section 32–2.

# 32–1 The Ray Model of Light

A great deal of evidence suggests that *light travels in straight lines* under a wide variety of circumstances.[†] For example, a source of light like the Sun (which at its great distance from us is nearly a "point source") casts distinct shadows, and the beam from a laser pointer appears to be a straight line. In fact, we infer the positions of objects in our environment by assuming that light moves from the object to our eyes in straight-line paths. Our orientation to the physical world is based on this assumption.

This reasonable assumption is the basis of the **ray model** of light. This model assumes that light travels in straight-line paths called **light rays**. Actually, a ray is an idealization; it is meant to represent an extremely narrow beam of light. When we see an object, according to the ray model, light reaches our eyes from each point on the object. Although light rays leave each point in many different directions, normally only a small bundle of these rays can enter the pupil of an observer's eye, as shown in Fig. 32–1. If the person's head moves to one side, a different bundle of rays will enter the eye from each point.

We saw in Chapter 31 that light can be considered as an electromagnetic wave. Although the ray model of light does not deal with this aspect of light (we discuss the wave nature of light in Chapters 34 and 35), the ray model has been very successful in describing many aspects of light such as reflection, refraction, and the formation of images by mirrors and lenses. Because these explanations involve straight-line rays at various angles, this subject is referred to as **geometric optics**.

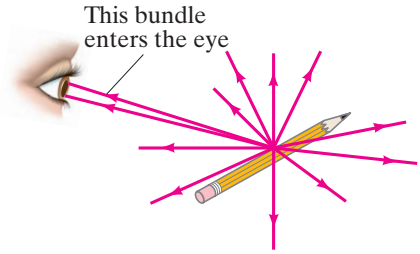

**FIGURE 32–1** Light rays come from each single point on an object. A small bundle of rays leaving one point is shown entering a person's eye. This is a fundamental diagram. It will help us understand how we see images made by mirrors and lenses. Rays entering the eye are diverging. Our eyes would be useless if they could not focus diverging rays!

# 32–2 Reflection; Image Formation by a Plane Mirror

When light strikes the surface of an object, some of the light is reflected. The rest can be absorbed by the object (and transformed to thermal energy) or, if the object is transparent like glass or water, part can be transmitted through. For a very smooth shiny object such as a silvered mirror, over 95% of the light may be reflected.

When a narrow beam of light strikes a flat surface (Fig. 32–2), we define the **angle of incidence**, $\theta_i$, to be the angle an incident ray makes with the normal (perpendicular) to the surface, and the **angle of reflection**, $\theta_r$, to be the angle the reflected ray makes with the normal. It is found that the *incident and reflected rays lie in the same plane with the normal to the surface*, and that

**the angle of reflection equals the angle of incidence, $\theta_r = \theta_i$.**

*LAW OF REFLECTION*

This is the **law of reflection**, and it is depicted in Fig. 32–2. It was known to the ancient Greeks and was mentioned by Dante in his great masterpiece, *The Divine Comedy*, written around 1300.[‡] You can confirm it yourself by shining a narrow flashlight beam or a laser pointer at a mirror in a darkened room.

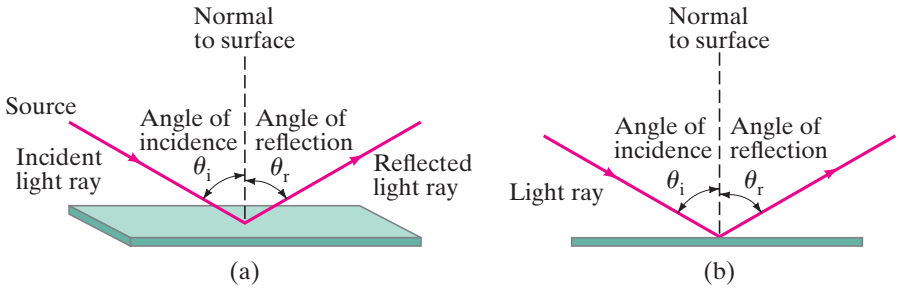

**FIGURE 32–2** Law of reflection: (a) shows a 3-D view of an incident ray being reflected at the top of a flat surface; (b) shows a side or "end-on" view, which we will usually use because of its clarity.

[†]In ignoring the wave properties of light we must be careful that when the light rays pass by objects or through apertures, these must be large compared to the wavelength of the light (so the wave phenomena of interference and diffraction, as discussed in Chapter 15, can be ignored), and we ignore what happens to the light at the edges of objects until we get to Chapters 34 and 35.

[‡]There can be science even in great poetry. Dante considered this symmetry of reflection as testimony to harmony in the universe. (Ref.: Part 2, Chapter 15.)

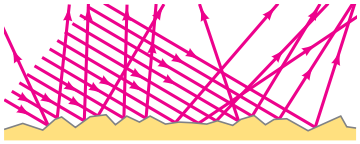

**FIGURE 32–3** Diffuse reflection from a rough surface.

When light is incident upon a rough surface, even microscopically rough such as this page, it is reflected in many directions, as shown in Fig. 32–3. This is called **diffuse reflection**. The law of reflection still holds, however, at each small section of the surface. Because of diffuse reflection in all directions, an ordinary object can be seen at many different angles by the light reflected from it. When you move your head to the side, different reflected rays reach your eye from each point on the object (such as this page), Fig. 32–4a. Let us compare diffuse reflection to reflection from a mirror, which is known as **specular reflection**. ("Speculum" is Latin for mirror.) When a narrow beam of light shines on a mirror, the light will not reach your eye unless your eye is positioned at just the right place where the law of reflection is satisfied, as shown in Fig. 32–4b. This is what gives rise to the special image-forming properties of mirrors.

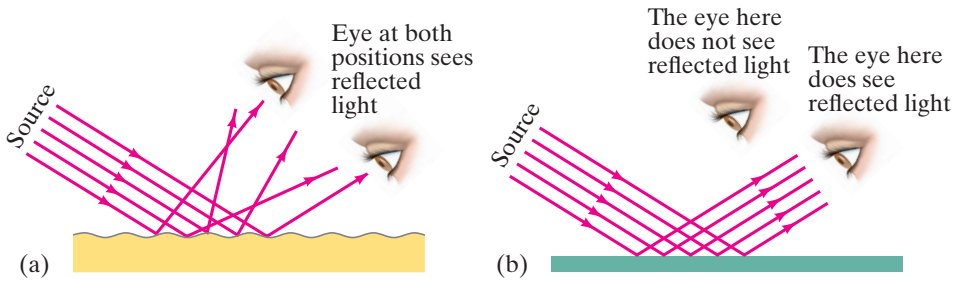

**FIGURE 32–4** A narrow beam of light shines on (a) white paper, and (b) a mirror. In part (a), you can see with your eye the white light reflected at various positions because of diffuse reflection. But in part (b), you see the reflected light only when your eye is placed correctly $(\theta_r = \theta_i)$. Mirror reflection is also known as specular reflection. (Galileo, using similar arguments, showed that the Moon must have a rough surface rather than a highly polished surface like a mirror, as some people thought.)

**EXAMPLE 32–1** **Reflection from flat mirrors.** Two flat mirrors are perpendicular to each other. An incoming beam of light makes an angle of 15° with the first mirror as shown in Fig. 32–5a. What angle will the outgoing beam make with the second mirror?

**APPROACH** We sketch the path of the beam as it reflects off the two mirrors, and draw the two normals to the mirrors for the two reflections. We use geometry and the law of reflection to find the various angles.

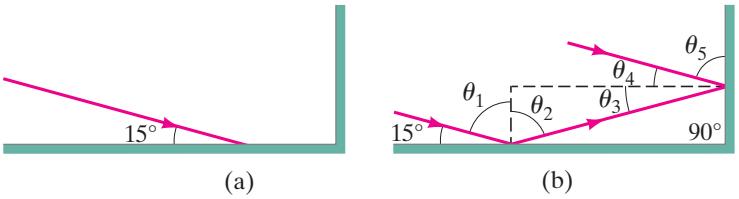

**FIGURE 32–5** Example 32–1.

**SOLUTION** In Fig. 32–5b, $\theta_1 + 15° = 90°$, so $\theta_1 = 75°$; by the law of reflection $\theta_2 = \theta_1 = 75°$ too. Using the fact that the sum of the three angles of a triangle is always 180°, and noting that the two normals to the two mirrors are perpendicular to each other, we have $\theta_2 + \theta_3 + 90° = 180°$. Thus $\theta_3 = 180° - 90° - 75° = 15°$. By the law of reflection, $\theta_4 = \theta_3 = 15°$, so $\theta_5 = 75°$ is the angle the reflected ray makes with the second mirror surface.

**NOTE** The outgoing ray is parallel to the incoming ray. Reflectors on bicycles, cars, and other applications use this principle. Light reflects back toward the source.

When you look straight into a mirror, you see what appears to be yourself as well as various objects around and behind you, Fig. 32–6. Your face and the other objects look as if they are in front of you, beyond the mirror. But what you see in the mirror is an **image** of the objects, including yourself, that are in front of the mirror. Also, you don't see yourself as others see you, because left and right appear reversed in the image. That dimple on your left cheek seems to be on the right cheek of the "person" in the mirror.

A **plane mirror** is one with a smooth flat reflecting surface. Figure 32–7 shows how an image is formed by a plane mirror according to the ray model. We are viewing the mirror, on edge, in the diagram of Fig. 32–7, and the rays are shown reflecting from the front surface. (Good mirrors are generally made by putting a highly reflective metallic coating on one surface of a very flat piece of glass.) Rays from two different points on an object (the bottle on the left in Fig. 32–7) are shown: two rays are shown leaving from a point on the top of the bottle, and two more from a point on the bottom. Rays leave each point on the object going in many directions (as in Fig. 32–1), but only those that enclose the bundle of rays that enter the eye from each of the two points are shown. Each set of diverging rays that reflect from the mirror and enter the eye *appears to come from a single point* behind the mirror, called the **image point**, as shown by the dashed lines. That is, our eyes and brain interpret any rays that enter an eye as having traveled straight-line paths, like in Fig. 32–1. The point from which each bundle of rays seems to come is one point on the image. For each point on the object, there is a corresponding image point. (This analysis of how a plane mirror forms an image was published by Kepler in 1604.)

**FIGURE 32–6** When you look in a mirror, you see an image of yourself and objects around you. You don't see yourself as others see you, because left and right appear reversed in the image. (Note photographer is visible in the mirror. Why?)

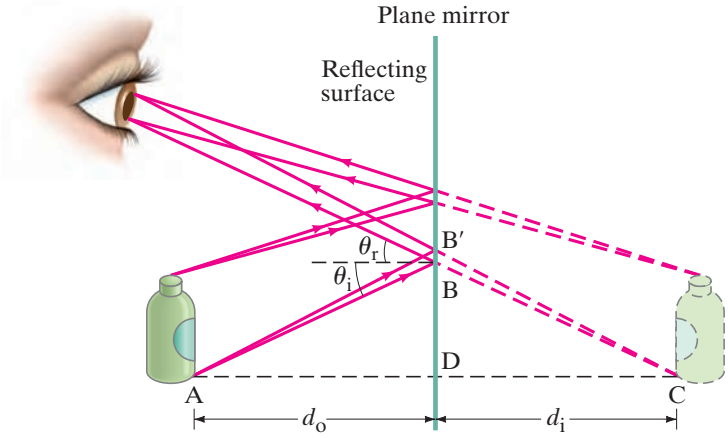

**FIGURE 32–7** Formation of a virtual image by a plane (flat) mirror. Only the bundle of rays from the top and bottom of the object which reach the eye is shown. (We will usually show images using dashed lines or paler colors.)

Let us concentrate on the two rays that leave point A on the object in Fig. 32–7, and strike the mirror at points B and B′. We use geometry now, for the rays at B. The angles ADB and CDB are right angles; and because of the law of reflection, $\theta_i = \theta_r$ at point B. Therefore, by geometry, angles ABD and CBD are also equal. The two triangles ABD and CBD are thus congruent, and the length AD = CD. That is, the image appears as far behind the mirror as the object is in front. The **image distance**, $d_i$ (perpendicular distance from mirror to image, Fig. 32–7), equals the **object distance**, $d_o$ (perpendicular distance from object to mirror). That is

$$d_i = d_o. \qquad \text{[plane mirror]}$$

From the geometry, we also can see that the height of the image is the same as that of the object.

The light rays do not actually pass through the image location itself in Fig. 32–7. (Note where the red lines are drawn dashed to show they are our projections, not rays.) The image would not appear on paper or film placed at the location of the image. Therefore, the image in a plane mirror is called a **virtual image**. This is to distinguish it from a **real image** in which the light *does* pass through the image and which therefore could appear on a white surface, or on film or on an electronic sensor placed at the image position. Our eyes can see both real and virtual images, as long as the diverging rays enter our pupils. We will see that curved mirrors and lenses can form real images, as well as virtual. A movie projector lens, for example, produces a real image that is visible on the screen.

**⚠ CAUTION**

*Light rays do not actually pass through image in a plane mirror*

**EXAMPLE 32–2** **How tall must a full-length mirror be?** A woman 1.60 m tall stands in front of a vertical plane mirror. What is the minimum height of the mirror, and how high must its lower edge be above the floor, if she is to be able to see her whole body? Assume that her eyes are 10 cm below the top of her head.

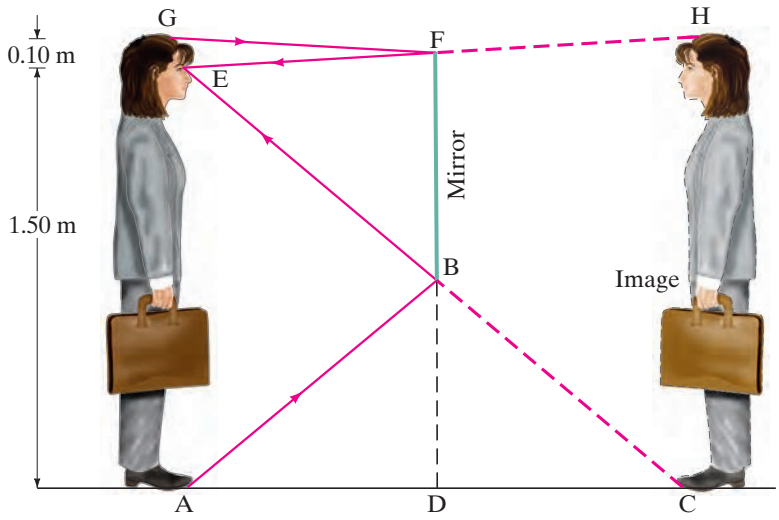

**FIGURE 32–8** Seeing oneself in a mirror. Example 32–2.

**APPROACH** For her to see her whole body, as in Fig. 32–8, light rays from the top of her head (point G) and from the bottom of her foot (A) must reflect from the mirror and enter her eye. We don't show two rays diverging from each point as we did in Fig. 32–7, where we wanted to find where the image is. Now that we know the image is the same distance behind a plane mirror as the object is in front, we only need to show one ray leaving point G (top of head) and one ray leaving point A (her toe), and then use geometry.

**PHYSICS APPLIED**
*How tall a mirror do you need to see a reflection of your entire self?*

**SOLUTION** First consider the ray that leaves her foot at A, reflects at B, and enters the eye at E. The mirror needs to extend no lower than B. The angle of reflection equals the angle of incidence, so the height BD is half of the height AE. Because $AE = 1.60\,\text{m} - 0.10\,\text{m} = 1.50\,\text{m}$, then $BD = 0.75\,\text{m}$. So the mirror's bottom edge must be 0.75 m above the floor. Similarly, if the woman is to see the top of her head, the top edge of the mirror only needs to reach point F, which is 5 cm below the top of her head (half of $GE = 10\,\text{cm}$). Thus, $DF = 1.55\,\text{m}$, and the mirror needs to have a vertical height of only $(1.55\,\text{m} - 0.75\,\text{m}) = 0.80\,\text{m}$.

**NOTE** We see that a mirror, if positioned at the correct height, as in Fig. 32–8, need be only half as tall as a person for that person to be able to see all of himself or herself.

**EXERCISE A** Does the result of Example 32–2 depend on your distance from the mirror? (Try it and see, it's fun.)

**EXERCISE B** Return to the Chapter-Opening Question, page 926, and answer it again now. Try to explain why you may have answered differently the first time.

**CONCEPTUAL EXAMPLE 32–3** **Is the photo upside down?** Close examination of the photograph on the first page of this Chapter, page 926, reveals that in the top portion the Sun is seen clearly, whereas in the lower portion the Sun is partially blocked by the tree branches. Show why the reflection is not the same as the real scene by drawing a sketch of this situation, showing the Sun, the camera, the branch, and two rays going from the Sun to the camera, one ray direct and one reflected. Is the photograph right side up?

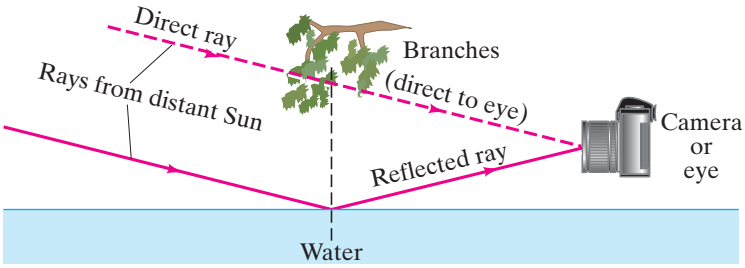

**FIGURE 32–9** Example 32–3, analyzing the photo on page 926 that opens this Chapter: is it right side up, or not?

**RESPONSE** Figure 32–9 is drawn assuming the photo on page 926 is upside down. The Sun is so far away, its light rays arrive parallel (see Figs. 32–12 and 32–13), and the Sun's rays as seen directly come through the branches (dashed red ray). The unblocked view of the Sun would be the reflection: the ray traveling below the branches would reflect off the water and into the camera. This works—it is what we see in the photo if we turn it upside down. But a diagram assuming the photo on page 926 is right side up (Sun seen directly is less high above the horizon than is the reflection) won't work (Problem 6). The photo on page 926 is upside down.

Also, what about the people in the photo? Try to draw a diagram showing why they don't appear in the reflection. [*Hint*: Assume they are not sitting at the edge of the pool, but back from the edge.] Then try to draw a diagram of the reverse (i.e., assume the photo is right side up so the people are visible only in the reflection). Reflected images are not perfect replicas when different planes (distances) are involved.

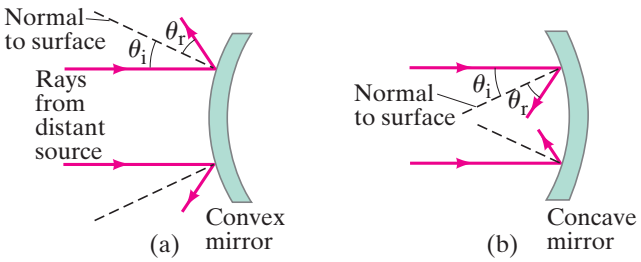

**FIGURE 32–10** Mirrors with convex and concave spherical surfaces. Note that $\theta_r = \theta_i$ for each ray. (The black dashed lines are perpendicular to the mirror surface at each point shown).

**FIGURE 32–11** (a) A concave cosmetic mirror gives a magnified image. (b) A convex mirror in a store reduces image size and so includes a wide field of view.

(a)

(b)

# 32–3 Formation of Images by Spherical Mirrors

Reflecting surfaces can also be *curved*, usually *spherical*, which means they form a section of a sphere. A **spherical mirror** is called **convex** if the reflection takes place on the outer surface of the spherical shape so that the center of the mirror surface bulges out toward the viewer, Fig. 32–10a. A mirror is called **concave** if the reflecting surface is on the inner surface of the center of the sphere so that the mirror surface curves away from the viewer (like a "cave"), Fig. 32–10b. Concave mirrors are used as shaving or cosmetic mirrors (**magnifying mirrors**), Fig. 32–11a, because they magnify. Convex mirrors are sometimes used on cars and trucks (rearview mirrors) and in shops (to watch for theft), because they take in a wide field of view, Fig. 32–11b.

## Focal Point and Focal Length

To see how spherical mirrors form images, we first consider an object that is very far from a concave mirror. For a distant object, as shown in Fig. 32–12, the rays from each point on the object that strike the mirror will be nearly parallel. *For an object infinitely far away* (the Sun and stars approach this), *the rays would be precisely parallel.*

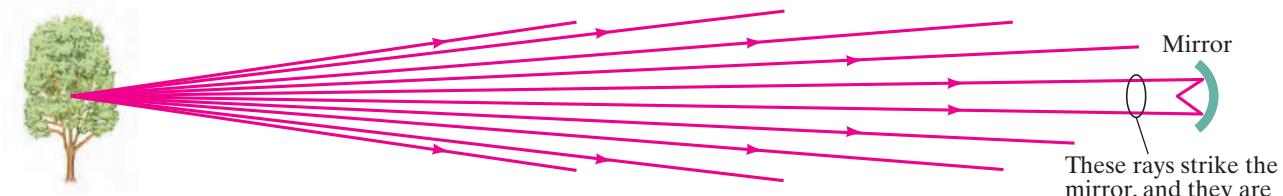

**FIGURE 32–12** If the object's distance is large compared to the size of the mirror (or lens), the rays arrive nearly parallel. They are parallel for an object at infinity ($\infty$).

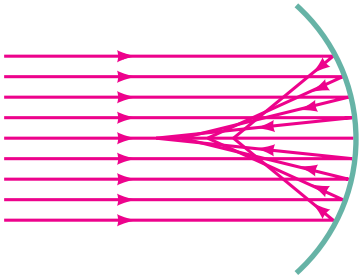

**FIGURE 32–13** Parallel rays striking a concave spherical mirror do not intersect (or focus) at precisely a single point. (This "defect" is referred to as "spherical aberration.")

Now consider such parallel rays falling on a concave mirror as in Fig. 32–13. The law of reflection holds for each of these rays at the point each strikes the mirror. As can be seen, they are not all brought to a single point. In order to form a sharp image, the rays must come to a point. Thus a spherical mirror will not make as sharp an image as a plane mirror will. However, as we show below, if the mirror is small compared to its radius of curvature, so that a reflected ray makes only a *small angle* with the incident ray ($2\theta$ in Fig. 32–14), then the rays will cross each other at very nearly a single point, or **focus**. In the case shown in Fig. 32–14, the incoming rays are parallel to the **principal axis**, which is defined as the straight line perpendicular to the curved surface at its center (line CA in Fig. 32–14). The point F, where incident parallel rays come to a focus after reflection, is called the **focal point** of the mirror. The distance between F and the center of the mirror, length FA, is called the **focal length**, $f$, of the mirror. The focal point is also the *image point for an object infinitely far away* along the principal axis. The image of the Sun, for example, would be at F.

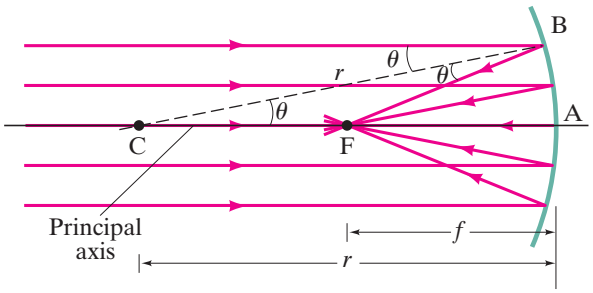

**FIGURE 32–14** Rays parallel to the principal axis of a concave spherical mirror come to a focus at F, the focal point, as long as the mirror is small in width as compared to its radius of curvature, $r$, so that the rays are "paraxial"—that is, make only small angles with the horizontal axis. The smaller the angles, the better the approximation.

Now we will show, for a mirror whose reflecting surface is small compared to its radius of curvature, that the rays very nearly meet at a common point, F, and we will also determine the focal length $f$. In this approximation, we consider only rays that make a small angle with the principal axis; such rays are called **paraxial rays**, and their angles are exaggerated in Fig. 32–14 to make the labels clear. First we consider a ray that strikes the mirror at B in Fig. 32–14. The point C is the center of curvature of the mirror (the center of the sphere of which the mirror is a part). So the dashed line CB is equal to $r$, the radius of curvature, and CB is normal to the mirror's surface at B. The incoming ray that hits the mirror at B makes an angle $\theta$ with this normal, and hence the reflected ray, BF, also makes an angle $\theta$ with the normal (law of reflection). The angle BCF is also $\theta$, as shown (parallel lines—see Fig. A–1 in Appendix A). The triangle CBF is isosceles because two of its angles are equal. Thus length CF = FB. We assume the mirror surface's height is small compared to the mirror's radius of curvature, so the angles are small,[†] and the length FB is nearly equal to length FA. In this approximation, FA = FC. But FA = $f$, the focal length, and CA = 2 × FA = $r$. Thus the focal length is half the radius of curvature:

*Focal length of spherical mirror*

$$f = \frac{r}{2}. \qquad \text{[spherical mirror]} \quad \textbf{(32–1)}$$

We assumed only that the angle $\theta$ was small, so this result applies for all other incident paraxial rays. Thus all paraxial rays pass through the same very tiny point F, the focal point.

Since it is only approximately true that the rays come to a perfect focus at F, the more curved the mirror, the worse the approximation (Fig. 32–13) and the more blurred the image. This "defect" of spherical mirrors is called **spherical aberration**; we will discuss it more with regard to lenses in Chapter 33. A **parabolic reflector**, on the other hand, will reflect the rays to a perfect focus. However, because parabolic shapes are much harder to make and thus much more expensive, spherical mirrors are used for most purposes. (Many astronomical telescopes use parabolic reflectors, as do TV satellite dish antennas which concentrate radio waves to nearly a point, Fig. 31–23.) We consider here only spherical mirrors and we will assume that they are small compared to their radius of curvature so that the image is sharp and Eq. 32–1 holds.

[†]Just to give an idea, the error in this assumption rises to 1% at $\theta \approx 15° = 0.25$ rad if we use $\sin\theta$ or $\tan\theta$ as our guide: $\tan\theta \approx \sin\theta \approx \theta$ in radians (0.259 vs. 0.262, page A-5 in Appendix A).

## Image Formation—Ray Diagrams

We saw that for an object at infinity, the image is located at the focal point of a concave spherical mirror, where $f = r/2$. But where does the image lie for an object not at infinity? First consider the object shown as an arrow in Fig. 32–15a, which is placed between F and C at point O (O for object). Let us determine where the image will be for a given point O′ at the top of the object, by finding the point where rays drawn from the tip of the arrow converge after reflecting from the mirror. To do this we can draw several rays and make sure these reflect from the mirror such that the angle of reflection equals the angle of incidence.

(a) Ray 1 goes out from O′ parallel to the axis and reflects through F.

(b) Ray 2 goes through F and then reflects back parallel to the axis.

(c) Ray 3 is perpendicular to mirror, and so must reflect back on itself and go through C (center of curvature).

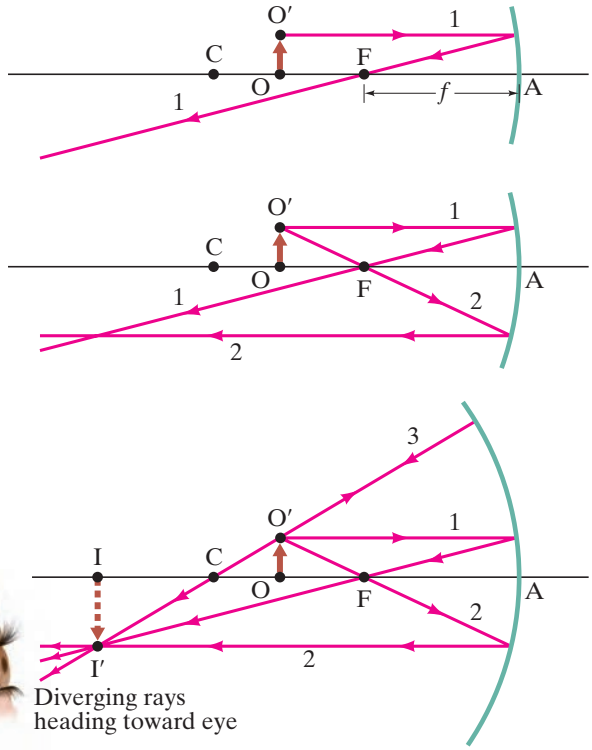

**FIGURE 32–15** Rays leave point O′ on the object (a brown arrow). Shown are the three most useful rays for determining where the image I′ is formed. The image is shown as a dashed brown arrow. [Note that our mirror is not small compared to $f$, so the rays shown are not actually paraxial and our diagram will not give the precise position of the image.]

Many rays could be drawn leaving any point on an object, but determining the image position is faster if we deal with three particular rays. These are the rays labeled 1, 2, and 3 in Fig. 32–15 and we draw them leaving object point O′ as follows:

Ray 1 leaving O′ is drawn parallel to the axis; therefore after reflection it must pass along a line through F, Fig. 32–15a (just as parallel rays did in Fig. 32–14).

Ray 2 leaves O′ and is made to pass through F (Fig. 32–15b); therefore it must reflect so it is parallel to the axis. (In reverse, a parallel ray passes through F.)

Ray 3 is drawn along a radius of the spherical surface (Fig. 32–15c) and is perpendicular to the mirror, so it is reflected back on itself and passes through C, the center of curvature.

**RAY DIAGRAM**
*Finding the image position for a curved mirror*

All three rays leave a single point O′ on the object. After reflection from a (small) mirror, the point at which these rays cross is the image point I′. All other rays from the same object point will also pass through this image point. To find the image point for any object point, only these three types of rays need to be drawn. Only two of these rays are needed, but the third serves as a check.

**PROBLEM SOLVING**
*Image point is where reflected rays intersect*

We have shown the image point in Fig. 32–15 only for a single point on the object. Other points on the object are imaged nearby. For instance, the bottom of the arrow, on the principal axis at point O, is imaged on the axis at point I. So a complete image of the object is formed (dashed arrow in Fig. 32–15c). Because the light actually passes through the image, this is a **real image** that will appear on a white surface or film placed there. This can be compared to the virtual image formed by a plane mirror (Fig. 32–7: the light does not pass through that image).

The image in Fig. 32–15 can be seen by the eye only when the eye is placed to the left of the image, so that rays *diverging* from a point on the image (as point I′) enter the eye as shown in Fig. 32–15c. A normal eye can focus parallel or *diverging* rays (not converging), as in normal viewing: see the important Fig. 32–1.

**CAUTION**
*Only diverging rays can be focused by the eye*

## Mirror Equation and Magnification

Image points can be determined, roughly, by drawing the three rays as just described, Fig. 32–15. But it is difficult to draw small angles for the "paraxial" rays as we assumed. For more accurate results, we now derive an equation that gives the image distance if the object distance and radius of curvature of the mirror are known. To do this, we refer to Fig. 32–16. The **object distance**, $d_o$, is the distance of the object (point O) from the center of the mirror. The **image distance**, $d_i$, is the distance of the image (point I) from the center of the mirror. The height of the object OO′ is called $h_o$ and the height of the image, II′, is $h_i$. Two rays leaving O′ are shown: O′FBI′, which is ray 2 in Fig. 32–15, plus ray O′AI′, which is a fourth type of ray that reflects at the center of the mirror (equal angles $\theta$) and in many cases can be useful to find an image point (labeled 4 in Fig. 32–16).

**RAY DIAGRAM**
*Ray 4 to help find image*

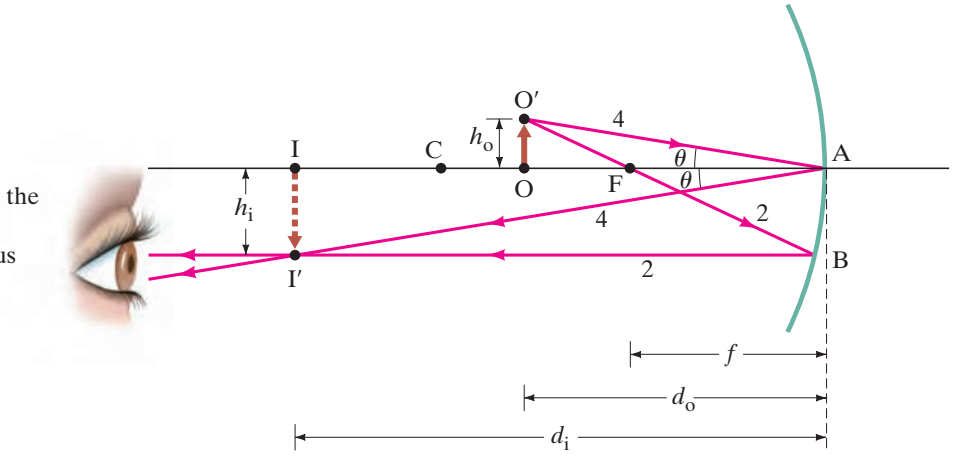

**FIGURE 32–16** Diagram for deriving the mirror equation. For the derivation, we assume the mirror size is small compared to its radius of curvature.

The ray O′AI′ obeys the law of reflection, so the two right triangles O′AO and I′AI are similar. Therefore, we have

$$\frac{h_o}{h_i} = \frac{d_o}{d_i}.$$

For the other ray shown, O′FBI′, we use the fact that for a mirror small compared to its radius, the triangles O′FO and AFB are similar (because the angles at F are equal and we use the approximation $AB = h_i$) and obtain

$$\frac{h_o}{h_i} = \frac{OF}{FA} = \frac{d_o - f}{f},$$

where we used the fact that $FA = f$, the focal length of the mirror.

The left sides of the two preceding expressions are the same, so we can equate the right sides:

$$\frac{d_o}{d_i} = \frac{d_o - f}{f}.$$

We now divide both sides by $d_o$ and rearrange to obtain

*MIRROR EQUATION*

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}. \qquad \textbf{(32–2)}$$

This is the equation we were seeking. It is called the **mirror equation** and relates the object and image distances to the focal length $f$ (where $f = r/2$).

The mirror equation also holds for a plane mirror: the focal length is $f = r/2 = \infty$ (Eq. 32–1) because $r = \infty$ for a flat surface, and Eq. 32–2 gives $d_i = -d_o$, as it should in accord with Fig. 32–7 and the discussion on page 929; the sign convention on the next page gives us the minus sign.

**⚠ CAUTION**
*Ray diagrams are not precise*

Note that the image distance cannot be obtained accurately by measuring on a ray diagram like Fig. 32–16, because our diagram violates the paraxial ray assumption (we draw rays at steeper angles to make them clearly visible).

The **lateral magnification**, $m$, of a mirror is defined as the height of the image divided by the height of the object. From our first set of similar triangles in Fig. 32–16, or the first equation on page 934, we can write:

$$m = \frac{h_i}{h_o} = -\frac{d_i}{d_o}. \qquad \textbf{(32–3)}$$

The minus sign in Eq. 32–3 is inserted as a convention. Indeed, we must be careful about the signs of all quantities in Eqs. 32–2 and 32–3. Sign conventions are chosen so as to give the correct locations and orientations of images, as predicted by ray diagrams. The **sign conventions** we use are:

**PROBLEM SOLVING**
*Sign conventions for mirrors*

1. the image height $h_i$ is positive if the image is upright, and negative if inverted, relative to the object (assuming $h_o$ is taken as positive);
2. $d_i$ or $d_o$ is positive if image or object is in front of the mirror (as in Fig. 32–16); if either image or object is behind the mirror, the corresponding distance is negative. [An example of $d_i < 0$ can be seen in Fig. 32–17, on the next page.][†]

Thus the lateral magnification (Eq. 32–3) is positive for an upright image and negative for an inverted image (upside down). In everyday life, what we usually mean by magnification is not lateral magnification but rather *angular* magnification, which we discuss shortly.

## Concave Mirror Examples

**EXAMPLE 32–4** **Image in a concave mirror.** A 1.50-cm-high object is placed 20.0 cm from a concave mirror with radius of curvature 30.0 cm. Determine (*a*) the position of the image, and (*b*) its size.

**APPROACH** The ray diagram is basically the same as Fig. 32–16, since the object is between F and C. We determine the focal length from the radius of curvature (Eq. 32–1), $f = r/2 = 15.0$ cm. The position and size of the image are found from Eqs. 32–2 and 32–3.

**SOLUTION** Referring to Fig. 32–16, we have CA $= r = 30.0$ cm, FA $= f = 15.0$ cm, and OA $= d_o = 20.0$ cm.

(*a*) We start with the mirror equation, Eq. 32–2, rearranging it:

$$\frac{1}{d_i} = \frac{1}{f} - \frac{1}{d_o} = \frac{1}{15.0\text{ cm}} - \frac{1}{20.0\text{ cm}} = 0.0167\text{ cm}^{-1}.$$

**CAUTION**
*Remember to take the reciprocal*

So $d_i = 1/(0.0167\text{ cm}^{-1}) = 60.0$ cm. Because $d_i$ is positive, the image is 60.0 cm in front of the mirror, on the same side as the object.

(*b*) From Eq. 32–3, the lateral magnification is

$$m = -\frac{d_i}{d_o} = -\frac{60.0\text{ cm}}{20.0\text{ cm}} = -3.00.$$

The image is 3.0 times larger than the object, and its height is

$$h_i = mh_o = (-3.00)(1.5\text{ cm}) = -4.5\text{ cm}.$$

The minus sign reminds us that the image is inverted, as shown in Fig. 32–16.

**NOTE** When an object is farther from a concave mirror than the focal point, we can see from Fig. 32–15 or 32–16 that the image is always inverted and real.

**CONCEPTUAL EXAMPLE 32–5** **Reversible rays.** If the object in Example 32–4 is placed instead where the image is (see Fig. 32–16), where will the new image be?

**RESPONSE** The mirror equation is *symmetric* in $d_o$ and $d_i$. Thus the new image will be where the old object was. Indeed, in Fig. 32–16 we need only reverse the direction of the rays to get our new situation.

[†] $d_o$ is always positive for a real object; $d_o$ can be negative only if the object is itself an image formed by another mirror or lens—see Example 33–6, next Chapter.

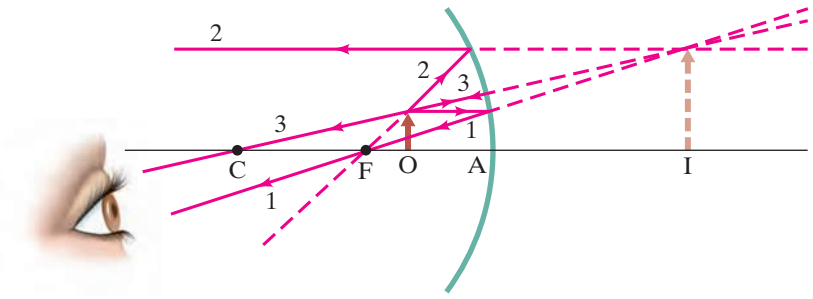

**FIGURE 32–17** Object placed within the focal point F. The image (dashed arrow) is *behind* the mirror and is *virtual*, Example 32–6. [Note that the vertical scale (height of object = 1.0 cm) is different from the horizontal (OA = 10.0 cm) for ease of drawing, and reduces the precision of the drawing.]

**EXAMPLE 32–6** **Object closer to concave mirror than focal point.** A 1.00-cm-high object is placed 10.0 cm from a concave mirror whose radius of curvature is 30.0 cm. (*a*) Draw a ray diagram to locate (approximately) the position of the image. (*b*) Determine the position of the image and the lateral magnification analytically.

**APPROACH** We draw the ray diagram using the rays as in Fig. 32–15, page 933. An analytic solution uses Eqs. 32–1, 32–2, and 32–3.

**SOLUTION** (*a*) Since $f = r/2 = 15.0\,\text{cm}$, the object $(d_o = 10.0\,\text{cm})$ is between the mirror and the focal point. We draw the three rays as described earlier (Fig. 32–15); they are shown leaving the tip of the object in Fig. 32–17. Ray 1 leaves the tip of our object heading toward the mirror parallel to the axis, and reflects through F. Ray 2 cannot head toward F because it would not strike the mirror; so ray 2 must point as if it started at F (dashed line in Fig. 32–17) and heads to the mirror, and then is reflected parallel to the principal axis. Ray 3 is perpendicular to the mirror and reflects back on itself. The rays reflected from the mirror diverge and so never meet at a point. They appear to be coming from a point behind the mirror (dashed red rays) just as for a flat mirror, Fig. 32–7. This point where the dashed rays meet is the image point of the tip of the arrow. The image is thus *behind* the mirror and is *virtual*.

(*b*) We use Eq. 32–2 to find $d_i$ when $d_o = 10.0\,\text{cm}$:

$$\frac{1}{d_i} = \frac{1}{f} - \frac{1}{d_o} = \frac{1}{15.0\,\text{cm}} - \frac{1}{10.0\,\text{cm}} = \frac{2-3}{30.0\,\text{cm}} = -\frac{1}{30.0\,\text{cm}}.$$

Therefore, $d_i = -30.0\,\text{cm}$. The minus sign means the image is behind the mirror, which our diagram also showed us. The lateral magnification is $m = -d_i/d_o = -(-30.0\,\text{cm})/(10.0\,\text{cm}) = +3.00$. So the image is 3.00 times larger than the object. The plus sign indicates that the image is upright (same as object), which is consistent with the ray diagram, Fig. 32–17.

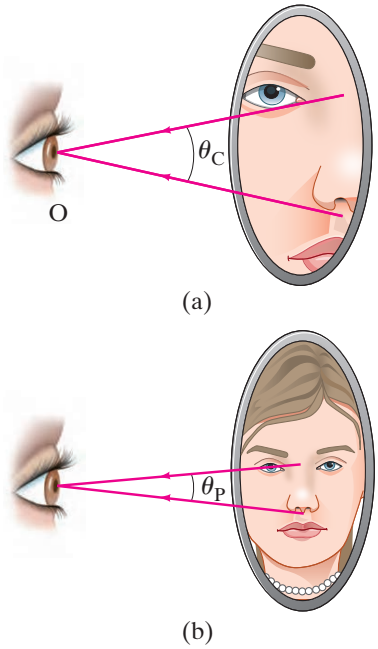

**FIGURE 32–18** Looking at your face (a) in a magnifying mirror, and (b) in a plane flat mirror. The eye on the left is yours (object O), looking at *your* image in the mirror.

## 32–4 Seeing Yourself in a Magnifying Mirror (Concave)

To understand how a concave mirror acts as a magnifying mirror, we start with Fig. 32–17 and assume the object O is *you*, or your eye and part of your face. When a makeup or shaving mirror claims to be 5×, for example, the mirror is supposed to make an image that looks 5 times larger than when you look in an ordinary plane mirror. In Fig. 32–18 we are looking at two such mirrors. The concave mirror in (a) shows less of your face than the plane mirror in (b). But the part of your face you can see in (a) looks enlarged and you can see more detail of your eyes, cheeks, and nose. To specify the magnification, we compare the angles that some feature in your image, such as your nose, subtends at your eye. These angles are labeled $\theta_C$ (C for concave) and $\theta_P$ (P for plane) in Fig. 32–18. Their ratio is defined as the **angular magnification** $M$:

$$M = \frac{\theta_C}{\theta_P},$$

and is roughly about 2× in Fig. 32–18. This $M$ corresponds to what we see, and usually mean in everyday life, vs. the $m$ of Eq. 32–3 which is different. [$M$ compares two different images; $m$ compares an object to an image (distances or heights).]

Let us make a calculation of $M$ using Fig. 32–17, but forget the eye shown on the left. Instead, we assume your eye and face are the object labeled O. Let us assume that the mirror has focal length $f = 15.0\,\text{cm}$ and your eye is at $d_o = 10.0\,\text{cm}$,

**PHYSICS APPLIED**
*Magnifying mirror: Seeing yourself upright and magnified in a concave mirror*

just as in Example 32–6, where we found the image distance to be $d_i = -30.0$ cm and the lateral magnification $m = 3.0$. Let the height of the object $h_o$ (in cm) be the height of your nose or maybe your eye. To find $\theta_C$ in Fig. 32–18a, we assume the angle is small so $\theta_C \approx$ (height of image)/(distance eye to image). The height of the image is $h_i = mh_o = 3.0h_o$ (Eq. 32–3), and the distance from your eye to the image (see Fig. 32–17) is your eye's distance to the mirror ($d_o = 10.0$ cm) plus the distance from the mirror to the image in Fig. 32–17, $|d_i| = 30.0$ cm. Thus (cm units omitted)

$$\theta_C = \frac{h_i}{d_o + |d_i|} = \frac{3.0h_o}{10.0 + 30.0} = \left(\frac{3}{40}\right)h_o.$$

The angle $\theta_P$ for the plane mirror in Fig. 32–18b is easier. The image height equals the object height, and the distance from your eye to the image is $d_o + |d_i| = 2d_o$ because the image distance equals the object distance for a plane mirror (Fig. 32–7). Thus

$$\theta_P = \frac{h_i}{2d_o} = \frac{h_o}{20.0} = \left(\frac{1}{20}\right)h_o.$$

Then

$$M = \frac{\theta_C}{\theta_P} = \frac{(3/40)h_o}{(1/20)h_o} = \frac{(3)(20)}{40} = 1.5\times.$$

To get a larger magnification, let us move our eye, which is object O in Fig. 32–17 (not the eye shown), very close to the focal point F, say $d_o = 14.0$ cm. To find $d_i$ we use Eq. 32–2

$$\frac{1}{d_i} = \frac{1}{f} - \frac{1}{d_o} = \frac{1}{15.0\text{ cm}} - \frac{1}{14.0\text{ cm}} = \frac{14.0\text{ cm} - 15\text{ cm}}{(15.0\text{ cm})(14.0\text{ cm})} = -\frac{1.0}{210\text{ cm}}.$$

Hence $d_i = -210$ cm and the lateral magnification is $m = h_i/h_o = -d_i/d_o =$ (210 cm)/(14.0 cm) = 15. The image height is $h_i = mh_o = 15h_o$ so when $d_o = 14.0$ cm,

$$\theta_C = \frac{15h_o}{d_o + |d_i|} = \frac{15h_o}{14.0 + 210} = 0.067h_o,$$

where we omitted units (all cm). Looking in a plane mirror from a distance of $d_o = 14.0$ cm means

$$\theta_P = \frac{h_o}{2d_o} = \left(\frac{1}{28}\right)h_o = 0.036h_o.$$

Hence

$$M = \frac{\theta_C}{\theta_P} = \frac{0.067h_o}{0.036h_o} = 1.9\times,$$

or almost 2×. If you move your eye (point O) closer and closer to F in Fig. 32–17, the angular magnification approaches 2.0×. That is in fact the best sharp image you can get from any spherical concave mirror.

What happens if you move your eye further from the mirror, so it is between F and C (center of mirror's curvature) as in Fig. 32–16? (Try it and see.) Your eye (and face) is the object at point O. If you set $d_o = 20.0$ cm, or any value between $d_o = f$ and $d_o = r = 2f$, your image will be real, *inverted*, and *behind* you (see Fig. 32–16 or use Eq. 32–2). In the ray diagram, the rays entering your eye are *converging* (imagine your eye just below point O in Fig. 32–16). But a normal eye is designed to focus *diverging* rays, as in reality (Fig. 32–1). Nonetheless, if you experiment with a concave mirror, as you place your eye farther back from the focal point ($d_o > f$), at first you will see an *upright* slightly blurry image of your face with $M > 2\times$. As you increase the distance between your eye and the mirror, the image gets larger but blurrier.† You maybe can reach 5× but the image is quite blurry. (10×, 20× is unrealistic!) As the eye-mirror distance, $d_o$, gets close to the mirror's radius of curvature (point C in Fig. 32–16) the image becomes one big blur. There seems to be a paradox when the object (your face) is between F and C. The image is *inverted* and *behind* you, as we just saw, yet you still *see* an upright image of yourself, though blurred. This can be explained: the converging rays from the mirror are intercepted by your eye but will *not* be focused by the eye's lens to a point on the retina, but instead as a small blob or circle (like "circles of confusion" discussed in the next Chapter).

Finally, what happens when your eye is beyond point C, the mirror's center of curvature. You can get a sharp image of yourself once again, but upside down. And it will seem small now because the mirror is rather far from you. This inverted image of yourself will be in front of you and readily visible. Draw the ray diagram, or see Fig. 32–50b (Problem 31).

†Farsighted eyes do better and focus slightly converging rays (see Fig. 33–27).

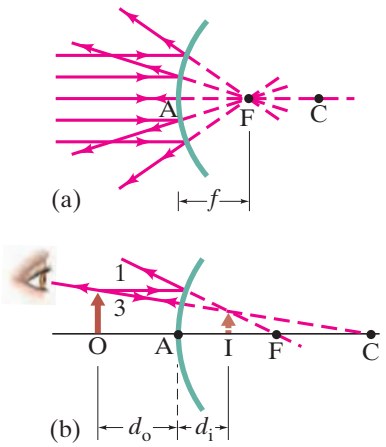

**FIGURE 32–19** Convex mirror: (a) the focal point is at F, behind the mirror; (b) the image I of the object at O is virtual, upright, and smaller than the object. [Not to scale for Example 32–7.]

## 32–5 Convex (Rearview) Mirrors

The analysis used for concave mirrors can be applied to **convex** mirrors. Even the mirror equation (Eq. 32–2) holds for a convex mirror. Figure 32–19a shows parallel rays falling on a convex mirror. Again spherical aberration is significant (Fig. 32–13), unless we assume the mirror is small compared to its radius of curvature. The rays reflected from the mirror diverge, but seem to come from point F *behind* the mirror, Fig. 32–19a. This is the **focal point**, and its distance from the center of the mirror (point A) is the **focal length**, $f$. The equation $f = r/2$ is valid also for a convex mirror. We see that an object at infinity (parallel rays) produces a virtual image in a convex mirror. Indeed, no matter where the object is placed on the reflecting side of a convex mirror, the image will be virtual and upright as seen in Fig. 32–19b. To find the image we draw rays 1 and 3 according to the rules used before (page 933), as shown in Fig. 32–19b. Note that although rays 1 and 3 don't actually pass through points F and C, the line along which each is drawn does (shown dashed).

The mirror equation, Eq. 32–2, holds for convex mirrors but the focal length $f$ and radius of curvature must be considered negative. The proof is left for you to do as Problem 23.

**PHYSICS APPLIED**
*Convex rearview mirror*

**FIGURE 32–20** Example 32–7.

**EXAMPLE 32–7** **Convex rearview mirror.** An external rearview car mirror is convex with a radius of curvature of 0.80 m (Fig. 32–20). Determine the location of the image and its lateral magnification for a truck 10.0 m from the mirror.

**APPROACH** The ray diagram will be like Fig. 32–19b, but the large object distance $(d_o = 10.0\,\text{m})$ makes a precise drawing difficult. We have a convex mirror, so $r$ is negative by convention.

**SOLUTION** The center of curvature of a convex mirror is behind the mirror, as is its focal point, so we set $r = -0.80\,\text{m}$ so that the focal length is $f = r/2 = -0.40\,\text{m}$. The object is in front of the mirror, $d_o = 10.0\,\text{m}$. Solving the mirror equation, Eq. 32–2, for $1/d_i$ gives

$$\frac{1}{d_i} = \frac{1}{f} - \frac{1}{d_o} = \frac{1}{-0.40\,\text{m}} - \frac{1}{10.0\,\text{m}} = \frac{-10.0 - 0.40}{4.0\,\text{m}} = -\frac{-10.4}{4.0\,\text{m}}.$$

Thus $d_i = -4.0\,\text{m}/10.4 = -0.38\,\text{m}$ or 38 cm behind the mirror. Equation 32–3 gives the lateral magnification

$$m = -\frac{d_i}{d_o} = -\frac{(-0.38\,\text{m})}{(10.0\,\text{m})} = +0.038.$$

**CAUTION**
*How large does the object seem, and how far away?*

How large does the truck *look* in the rearview mirror of Fig. 32–20? We again use *angular magnification*, $M = \theta_C/\theta_P$, as we did in Section 32–4, because we want to compare the size of the image in the convex rearview mirror to what it would be in a flat mirror. In the convex mirror, the angle that the image of the truck makes with your eye (note Figs. 32–18 and 32–19) is $\theta_C = h_i/(d_{eye} + |d_i|)$ where $d_{eye}$ is the distance of your eye from the mirror, about 0.5 m for a mirror on the driver's side. In Example 32–7, $|d_i| = 0.38\,\text{m}$ and $h_i = mh_o = 0.038h_o$, so $\theta_C = 0.038h_o/(0.5\,\text{m} + 0.38\,\text{m}) = 0.043h_o$ where $h_o$ is the height of the truck in meters. But if you looked in a *plane* mirror, the lateral magnification $m = 1$, so $h_i = h_o$, and $|d_i| = d_o = 10\,\text{m}$. So the angle you would view the truck is $\theta_P = h_o/(d_{eye} + d_o) = h_o/(0.5\,\text{m} + 10\,\text{m}) = 0.095h_o$. The angular magnification is

$$M = \frac{\theta_C}{\theta_P} = \frac{0.043h_o}{0.095h_o} = 0.45,$$

**CAUTION**
*This object is **closer** than it seems in a convex mirror (BEWARE)*

so the image in the convex mirror is about half what it would be in a normal plane mirror. The truck would thus look *twice as far away* as it really is!

If we consider the mirror on the passenger side, $d_{eye} \approx 1.5\,\text{m}$, you will get a smaller result (see Problem 96).

# 32–6 Index of Refraction

We saw in Chapter 31 that the speed of light in vacuum (like other EM waves) is

$$c = 2.99792458 \times 10^8 \text{ m/s},$$

which is usually rounded off to

$$3.00 \times 10^8 \text{ m/s}$$

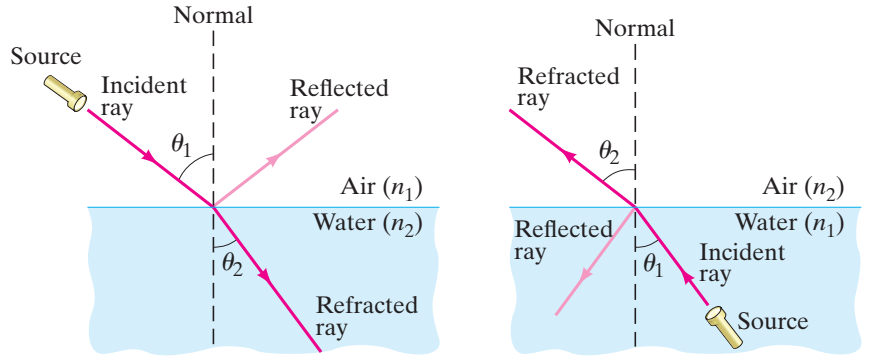
when extremely precise results are not required. In air, the speed is only slightly less. In other transparent materials, such as glass and water, the speed is always less than that in vacuum. For example, in water light travels at about $\frac{3}{4}c$. The ratio of the speed of light in vacuum to the speed $v$ in a given material is called the **index of refraction**, $n$, of that material:

$$n = \frac{c}{v}. \tag{32–4}$$

The index of refraction is never less than 1, and values for various materials are given in Table 32–1. For example, since $n = 1.33$ for water, the speed of light in water is

$$v = \frac{c}{n} = \frac{(3.00 \times 10^8 \text{ m/s})}{1.33} = 2.26 \times 10^8 \text{ m/s}.$$

As we shall see later, $n$ varies somewhat with the wavelength of the light—except in vacuum—so a particular wavelength is specified in Table 32–1, that of yellow light with wavelength $\lambda = 589$ nm.



That light travels more slowly in matter than in vacuum can be explained at the atomic level as being due to the absorption and reemission of light by atoms and molecules of the material.

**TABLE 32–1 Indices of Refraction (at $\lambda = 589$ nm)**

| Material | $n = \frac{c}{v}$ |
|---|---|
| Vacuum | 1.0000 |
| Air (at STP) | 1.0003 |
| Water | 1.33 |
| Ethyl alcohol | 1.36 |
| Glass | |
| Fused quartz | 1.46 |
| Crown glass | 1.52 |
| Light flint | 1.58 |
| Plastic | |
| Acrylic, Lucite, CR-39 | 1.50 |
| Polycarbonate | 1.59 |
| "High-index" | 1.6–1.7 |
| Sodium chloride | 1.53 |
| Diamond | 2.42 |

# 32–7 Refraction: Snell's Law

When light passes from one transparent medium into another with a different index of refraction, some or all of the incident light is reflected at the boundary. The rest passes into the new medium. If a ray of light is incident at an angle to the surface (other than perpendicular), the ray changes direction as it enters the new medium. This change in direction, or bending, of the light ray is called **refraction**.

(a) $n_2 > n_1$: Ray bends toward ⊥ (b) $n_1 > n_2$: Ray bends away from ⊥

**FIGURE 32–21** Refraction. (a) Light refracted when passing from air $(n_1)$ into water $(n_2)$: $n_1 < n_2$. (b) Light refracted when passing from water $(n_1)$ into air $(n_2)$: $n_1 > n_2$.

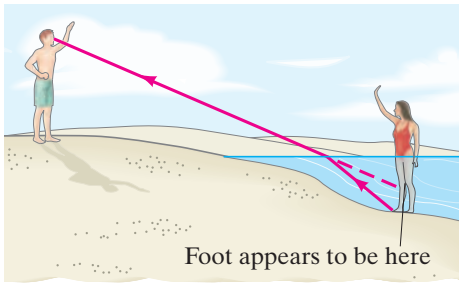


Figure 32–21a shows a ray passing from air into water. Angle $\theta_1$ is the angle the incident ray makes with the normal (perpendicular) to the surface and is called the **angle of incidence**. Angle $\theta_2$ is the **angle of refraction**, the angle the refracted ray makes with the normal to the surface. Notice that the ray bends toward the normal when entering the water. This is always the case when the ray enters a medium where the speed of light is *less* (and the index of refraction greater, Eq. 32–4). If light travels from one medium into a second where its speed is *greater*, the ray bends away from the normal; this is shown in Fig. 32–21b for a ray traveling from water to air.

**⚠ CAUTION**

*Angles of incidence and refraction are measured from the perpendicular, not from the surface*

(a)

(b)

**FIGURE 32–22** (a) Photograph, and (b) ray diagram showing why a person's legs look shorter standing in water: a ray from the bather's foot to the observer's eye bends at the water's surface, and our brain interprets the light as traveling in a straight line, from higher up (dashed line).

**FIGURE 32–23** A straw in water looks bent even when it isn't.

Refraction is responsible for optical illusions, such as a person standing in water appears to have shortened legs (Fig. 32–22). Rays leaving the person's foot are bent at the surface. The observer's brain assumes the rays to have traveled a straight-line path (dashed red line), and so the feet appear to be higher than they really are. Similarly, when you put a straw in water, it appears to be bent (Fig. 32–23). This also means that water is deeper than it appears.

## Snell's Law

We can write an equation that relates the angle of refraction to the angle of incidence at an interface (Fig. 32–21), and we might expect that it would depend on the speed of light in the two media. In about 1621, Willebrord Snell (1591–1626) found just such a relationship experimentally. Known as **Snell's law**, it is written:

*SNELL'S LAW (LAW OF REFRACTION)*

$$n_1 \sin\theta_1 = n_2 \sin\theta_2. \qquad \textbf{(32–5)}$$

$\theta_1$ is the angle of incidence and $\theta_2$ is the angle of refraction; $n_1$ and $n_2$ are the respective indices of refraction in the materials. See Fig. 32–21. The incident and refracted rays lie in the same plane, which also includes the perpendicular to the surface. Snell's law is the **law of refraction**. (Snell's law was derived in Section 15–10 for water waves where Eq. 15–19 is just a combination of Eqs. 32–5 and 32–4, and we derive it again in Chapter 34 using the wave theory of light.)

Snell's law shows that if $n_2 > n_1$, then $\theta_2 < \theta_1$. Thus, if light enters a medium where $n$ is greater (and its speed is less), the ray is bent toward the normal. And if $n_2 < n_1$, then $\theta_2 > \theta_1$, so the ray bends away from the normal. See Fig. 32–21.

**EXERCISE C** Light passes from a medium with $n = 1.3$ (water) into a medium with $n = 1.5$ (glass). Is the light bent toward or away from the perpendicular to the interface?

**EXAMPLE 32–8** **Refraction through flat glass.** Light traveling in air strikes a flat piece of uniformly thick glass at an incident angle of 60.0°, as shown in Fig. 32–24. If the index of refraction of the glass is 1.50, (*a*) what is the angle of refraction $\theta_A$ in the glass; (*b*) what is the angle $\theta_B$ at which the ray emerges from the glass?

**APPROACH** We apply Snell's law twice: at the first surface, where the light enters the glass, and again at the second surface where it leaves the glass and enters the air.

**SOLUTION** (*a*) The incident ray is in air, so $n_1 = 1.00$ and $n_2 = 1.50$. Applying Snell's law where the light enters the glass $(\theta_1 = 60.0°,\ \theta_2 = \theta_A)$ gives

$$(1.00)\sin 60.0° = (1.50)\sin\theta_A$$

or

$$\sin\theta_A = \frac{1.00}{1.50}\sin 60.0° = 0.5774,$$

so $\theta_A = 35.3°$.

(*b*) Since the faces of the glass are parallel, the incident angle at the second surface is also $\theta_A$ (geometry), so $\sin\theta_A = 0.5774$. At this second interface, $n_1 = 1.50$ and $n_2 = 1.00$. Thus the ray re-enters the air at an angle $\theta_B$ given by

$$\sin\theta_B = \frac{1.50}{1.00}\sin\theta_A = 0.866,$$

and $\theta_B = 60.0°$. The direction of a light ray is thus unchanged by passing through a flat piece of glass of uniform thickness.

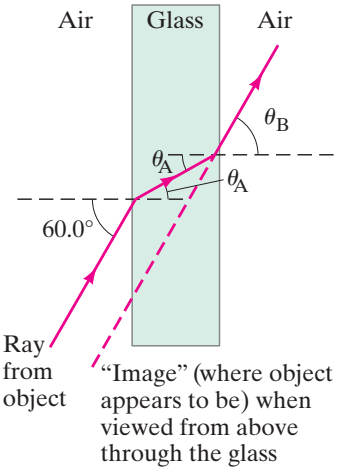

**FIGURE 32–24** Light passing through a piece of glass (Example 32–8).

**NOTE** This result is valid for any angle of incidence. The ray is displaced slightly to one side, however. You can observe this by looking through a piece of glass (near its edge) at some object and then moving your head to the side slightly so that you see the object directly. It "jumps."

**EXAMPLE 32–9** **Apparent depth of a pool.** A swimmer has dropped her goggles to the bottom of a pool at the shallow end, marked as 1.0 m deep. But the goggles don't appear to be that deep. Why? How deep do the goggles appear to be when you look straight down into the water?

**APPROACH** We draw a ray diagram showing two rays going upward at a small angle, heading toward your eye, from a point on the goggles on the bottom of the pool, and being refracted at the water's (flat) surface, Fig. 32–25. The two rays traveling upward from the goggles are refracted *away* from the normal as they exit the water, and so appear to be diverging from a point above the goggles (dashed lines), which is why the water appears to be less deep than it actually is. We are looking straight down, so all angles are small (but exaggerated in Fig. 32–25 for clarity).

**SOLUTION** To calculate the apparent depth $d'$ (Fig. 32–25), given a real depth $d = 1.0\,\text{m}$, we use Snell's law with $n_1 = 1.33$ for water and $n_2 = 1.0$ for air:

$$\sin\theta_2 = n_1 \sin\theta_1 .$$

We are considering only small angles, so $\sin\theta \approx \tan\theta \approx \theta$, with $\theta$ in radians. So Snell's law becomes

$$\theta_2 \approx n_1\theta_1 .$$

From Fig. 32–25, we see that $\theta_2 \approx \tan\theta_2 = x/d'$ and $\theta_1 \approx \tan\theta_1 = x/d$. Putting these into Snell's law, $\theta_2 \approx n_1\theta_1$, we get

$$\frac{x}{d'} \approx n_1 \frac{x}{d}$$

or

$$d' \approx \frac{d}{n_1} = \frac{1.0\,\text{m}}{1.33} = 0.75\,\text{m}.$$

The pool seems only three-fourths as deep as it actually is.

**NOTE** Water in general is deeper than it looks—a useful safety guideline.

**⚠ CAUTION (real life)**
*Water is deeper than it looks*

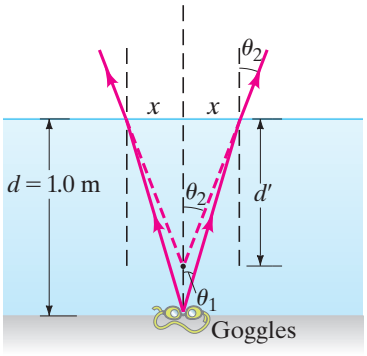

**FIGURE 32–25** Example 32–9. Objects under water appear to be less deep than they actually are.

# 32–8 The Visible Spectrum and Dispersion

Two important properties of light are intensity (or brightness) and color. The **intensity** of light is the energy it carries per unit area per unit time (see Eqs. 31–18 and 31–19). The **color** of light, as we shall discuss in Chapter 34, is related to the frequency $f$ or wavelength $\lambda$ of the light. (Recall $\lambda f = c = 3.0 \times 10^8\,\text{m/s}$, Eq. 31–14.) Visible light—that to which our eyes are sensitive—consists of frequencies from about $4 \times 10^{14}\,\text{Hz}$ to $7.5 \times 10^{14}\,\text{Hz}$, corresponding to wavelengths in air of about 400 nm to 700 nm.[†] This is the **visible spectrum**, and within it lie the different colors from violet to red, as shown in Fig. 32–26.

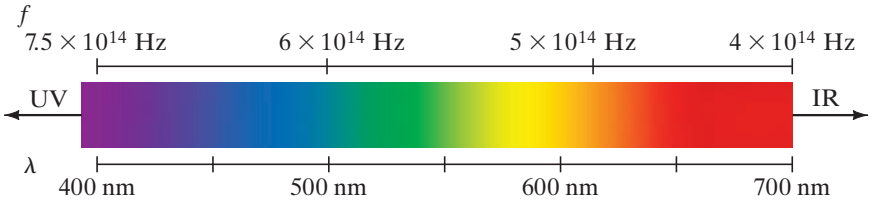

**FIGURE 32–26** The spectrum of visible light, showing the range of frequencies and wavelengths in air for the various colors. Many colors, such as brown, do not appear in the spectrum; they are made from a mixture of wavelengths.

Light with wavelength (in air) shorter than 400 nm (= violet) is called **ultraviolet** (UV), and light with wavelength longer than 700 nm (= red) is called **infrared** (IR).[‡] Although human eyes are not sensitive to UV or IR, some types of photographic film and detectors do respond to them.

[†]Sometimes the angstrom (Å) unit is used when referring to light: $1\,\text{Å} = 1 \times 10^{-10}\,\text{m}$. Visible light has wavelengths in air of 4000 Å to 7000 Å.

[‡]The complete electromagnetic spectrum is illustrated in Fig. 31–12.

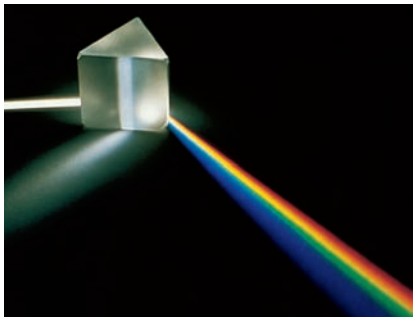

**FIGURE 32–27** White light passing through a prism is broken down into its constituent colors.

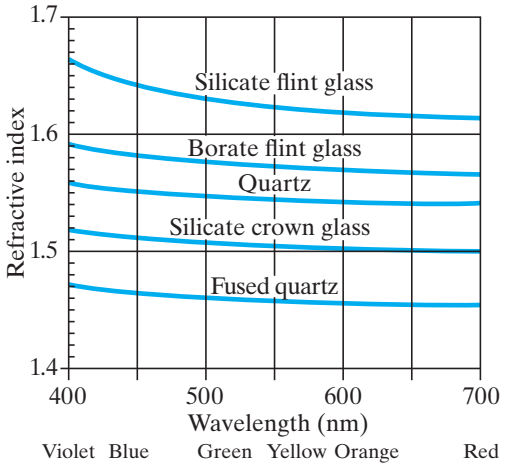

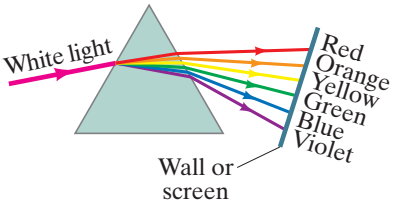

**FIGURE 32–28** Index of refraction as a function of wavelength for various transparent solids.

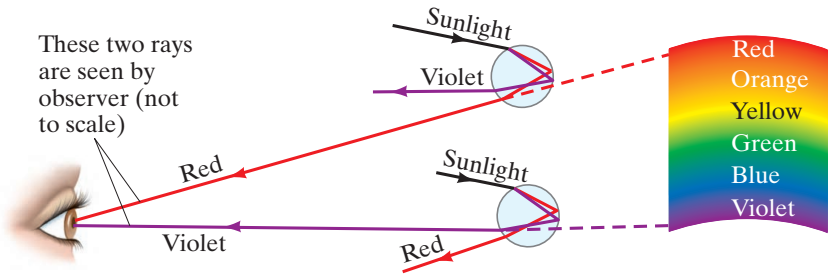
**FIGURE 32–29** White light dispersed by a prism into the visible spectrum.



**PHYSICS APPLIED**

*Rainbows*

A prism can separate white light into a rainbow of colors, as shown in Fig. 32–27. This happens when the index of refraction of a material depends on the wavelength, as shown for several materials in Fig. 32–28. **White light** from the Sun is a mixture of all visible wavelengths, and when incident on a prism, as in Fig. 32–29, the different wavelengths are bent to varying degrees. Because the index of refraction is greater for the shorter wavelengths, violet light is bent the most and red the least, as shown in Fig. 32–29. This spreading of white light into the full spectrum is called **dispersion**.

Rainbows are a spectacular example of dispersion—by drops of water. You can see rainbows when you look at falling water droplets (rain) with the Sun behind you. Figure 32–30 shows how red and violet rays are bent by spherical water droplets and are reflected off the back surface of the droplet. Red is bent the least and so reaches the observer's eyes from droplets higher in the sky, as shown in Fig. 32–30a. Thus the top of the rainbow is red.

**FIGURE 32–30** (a) Ray diagram explaining how a rainbow (b) is formed.

(a)

(b)

The visible spectrum, Fig. 32–26, does not show all the colors seen in nature. For example, there is no brown in Fig. 32–26. Many of the colors we see are a mixture of wavelengths. For practical purposes, most natural colors can be reproduced using three primary colors. They are red, green, and blue for direct source viewing such as TV and computer monitors. For inks used in printing, the primary colors are cyan (the blue color of the margin notes in this book), yellow, and magenta (the pinkish red color we use for light rays in ray diagrams).

For any wave, its velocity $v$ is related to its wavelength $\lambda$ and frequency $f$ by $v = f\lambda$ (Eq. 15–1 or 31–14). When a mechanical wave, such as sound, travels from one material into another, the frequency of the wave does not change across the boundary. The reason is that at the boundary, a point (an atom) is forced to oscillate at that frequency, and so do adjacent points (atoms) beyond the boundary as the wave continues to move.

In the same way, an EM wave does not change frequency when it crosses a boundary. Thus if light travels from air into a material with index of refraction $n$, the wavelength becomes (recall Eq. 32–4):

$$\lambda_n = \frac{v}{f} = \frac{c}{nf} = \frac{\lambda}{n} \qquad \textbf{(32–6)}$$

where $\lambda$ is the wavelength in vacuum or air and $\lambda_n$ is the wavelength in the material with index of refraction $n$.

**CONCEPTUAL EXAMPLE 32–10** **Observed color of light under water.** We said that color depends on wavelength. For example, for light of wavelength $\lambda_0 = 650\,\text{nm}$ in air, we see red. If we observe the same object when under water, it still looks red. But the wavelength in water $\lambda_w$ is (Eq. 32–6) $\lambda_w = \lambda_0/n_w = 650\,\text{nm}/1.33 = 489\,\text{nm}$. Light with wavelength 489 nm in air would appear blue in air. Can you explain why the light appears red rather than blue when observed under water?

**RESPONSE** Today we have little doubt that it is our brains that express colors, based on the frequencies of light that strike the receptor cells within the retina (at the rear of the eyeball, as diagrammed in the next Chapter, Fig. 33–25). For objects under water, the water does nothing to change the frequency, but does change the wavelength to $\lambda_0/n_w$. When that light enters the eye, the frequency is still unchanged, but the speed is changed to $c/n_{eye}$ where $n_{eye}$ is the index of refraction of the fluid that fills the interior of the eye and is in contact with the retina. The wavelength of light that reaches the retina is $\lambda_{eye} = \lambda_0/n_{eye}$, and is the same whether the light enters from the air or from water. Another way of saying this is that color depends on the *frequency* of the light, which does not change.

# 32–9 Total Internal Reflection; Fiber Optics

When light passes from one material into a second material where the index of refraction is less (say, from water into air), the refracted light ray bends away from the normal, as for rays I and J in Fig. 32–31. At a particular incident angle, the angle of refraction will be 90°, and the refracted ray would skim the surface (ray K). The incident angle at which this occurs is called the **critical angle**, $\theta_C$.

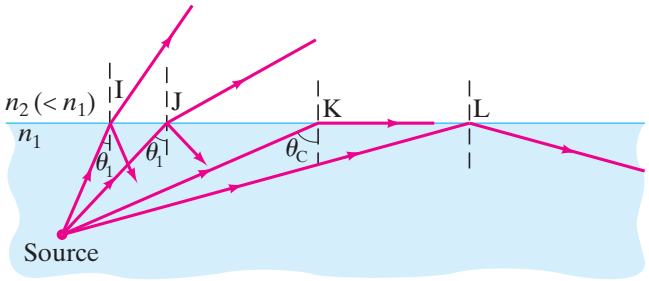


**FIGURE 32–31** Since $n_2 < n_1$, light rays are totally internally reflected if the incident angle $\theta_1 > \theta_C$, as for ray L. If $\theta_1 < \theta_C$, as for rays I and J, only a part of the light is reflected, and the rest is refracted.

From Snell's law, the critical angle $\theta_C$ is given by

$$\sin\theta_C = \frac{n_2}{n_1}\sin 90^\circ = \frac{n_2}{n_1}. \qquad \textbf{(32–7)}$$

For any incident angle less than $\theta_C$, there will be a refracted ray, although part of the light will also be reflected at the boundary. However, for incident angles $\theta_1$ greater than $\theta_C$, Snell's law would tell us that $\sin\theta_2$ $(= n_1 \sin\theta_1/n_2)$ would be greater than 1.00 when $n_2 < n_1$. Yet the sine of an angle can never be greater than 1.00. In this case there is no refracted ray at all, and *all of the light is reflected*, as for ray L in Fig. 32–31. This effect is called **total internal reflection**. Total internal reflection occurs only when light strikes a boundary where the medium beyond has a *lower* index of refraction.

**⚠ CAUTION**
*Total internal reflection (occurs only if refractive index is* smaller *beyond boundary)*

**CONCEPTUAL EXAMPLE 32–11** **View up from under water.** Describe what a person would see who looked up at the world from beneath the perfectly smooth surface of a lake or swimming pool.

**RESPONSE** For an air–water interface, the critical angle is given by

$$\sin\theta_C = \frac{1.00}{1.33} = 0.750.$$

Therefore, $\theta_C = 49°$. Thus the person would see the outside world compressed into a circle whose edge makes a 49° angle with the vertical. Beyond this angle, the person would see reflections from the sides and bottom of the lake or pool (Fig. 32–32).

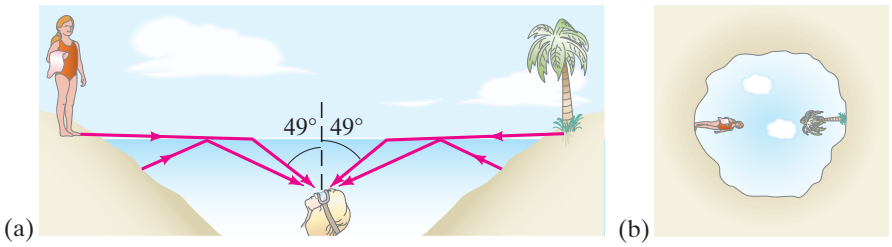

**FIGURE 32–32** (a) Light rays entering submerged person's eye, and (b) view looking upward from beneath the water (the surface of the water must be very smooth). Example 32–11.

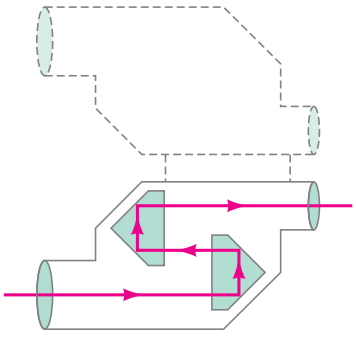
**EXERCISE D** Light traveling in air strikes a glass surface with $n = 1.48$. For what range of angles will total internal reflection occur?



**EXERCISE E** Fill a sink with water. Place a friend's waterproof watch just below the surface with the watch's flat crystal parallel to the water surface. From above you can still see the watch reading. As you move your head to one side far enough what do you see, and why?

Diamonds achieve their brilliance (Fig. 32–33) from a combination of dispersion and total internal reflection. Because diamonds have a very high index of refraction of about 2.4, the critical angle for total internal reflection is only 25°.

**FIGURE 32–33** Diamond.

**FIGURE 32–34** Total internal reflection of light by prisms in binoculars.

The light dispersed into a spectrum inside the diamond therefore strikes many of the internal surfaces of the diamond before it strikes one at less than 25° and emerges. After many such reflections, the light has traveled far enough that the colors have become sufficiently separated to be seen individually and brilliantly by the eye after leaving the diamond.

Many optical instruments, such as binoculars, use total internal reflection within a prism to reflect light. The advantage is that very nearly 100% of the light is reflected, whereas even the best mirrors reflect somewhat less. Thus the image is brighter, especially after several reflections. For glass with $n = 1.50$, $\theta_C = 41.8°$. Therefore, 45° prisms will reflect all the light internally, if oriented as shown in the binoculars of Fig. 32–34.

**EXERCISE F** What would happen if we immersed the 45° glass prisms in Fig. 32–34 in water?

## Fiber Optics; Medical Instruments

Total internal reflection is the principle behind **fiber optics**. Glass and plastic fibers as thin as a few micrometers in diameter are commonly used. A bundle of such slender transparent fibers is called a **light pipe** or **fiber-optic cable**. Light[†] can be transmitted along the fiber with almost no loss because of total internal reflection. Figure 32–35 shows how light traveling down a thin fiber makes only glancing collisions with the walls so that total internal reflection occurs. Even if the light pipe is bent gently into a complicated shape, the critical angle still won't be exceeded, so light is transmitted practically undiminished to the other end. Very small losses do occur, mainly by reflection at the ends and absorption within the fiber. The angles in Fig. 32–35 are very small in the thin fibers so the light travels nearly parallel to the walls; its speed is $c/n = c/1.5 \approx \frac{2}{3}c$ for glass fibers.[‡]

**FIGURE 32–35** Light reflected totally at the interior surface of a glass or transparent plastic fiber.

Important applications of fiber-optic cables are in communications and medicine. They are used in place of wire to carry telephone calls, video signals, and computer data. The signal is a modulated light beam (a light beam whose intensity can be varied—see Figs. 31–18 and 31–19) and data is transmitted at a much higher rate and with less loss and less interference than an electrical signal in a copper wire. Fibers have been developed that can support several hundred separate wavelengths, each modulated to carry more than 500 gigabits $(5\times10^{11}\text{ bits})$ of information per second. That amounts to more than 50 terabits $(5\times10^{13}\text{ bits})$ per second for one hundred wavelengths.

**PHYSICS APPLIED**

*Fiber optics in communications and medicine—bronchoscopes, colonoscopes, endoscopes*

The use of fiber optics to transmit a clear picture is particularly useful in medicine, Fig. 32–36. For example, a patient's lungs can be examined by inserting a fiber-optic cable known as a **bronchoscope** through the mouth and down the bronchial tube. Light is sent down an outer set of fibers to illuminate the lungs. The reflected light returns up a central core set of fibers. Light directly in front of each fiber travels up that fiber. At the opposite end, a viewer sees a series of bright and dark spots, much like a TV screen—that is, a picture of what lies at the opposite end. Lenses are used at each end of the cable. The image may be viewed directly or on a monitor screen or film. The fibers must be optically insulated from one another, usually by a thin coating of material with index of refraction less than that of the fiber. The more fibers there are, and the thinner they are, the more detailed the picture. Such instruments, including bronchoscopes, colonoscopes (for viewing the colon), and **endoscopes** (stomach or other organs), are extremely useful for examining hard-to-reach places.

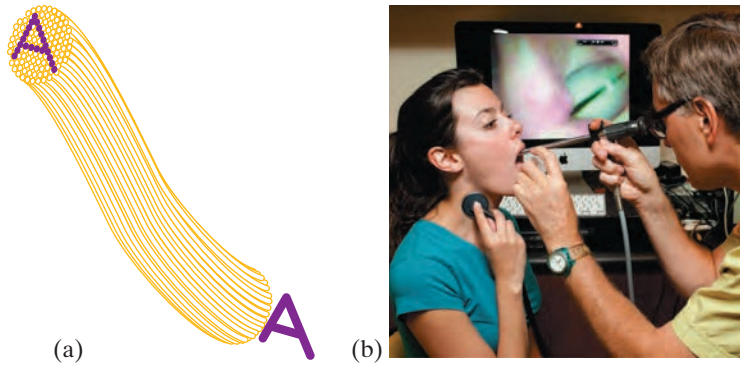


**FIGURE 32–36** (a) How a fiber-optic image is made. (b) Example of a fiber-optic device inserted through the mouth to view the vocal cords, with image on screen.

[†]Fiber-optic devices use not only visible light but also infrared light, ultraviolet light, and microwaves.

[‡]A few years back, some Wall Street "traders" made money utilizing the finite speed of light, $\approx \frac{2}{3}c \approx 200\text{ km}$ per millisecond (ms). Actual transactions took place some distance from New York City. By intercepting large stock orders before they arrived, these techies could make their own orders that took advantage of their foreknowledge. It was "high-frequency trading."

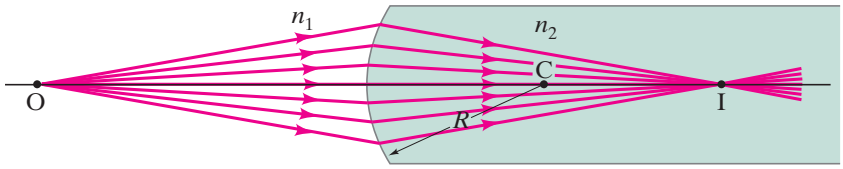

**FIGURE 32–37** Rays from a point O on an object will be focused at a single image point I by a spherical boundary between two transparent materials $(n_2 > n_1)$, as long as the rays make small angles with the axis.

## *32–10 Refraction at a Spherical Surface

We now examine the refraction of rays at the spherical surface of a transparent material. Such a surface could be one face of a lens or the cornea of the eye. To be general, let us consider an object which is located in a medium whose index of refraction is $n_1$ (it may or may not be air), and rays from each point on the object can enter a medium whose index of refraction is $n_2$. The radius of curvature of the spherical boundary is $R$, and its center of curvature is at point C, Fig. 32–37. We now show that all rays leaving a point O on the object will be focused at a single point I, the image point, if we consider only *paraxial* rays: rays that make a small angle with the axis. To do so, we consider a single ray that leaves point O as shown in Fig. 32–38, and reaches the spherical surface at point P.

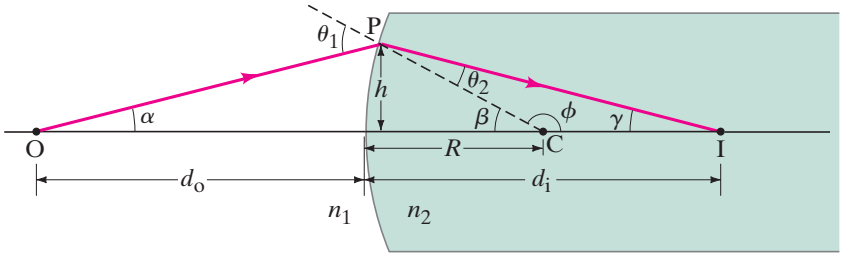

**FIGURE 32–38** Diagram for showing that all paraxial rays from O focus at the same point I $(n_2 > n_1)$.

From Snell's law, Eq. 32–5, we have

$$n_1 \sin\theta_1 = n_2 \sin\theta_2.$$

We are assuming that angles $\theta_1$, $\theta_2$, $\alpha$, $\beta$, and $\gamma$ are small, so $\sin\theta \approx \theta$ (in radians), and Snell's law becomes, approximately,

$$n_1\theta_1 = n_2\theta_2.$$

Also, $\beta + \phi = 180°$ and $\theta_2 + \gamma + \phi = 180°$, so

$$\beta = \gamma + \theta_2,$$

or

$$\theta_2 = \beta - \gamma.$$

Similarly for triangle OPC,

$$\theta_1 = \alpha + \beta.$$

The $\theta_1$ and $\theta_2$ in these last two equations can be substituted into $n_1\theta_1 = n_2\theta_2$ to yield

$$n_1\alpha + n_2\gamma = (n_2 - n_1)\beta.$$

Since we are considering only the case of small angles, we can write, approximately,

$$\alpha = \frac{h}{d_o}, \qquad \beta = \frac{h}{R}, \qquad \gamma = \frac{h}{d_i},$$

where $d_o$ and $d_i$ are the object and image distances and $h$ is the height as shown in Fig. 32–38. We substitute these into the previous equation, divide through

by $h$, and obtain

$$\frac{n_1}{d_o} + \frac{n_2}{d_i} = \frac{n_2 - n_1}{R}. \qquad \textbf{(32–8)}$$

For a given object distance $d_o$, this equation tells us $d_i$, the image distance, does not depend on the angle of a ray. Hence all paraxial rays meet at the same point I (within the accuracy of the approximation $\sin\theta \approx \theta$). This is true only for rays that make small angles with the axis and with each other, and is equivalent to assuming that the width of the refracting spherical surface is small compared to its radius of curvature. If this assumption is not true, the rays will not converge to a point; there will be spherical aberration, just as there is for a mirror (see Fig. 32–13), and the image will be blurry. (Spherical aberration will be discussed further in Section 33–10.)

We derived Eq. 32–8 using Fig. 32–38 for which the spherical surface is convex (as viewed by the incoming ray). It is also valid for a concave surface—as can be seen using Fig. 32–39—if we use the following sign conventions:

1. If the surface is convex (so the center of curvature C is on the side of the surface opposite to that from which the light comes), $R$ is positive. If the surface is concave (C on the same side from which the light comes), $R$ is negative.
2. The image distance, $d_i$, follows the same convention: positive if on the opposite side from where the light comes, negative if on the same side.
3. The object distance is positive if on the same side from which the light comes (this is the normal case, although when several surfaces bend the light it may not be so); otherwise it is negative.

For the case shown in Fig. 32–39 with a concave surface, both $R$ and $d_i$ are negative when used in Eq. 32–8. Note, in this case, that the image is virtual.

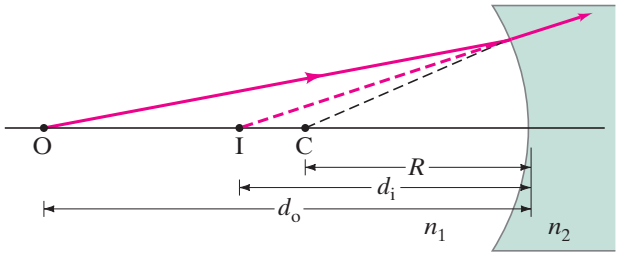

**FIGURE 32–39** Rays from O refracted by a concave surface form a virtual image $(n_2 > n_1)$. Per our conventions, $R < 0$, $d_i < 0$, $d_o > 0$.

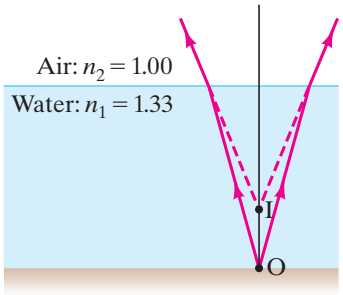
**EXAMPLE 32–12 Apparent depth II.** A person looks vertically down into a 1.0-m-deep pool. How deep does the water appear to be?



**APPROACH** Example 32–9 solved this problem using Snell's law. Here we use Eq. 32–8.

**SOLUTION** A ray diagram is shown in Fig. 32–40. Point O represents a point on the pool's bottom. The rays diverge and appear to come from point I, the image. We have $d_o = 1.0\,\text{m}$ and, for a flat surface, $R = \infty$. Then Eq. 32–8 becomes

$$\frac{1.33}{1.0\,\text{m}} + \frac{1.00}{d_i} = \frac{(1.00 - 1.33)}{\infty} = 0.$$

Hence $d_i = -(1.0\,\text{m})/(1.33) = -0.75\,\text{m}$. So the pool appears to be only three-fourths as deep as it actually is, the same result we found in Example 32–9. The minus sign tells us the image point I is on the same side of the surface as O, and the image is virtual. At angles other than vertical, this conclusion must be modified.

**FIGURE 32–40** Example 32–12.

**EXAMPLE 32–13** **A spherical "lens."** A point source of light is placed at a distance of 25.0 cm from the center of a glass sphere $(n = 1.5)$ of radius 10.0 cm, Fig. 32–41. Find the image of the source (= object).

**APPROACH** As shown in Fig. 32–41, there are two refractions, and we treat them successively, one at a time. The light rays from the source first refract from the convex glass surface facing the source. We analyze this first refraction, treating it as in Fig. 32–37, ignoring the back side of the sphere. Then we treat the back surface, using the first image as the object for the second surface. To use Eq. 32–8 we need to consider only paraxial rays, so we need to block light from entering too high or too low into the sphere (the vertical brown lines).

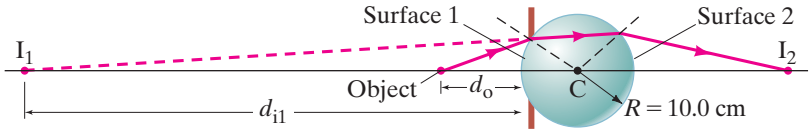


**FIGURE 32–41** Example 32–13.

**SOLUTION** Using Eq. 32–8 (assuming paraxial rays) with $n_1 = 1.0$, $n_2 = 1.5$, $R = 10.0$ cm, and $d_o = 25.0\text{ cm} - 10.0\text{ cm} = 15.0$ cm, we solve for the image distance as formed at surface 1, $d_{i1}$:

$$\frac{1}{d_{i1}} = \frac{1}{n_2}\left(\frac{(n_2 - n_1)}{R} - \frac{n_1}{d_o}\right) = \frac{1}{1.5}\left(\frac{1.5 - 1.0}{10.0\text{ cm}} - \frac{1.0}{15.0\text{ cm}}\right) = -\frac{1}{90.0\text{ cm}}.$$

Thus, the image $I_1$ of the first refraction is located 90.0 cm *to the left* of the front surface, and is virtual. This image $(I_1)$ now serves as the "object" for the refraction occurring at the back surface (surface 2) of the sphere. This surface is concave so $R = -10.0$ cm, and we consider a ray close to the axis. Then the object distance (from surface 2) is $d_{o2} = 90.0\text{ cm} + 2(10.0\text{ cm}) = 110.0$ cm, and Eq. 32–8 yields, with $n_1 = 1.5$, $n_2 = 1.0$,

$$\frac{1}{d_{i2}} = \frac{1}{1.0}\left(\frac{1.0 - 1.5}{-10.0\text{ cm}} - \frac{1.5}{110.0\text{ cm}}\right) = \frac{4.0}{110.0\text{ cm}}$$

so $d_{i2} = 110.0\text{ cm}/4.0 \approx 28$ cm. Thus, the final image is located a distance 28 cm from the back side of the sphere, or 38 cm from the center of the sphere.

# Summary

Light appears to travel along straight-line paths, called **rays**, through uniform transparent materials including air and glass. When light reflects from a flat surface, the *angle of reflection equals the angle of incidence*. This **law of reflection** explains why mirrors can form **images**.

In a **plane mirror**, the image is virtual, upright, the same size as the object, and located as far behind the mirror as the object is in front.

A **spherical mirror** can be concave or convex. A **concave** spherical mirror focuses parallel rays of light (light from a very distant object) to a point called the **focal point**. The distance of this point from the mirror is the **focal length** $f$ of the mirror and

$$f = \frac{r}{2} \qquad \textbf{(32–1)}$$

where $r$ is the radius of curvature of the mirror.

Parallel rays falling on a **convex mirror** reflect from the mirror as if they diverged from a common point behind the mirror. The distance of this point from the mirror is the focal length and is considered negative for a convex mirror.

For a given object, the approximate position and size of the image formed by a mirror can be found by ray tracing. More precisely, the relation between image and object distances, $d_i$ and $d_o$, and the focal length $f$, is given by the **mirror equation**:

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}. \qquad \textbf{(32–2)}$$

The ratio of image height $h_i$ to object height $h_o$, which equals the lateral magnification $m$ of a spherical mirror, is

$$m = \frac{h_i}{h_o} = -\frac{d_i}{d_o}. \qquad \textbf{(32–3)}$$

If the rays that converge to form an image actually pass through the image, so the image would appear on a screen or film placed there, the image is said to be a **real image**. If the light rays do not actually pass through the image, the image is a **virtual image**.

The speed of light $v$ depends on the **index of refraction**, $n$, of the material:

$$n = \frac{c}{v}, \qquad \textbf{(32–4)}$$

where $c$ is the speed of light in vacuum.

When light passes from one transparent medium into another, the rays bend or refract. The **law of refraction** (**Snell's law**) states that

$$n_1 \sin\theta_1 = n_2 \sin\theta_2, \qquad \textbf{(32–5)}$$

where $n_1$ and $\theta_1$ are the index of refraction and angle with the normal (perpendicular) to the surface for the incident ray, and $n_2$ and $\theta_2$ are for the refracted ray.

When light of wavelength $\lambda$ enters a medium with index of refraction $n$, the wavelength is reduced to

$$\lambda_n = \frac{\lambda}{n}. \qquad \textbf{(32–6)}$$

The frequency does not change.

The frequency or wavelength of light determines its color. The **visible spectrum** in air extends from about 400 nm (violet) to about 750 nm (red).

Glass prisms spread white light out into its constituent colors because the index of refraction varies with wavelength, a phenomenon known as **dispersion**.

When light rays reach the boundary of a material where the index of refraction decreases, the rays will be **totally internally reflected** if the incident angle, $\theta_1$, is such that Snell's law would predict $\sin\theta_2 > 1$. This occurs if $\theta_1$ exceeds the critical angle $\theta_C$ given by

$$\sin\theta_C = \frac{n_2}{n_1}. \qquad \textbf{(32–7)}$$

# Questions

1. What would be the appearance of the Moon if it had (*a*) a rough surface; (*b*) a polished mirrorlike surface?
2. Archimedes is said to have burned the whole Roman fleet in the harbor of Syracuse, Italy, by focusing the rays of the Sun with a huge spherical mirror. Is this[†] reasonable?
3. What is the focal length of a plane mirror? What is the magnification of a plane mirror?
4. An object is placed along the principal axis of a spherical mirror. The magnification of the object is −3.0. Is the image real or virtual, inverted or upright? Is the mirror concave or convex? On which side of the mirror is the image located?
5. Using the rules for the three rays discussed with reference to Fig. 32–15, draw ray 2 for Fig. 32–19b.
6. Does the mirror equation, Eq. 32–2, hold for a plane mirror? Explain.
7. If a concave mirror produces a real image, is the image necessarily inverted?
8. How might you determine the speed of light in a solid, rectangular, transparent object?
9. When you look at the Moon's reflection from a ripply sea, it appears elongated (Fig. 32–42). Explain.
10. How can you "see" a round drop of water on a table even though the water is transparent and colorless?
11. What is the angle of refraction when a light ray is incident perpendicular to the boundary between two transparent materials?
12. When you look down into a swimming pool or a lake, are you likely to overestimate or underestimate its depth? Explain. How does the apparent depth vary with the viewing angle? (Use ray diagrams.)
13. Draw a ray diagram to show why a stick or straw looks bent when part of it is under water (Fig. 32–23).
14. Although a plane mirror appears to reverse left and right, it doesn't reverse up and down. Discuss why this happens, noting that front to back is also reversed. Also discuss what happens if, while standing, you look up vertically at a horizontal mirror on the ceiling.
15. When a wide beam of parallel light enters water at an angle, the beam broadens. Explain.
16. You look into an aquarium and view a fish inside. One ray of light from the fish as it exits the tank is shown in Fig. 32–43. The apparent position of the fish is also shown. In the drawing, indicate the approximate position of the *actual* fish. Briefly justify your answer.

**FIGURE 32–42**
Question 9.

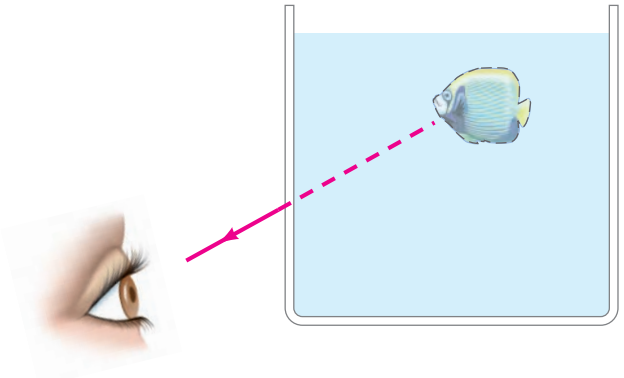

**FIGURE 32–43** Question 16.

[†]Students at MIT did a feasibility study. See web.mit.edu/2.009/www/experiments/deathray/10_ArchimedesResult.html.

17. A child looks into a pool to see how deep it is. She then drops a small toy into the pool to help decide how deep the pool is. After this careful investigation, she decides it is safe to jump in—only to discover the water is over her head. What went wrong with her interpretation of her experiment?

18. What type of mirror is shown in Fig. 32–44? Explain.

**FIGURE 32–44** Question 18 and Problem 15.

19. Can a light ray traveling in air be totally reflected when it strikes a smooth water surface if the incident angle is chosen correctly? Explain.

20. When you look up at an object in air from beneath the surface in a swimming pool, does the object appear to be the same size as when you see it directly in air? Explain. (See Fig. 32–32.)

21. Light rays from stars (including our Sun) always bend toward the vertical direction as they pass through the Earth's atmosphere. (*a*) Why does this make sense? (*b*) What can you conclude about the apparent positions of stars as viewed from Earth?

## MisConceptual Questions

1. Suppose you are standing about 3 m in front of a mirror. You can see yourself just from the top of your head to your waist, where the bottom of the mirror cuts off the rest of your image. If you walk one step closer to the mirror
   (*a*) you will not be able to see any more of your image.
   (*b*) you will be able to see more of your image, below your waist.
   (*c*) you will see less of your image, with the cutoff rising to be above your waist.

2. When light traveling in air enters water at an angle,
   (*a*) it changes direction by bending away from the surface.
   (*b*) it slows down.
   (*c*) its wavelength changes.
   (*d*) Statements (*a*) and (*b*) are true but (*c*) is not.
   (*e*) Statements (*a*), (*b*), and (*c*) are all true.
   (*f*) None of these statements is true.

3. If you want to see yourself full-length in a mirror, what must be the *minimum* size of the mirror? (Try it and see to be sure.)
   (*a*) Your full height and body width.
   (*b*) Your full height and twice your body width.
   (*c*) Half of your height and half body width.
   (*d*) Half of your height and twice your body width.
   (*e*) It depends on how far from the mirror you stand.

4. You want to create a spotlight that will shine a bright beam of light with all of the light rays parallel to each other. You have a large concave spherical mirror and a small lightbulb. Where should you place the lightbulb?
   (*a*) At the focal point of the mirror.
   (*b*) At the radius of curvature of the mirror.
   (*c*) At any point, because all rays bouncing off the mirror will be parallel.
   (*d*) None of the above; you can't make parallel rays with a concave mirror.

5. Which of the following statements about the focal point of a concave spherical mirror is true?
   (*a*) Parallel rays incident on the mirror are reflected through the focal point.
   (*b*) The image produced by the mirror is at the focal point.
   (*c*) The location of the focal point depends on where the object is located.
   (*d*) None of the above.

6. When you look at a fish in a still stream from the bank, the fish appears shallower than it really is due to refraction. From directly above, it appears
   (*a*) deeper than it really is.
   (*b*) at its actual depth.
   (*c*) shallower than its real depth.
   (*d*) It depends on your height above the water.

7. Images are
   (*a*) always smaller than the object.
   (*b*) always inverted relative to the object.
   (*c*) always at the point where light rays from a point object would cross.
   (*d*) always the same size as the object.
   (*e*) None of the above.

8. If you shine a light through an optical fiber, why does it come out the end but not out the sides?
   (*a*) It does come out the sides, but this effect is not obvious because the sides are so much longer than the ends.
   (*b*) The sides are mirrored, so the light reflects.
   (*c*) Total internal reflection makes the light reflect from the sides.
   (*d*) The light flows along the length of the fiber, never touching the sides.

9. When moonlight strikes the surface of a calm lake, what happens to this light?
   (*a*) All of it reflects from the water surface back to the air.
   (*b*) Some of it reflects back to the air; some enters the water.
   (*c*) All of it enters the water.
   (*d*) All of it disappears via absorption by water molecules.

**10.** The colors in a rainbow are caused by
(*a*) the interaction of the light reflected from different raindrops.
(*b*) different amounts of absorption for light of different colors by the water in the raindrops.
(*c*) different amounts of refraction for light of different colors by the water in the raindrops.
(*d*) the downward motion of the raindrops.

**11.** An observer directly above two closely spaced lines on paper, views them through an angled piece of glass, Fig. 32–45. To the observer, the lines appear
(*a*) shifted to the right.
(*b*) shifted to the left.
(*c*) spaced farther apart.
(*d*) spaced closer together.
(*e*) the same as if the glass were not there.

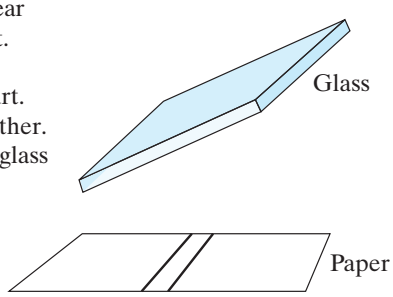

**FIGURE 32–45**
MisConceptual Question 11.

**12.** To shoot a swimming fish with an intense light beam from a *laser gun*, you should aim
(*a*) directly at the image.
(*b*) slightly above the image.
(*c*) slightly below the image.

**13.** Parallel light rays cross interfaces from medium 1 into medium 2 and then into medium 3 as shown in Fig. 32–46. What can we say about the relative sizes of the indices of refraction of these media?
(*a*) $n_1 > n_2 > n_3$.
(*b*) $n_3 > n_2 > n_1$.
(*c*) $n_2 > n_3 > n_1$.
(*d*) $n_1 > n_3 > n_2$.
(*e*) $n_2 > n_1 > n_3$.
(*f*) None of the above.

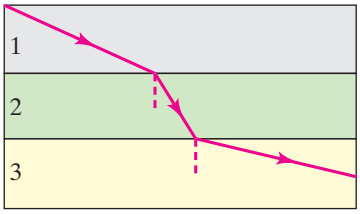

**FIGURE 32–46**
MisConceptual Question 13.

# Problems

## 32–2 Reflection; Plane Mirrors

**1.** (I) When you look at yourself in a 60-cm-tall plane mirror, you see the same amount of your body whether you are close to the mirror or far away. (Try it and see.) Use ray diagrams to show why this should be true.

**2.** (I) Suppose that you want to take a photograph of yourself as you look at your image in a mirror 2.4 m away. For what distance should the camera lens be focused?

**3.** (II) Two plane mirrors meet at a 135° angle, Fig. 32–47. If light rays strike one mirror at 32° as shown, at what angle $\phi$ do they leave the second mirror?

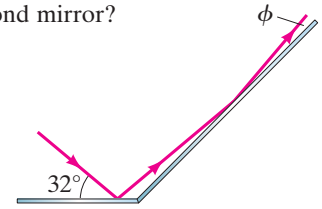

**FIGURE 32–47**
Problem 3.

**4.** (II) A person whose eyes are 1.64 m above the floor stands 2.60 m in front of a vertical plane mirror whose bottom edge is 38 cm above the floor, Fig. 32–48. What is the horizontal distance $x$, from the base of the wall supporting the mirror to the nearest point on the floor that can be seen reflected in the mirror?

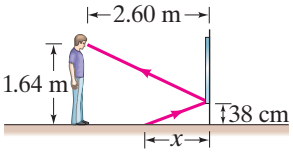

**FIGURE 32–48**
Problem 4.

**5.** (II) Show that if two plane mirrors meet at an angle $\phi$, a single ray reflected successively from both mirrors is deflected through an angle of $2\phi$ independent of the incident angle. Assume $\phi < 90°$ and that *only* two reflections, one from each mirror, take place.

**6.** (II) (*a*) Use a ray diagram, as we did in Example 32–3, to show that this Chapter's opening photograph, page 926, cannot be right-side up considering the position of the Sun. (*b*) Confirm this result by using ray diagrams involving the people shown.

**7.** (II) Suppose you are 96 cm from a plane mirror. What area of the mirror is used to reflect the rays entering one eye from a point on the tip of your nose if your pupil diameter is 4.5 mm?

**8.** (II) Stand up two plane mirrors so they form a 90.0° angle as in Fig. 32–49. When you look into this double mirror, you see yourself as others see you, instead of reversed as in a single mirror. Make a ray diagram to show how this occurs.

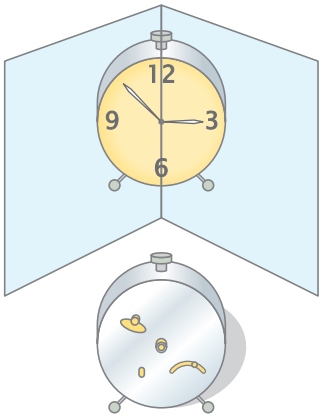

**FIGURE 32–49**
Problems 8 and 9.

**9.** (III) Suppose a third mirror is placed beneath the two shown in Fig. 32–49, so that all three are perpendicular to each other. (*a*) Show that for such a "corner reflector," any incident ray will return in its original direction after three reflections. (*b*) What happens if it makes only two reflections?

## 32–3 to 32–5 Spherical Mirrors

**10.** (I) A solar cooker, really a concave mirror pointed at the Sun, focuses the Sun's rays 17.2 cm in front of the mirror. What is the radius of the spherical surface from which the mirror was made?

**11.** (I) How far from a concave mirror (radius 30.0 cm) must an object be placed if its image is to be at infinity?

**12.** (II) The lateral magnification of a convex mirror is +0.75 for objects 3.2 m from the mirror. What is the focal length of this mirror?

**13.** (II) A small candle is 41 cm from a concave mirror having a radius of curvature of 24 cm. (*a*) What is the focal length of the mirror? (*b*) Where will the image of the candle be located? (*c*) Will the image be upright or inverted?

**14.** (II) You look at yourself in a shiny 8.4-cm-diameter Christmas tree ball. If your face is 25.0 cm away from the ball's front surface, where is your image? Is it real or virtual? Is it upright or inverted?

**15.** (II) A mirror at an amusement park shows an upright image of any person who stands 2.1 m in front of it. If the image height is three times the person's height, what is the radius of curvature of the mirror? (See Fig. 32–44.)

**16.** (II) A dentist wants a small mirror that, when 2.00 cm from a tooth, will produce a 3.0× upright image. What kind of mirror must be used and what must its radius of curvature be?

**17.** (II) A 4.2-cm-tall object is placed 26 cm in front of a spherical mirror. It is desired to produce a virtual image that is upright and 3.2 cm tall. (*a*) What type of mirror should be used? (*b*) Where is the image located? (*c*) What is the focal length of the mirror? (*d*) What is the radius of curvature of the mirror?

**18.** (II) You are standing 2.7 m from a convex security mirror in a store. You estimate the height of your image to be half what it would be in a plane mirror at the same place. Estimate the radius of curvature of the mirror.

**19.** (II) An object 4.0 mm high is placed 18 cm from a convex mirror of radius of curvature 18 cm. (*a*) Show by ray tracing that the image is virtual, and estimate the image distance. (*b*) Show that the (negative) image distance can be computed from Eq. 32–2 using a focal length of −9.0 cm. (*c*) Compute the image size, using Eq. 32–3.

**20.** (II) The image of a distant tree is virtual, very small, and 13.0 cm behind a curved mirror. What kind of mirror is it, and what is its radius of curvature?

**21.** (II) Use two techniques, (*a*) a ray diagram, and (*b*) the mirror equation, to show that the magnitude of the lateral magnification of a concave mirror is less than 1 if the object is beyond the center of curvature C $(d_o > r)$, and is greater than 1 if the object is within C $(d_o < r)$.

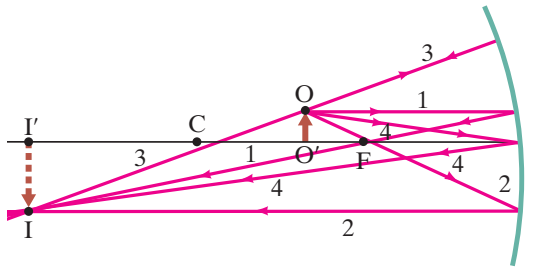
**22.** (II) Show, using a ray diagram, that the lateral magnification $m$ of a convex mirror is $m = -d_i/d_o$, just as for a concave mirror. [*Hint*: Consider a ray from the top of the object that reflects at the center of the mirror.]

**23.** (II) Use ray diagrams to show that the mirror equation, Eq. 32–2, is valid for a convex mirror as long as $f$ is considered negative.

**24.** (II) In Example 32–4, show that if the object is moved 10.0 cm farther from the concave mirror, the object's image size will equal the object's actual size. Stated as a multiple of the focal length, what is the object distance for this "actual-sized image" situation?

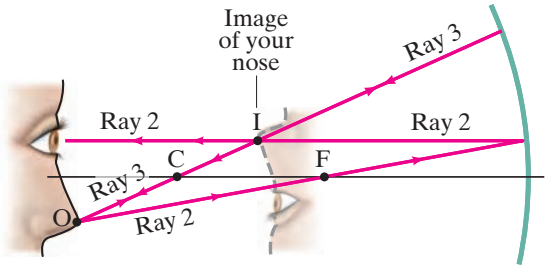
**25.** (II) (*a*) Where should an object be placed in front of a concave mirror so that it produces an image at the same location as the object? (*b*) Is the image real or virtual? (*c*) Is the image inverted or upright? (*d*) What is the lateral magnification of the image?

**26.** (II) Let the focal length of a convex mirror be written as $f = -|f|$. Show that the lateral magnification $m$ of an object a distance $d_o$ from this mirror is given by $m = |f|/(d_o + |f|)$. Based on this relation, explain why your nose looks bigger than the rest of your face when looking into a convex mirror.



**27.** (II) A spherical mirror of focal length $f$ produces an image of an object with lateral magnification $m$. (*a*) Show that the object is a distance $d_o = f\left(1 - \frac{1}{m}\right)$ from the reflecting side of the mirror. (*b*) Use the relation in part (*a*) to show that, no matter where an object is placed in front of a convex mirror, its image will have a lateral magnification in the range $0 \le m \le +1$.

**28.** (II) A concave mirror has focal length $f$. When an object is placed a distance $d_o > f$ from this mirror, a real image with lateral magnification $m$ is formed. (*a*) Show that $m = f/(f - d_o)$. (*b*) Sketch $m$ vs. $d_o$ over the range $f < d_o < +\infty$ where $f = 0.45$ m. (*c*) For what value of $d_o$ will the real image have the same size as the object? (*d*) To obtain a real image that is much larger than the object, in what general region should the object be placed relative to the mirror?



**29.** (II) When walking toward a concave mirror you notice that your image flips at a distance of 0.80 m from the mirror. What is the radius of curvature of the mirror? [*Hint*: Carefully examine Section 32–4.]

**30.** (II) A shaving or makeup mirror is designed to magnify your face by a factor of 1.8 (when compared to a flat mirror) when your face is placed 20.0 cm in front of it. (*a*) What type of mirror is it? (*b*) Describe the type of image that it makes of your face. (*c*) Calculate the required radius of curvature for the mirror.

**31.** (III) Two ray diagrams involving a concave mirror are shown in Figs. 32–50a and b. (*a*) and (*b*): you are looking into the mirror. The object is OO′, which includes your eye O and maybe a point on your nose, O′. Describe the situation for each diagram, where the image is, and what you see. In part (*a*), explain why what you actually see—a blurry image—is not inverted as shown. In part (*b*) note that rays moving left from I toward your eye are *diverging* so make a sharp image. (*c*) In Fig. 32–50a, suppose the object OO′, is *not* you, but is some ordinary object, such as an arrow, and your eye is on the far left, beyond the image I I′ so diverging rays enter your eye. Describe what you see in the mirror in detail and any other pertinent details.

(a)

(b)

**FIGURE 32–50** Problem 31.

**32.** (III) An object is placed a distance $r$ in front of a wall, where $r$ exactly equals the radius of curvature of a certain concave mirror. At what distance from the wall should this mirror be placed so that a real image of the object is formed on the wall? What is the lateral magnification of the image?

**33.** (III) A short thin object (like a short length of wire) of length $\ell$ is placed along the axis of a spherical mirror (perpendicular to the glass surface). Show that its image has length $\ell' = m^2\ell$ so the **longitudinal magnification** is equal to $-m^2$ where $m$ is the normal "lateral" magnification, Eq. 32–3. Why the minus sign? [*Hint*: Find the image positions for both ends of the wire, and assume $\ell$ is very small.]

## 32–6 Index of Refraction

**34.** (I) The speed of light in ice is $2.29 \times 10^8$ m/s. What is the index of refraction of ice?

**35.** (I) What is the speed of light in (*a*) ethyl alcohol, (*b*) lucite, (*c*) crown glass?

**36.** (II) The speed of light in a certain substance is 78% of its value in water. What is the index of refraction of that substance?

## 32–7 Refraction: Snell's Law

**37.** (I) A diver shines a narrow flashlight beam upward from beneath the water at a 32.8° angle to the vertical. At what angle does the light leave the water?

**38.** (I) A flashlight beam strikes the surface of a pane of glass ($n = 1.56$) at a 69° angle to the normal. What is the angle of refraction?

**39.** (I) Rays of the Sun are seen to make a 38.0° angle to the vertical beneath the water. At what angle above the horizon is the Sun?

**40.** (I) A light beam coming from an underwater spotlight exits the water at an angle of refraction equal to 52.0°. At what angle of incidence did it hit the air-water interface from below the surface?

**41.** (II) A beam of light in air strikes a slab of glass ($n = 1.62$) and is partially reflected and partially refracted. Determine the angle of incidence if the angle of reflection is twice the angle of refraction.

**42.** (II) A light beam strikes a 2.5-cm-thick piece of plastic with a refractive index of 1.62 at a 45° angle. The plastic is on top of a 3.8-cm-thick piece of glass for which $n = 1.47$. What is the distance $D$ in Fig. 32–51?

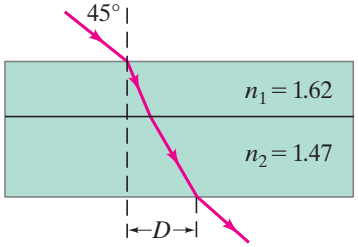


**FIGURE 32–51**
Problem 42.

**43.** (II) An aquarium filled with water has flat glass sides whose index of refraction is 1.51. A beam of light from outside the aquarium strikes the glass at a 43.5° angle to the perpendicular (Fig. 32–52). What is the angle of this light ray when it enters (*a*) the glass, and then (*b*) the water? (*c*) What would be the refracted angle if the ray entered the water directly?

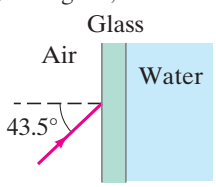

**FIGURE 32–52**
Problem 43.

**44.** (II) In searching the bottom of a pool at night, a watchman shines a narrow beam of light from his flashlight, 1.3 m above the water level, onto the surface of the water at a point 2.8 m from his foot at the edge of the pool (Fig. 32–53). Where does the spot of light hit the bottom of the pool which is 2.1 m deep? Measure from the bottom of the wall beneath his foot.

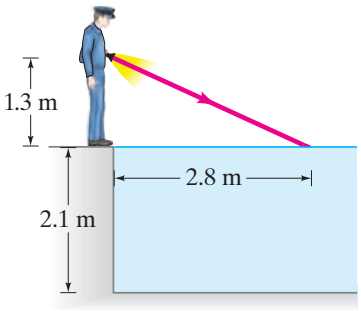

**FIGURE 32–53**
Problem 44.

**45.** (II) The block of glass ($n = 1.5$) shown in cross section in Fig. 32–54 is surrounded by air. A ray of light enters the block at its left-hand face with incident angle $\theta_1$ and reemerges into the air from the right-hand face directed parallel to the block's base. Determine $\theta_1$.

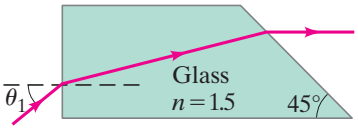

**FIGURE 32–54** Problem 45.

**46.** (II) A laser beam of circular cross-section has diameter $d_1 = 3.0$ mm. It strikes a flat air–glass surface at an incident angle $\theta_1 = 22°$. The refracted beam in the glass ($n = 1.50$) is oval. Determine the length and width of the oval laser beam in the glass.

**47.** (II) A light ray is incident on an equilateral glass prism at a 45.0° angle to one face, Fig. 32–55. Calculate the angle at which the light ray emerges from the opposite face. Assume that $n = 1.58$.

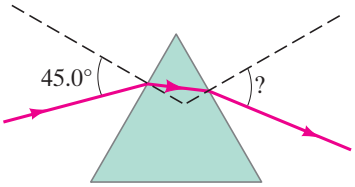

**FIGURE 32–55** Problems 47 and 61.

**48.** (II) Show in general that for a light beam incident on a uniform layer of transparent material, as in Fig. 32–24, the direction of the emerging beam is parallel to the incident beam, independent of the incident angle $\theta$. Assume the air on the two sides of the transparent material is the same.

**49.** (III) A light ray is incident on a flat piece of glass with index of refraction $n$ as in Fig. 32–24. Show that if the incident angle $\theta$ is small, the emerging ray is displaced a distance $d = t\theta(n-1)/n$, where $t$ is the thickness of the glass, $\theta$ is in radians, and $d$ is the perpendicular distance between the incident ray and the (dashed) line of the emerging ray (Fig. 32–24).

## 32–8 Visible Spectrum; Dispersion

**50.** (I) By what percent is the speed of blue light (450 nm) less than the speed of red light (680 nm), in silicate flint glass (see Fig. 32–28)?

**51.** (I) A light beam strikes a piece of glass at a 55.00° incident angle. The beam contains two wavelengths, 450.0 nm and 700.0 nm, for which the index of refraction of the glass is 1.4831 and 1.4754, respectively. What is the angle between the two refracted beams?

**52.** (II) A parallel beam of light containing two wavelengths, $\lambda_1 = 461$ nm and $\lambda_2 = 656$ nm, enters the silicate flint glass of an equilateral prism as shown in Fig. 32–56. At what angle does each beam leave the prism (give angle with normal to the face)? See Fig. 32–28.

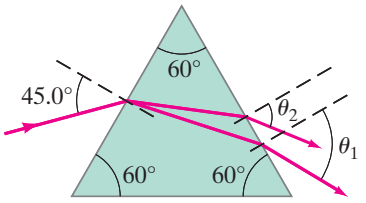

**FIGURE 32–56** Problem 52.

**53.** (III) For visible light, the index of refraction $n$ of glass is roughly 1.5, although this value varies by about 1% across the visible range. Consider a ray of white light incident from air at angle $\theta_1$ onto a flat piece of glass. (*a*) Show that, upon entering the glass, the visible colors contained in this incident ray will be dispersed over a range of refracted angles given approximately by

$$\Delta\theta_2 \approx \frac{\sin\theta_1}{\sqrt{n^2 - \sin^2\theta_1}}\frac{\Delta n}{n}.$$

[*Hint*: For $x$ in radians, $(d/dx)(\sin^{-1}x) = 1/\sqrt{1-x^2}$.] (*b*) If $\theta_1 = 0°$, what is $\Delta\theta_2$ in degrees? (*c*) If $\theta_1 = 90°$, what is $\Delta\theta_2$ in degrees?

## 32–9 Total Internal Reflection

**54.** (I) What is the critical angle for the interface between water and crown glass? To be internally reflected, the light must start in which material?

**55.** (I) The critical angle for a certain liquid–air surface is 52.6°. What is the index of refraction of the liquid?

**56.** (II) A beam of light is emitted in a pool of water from a depth of 65.0 cm. Where must it strike the air–water interface, relative to the spot directly above it, in order that the light does *not* exit the water?

**57.** (II) A ray of light, after entering a light fiber, reflects at an angle of 14.5° with the long axis of the fiber, as in Fig. 32–57. Calculate the distance along the axis of the fiber that the light ray travels between successive reflections off the sides of the fiber. Assume that the fiber has an index of refraction of 1.55 and is $1.60 \times 10^{-4}$ m in diameter.

**FIGURE 32–57** Problem 57.

**58.** (II) A beam of light is emitted 7.7 cm beneath the surface of a liquid and strikes the surface 7.2 cm from the point directly above the source. If total internal reflection occurs, what can you say about the index of refraction of the liquid?

**59.** (II) Two rays A and B travel down a cylindrical optical fiber of diameter $d = 75.0\,\mu$m, length $\ell = 1.0$ km, and index of refraction $n_1 = 1.465$. Ray A travels a straight path down the fiber's axis, whereas ray B propagates down the fiber by repeated reflections at the critical angle each time it impinges on the fiber's boundary. Determine the extra time $\Delta t$ it takes for ray B to travel down the entire fiber in comparison with ray A (Fig. 32–58), assuming (*a*) the fiber is surrounded by air, (*b*) the fiber is surrounded by a cylindrical glass "cladding" with index of refraction $n_2 = 1.460$.

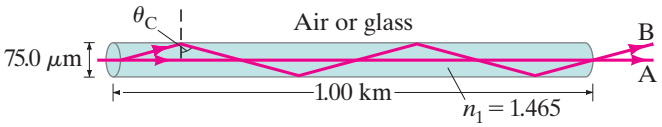

**FIGURE 32–58** Problem 59.

**60.** (II) (*a*) What is the minimum index of refraction for a glass or plastic prism to be used in binoculars (Fig. 32–34) so that total internal reflection occurs at 45°? (*b*) Will binoculars work if their prisms (assume $n = 1.58$) are immersed in water? (*c*) What minimum $n$ is needed if the prisms are immersed in water?

**61.** (III) Suppose a ray strikes the left face of the prism in Fig. 32–55 at 45.0° as shown, but is totally internally reflected at the opposite side. If the apex angle (at the top) is $\theta = 63.0°$, what can you say about the index of refraction of the prism?

**62.** (III) A beam of light enters the end of an optic fiber as shown in Fig. 32–59. (*a*) Show that we can guarantee total internal reflection at the side surface of the material (at point A), if the index of refraction is greater than about 1.42. In other words, regardless of the angle $\alpha$, the light beam reflects back into the material at point A, assuming air outside. (*b*) What if the fiber is immersed in water?

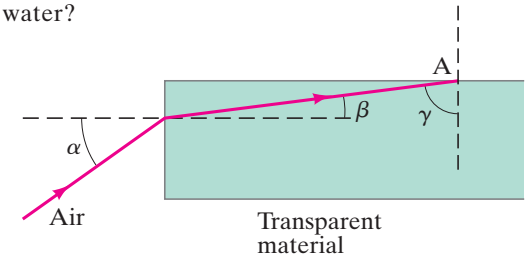

**FIGURE 32–59** Problem 62.

## *32–10 Refraction at Spherical Surface

***63.** (II) A 13.0-cm-thick plane piece of glass ($n = 1.54$) lies on the surface of a 12.0-cm-deep pool of water. How far below the top of the glass does the bottom of the pool seem, as viewed from directly above?

***64.** (II) A fish is swimming in water inside a thin spherical glass bowl of uniform thickness. Assuming the radius of curvature of the bowl is 32.0 cm, locate the image of the fish if the fish is located: (*a*) at the center of the bowl; (*b*) 20.0 cm from the side of the bowl between the observer and the center of the bowl. Assume the fish is small.

***65.** (III) In Section 32–8, we derived Eq. 32–8 for a convex spherical surface with $n_2 > n_1$. Using the same conventions and using diagrams similar to Fig. 32–38, show that Eq. 32–8 is valid also for (*a*) a convex spherical surface with $n_2 < n_1$, (*b*) a concave spherical surface with $n_2 > n_1$, and (*c*) a concave spherical surface with $n_2 < n_1$.

# General Problems

**66.** Two identical concave mirrors are set facing each other 1.0 m apart. A small lightbulb is placed halfway between the mirrors. A small piece of paper placed just to the left of the bulb prevents light from the bulb from directly shining on the left mirror, but light reflected from the right mirror still reaches the left mirror. A good image of the bulb appears on the left side of the piece of paper. What is the focal length of the mirrors?

**67.** A pulse of light takes 2.63 ns (see Table 1–4) to travel 0.500 m in a certain material. Determine the material's index of refraction, and identify this material.

**68.** (*a*) A plane mirror can be considered a limiting case of a spherical mirror. Specify what this limit is. (*b*) Determine an equation that relates the image and object distances in this limit of a plane mirror. (*c*) Determine the magnification of a plane mirror in this same limit. (*d*) Are your results in parts (*b*) and (*c*) consistent with the discussion of Section 32–2 on plane mirrors?

**69.** The critical angle of a certain piece of plastic in air is $\theta_C = 35.8°$. What is the critical angle of the same plastic if it is immersed in water?

**70.** Two plane mirrors are facing each other 2.2 m apart as in Fig. 32–60. You stand 1.5 m away from one of these mirrors and look into it. You will see multiple images of yourself. (*a*) How far away from you are the first three images of yourself in the mirror in front of you? (*b*) Are these first three images facing toward you or away from you?

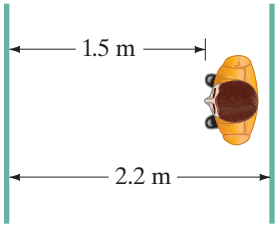

**FIGURE 32–60** Problem 70.

**71.** We wish to determine the depth of a swimming pool filled with water by measuring the width ($x = 5.20$ m) and then noting that the bottom edge of the pool is just visible at an angle of 13.0° above the horizontal as shown in Fig. 32–61. Calculate the depth of the pool.

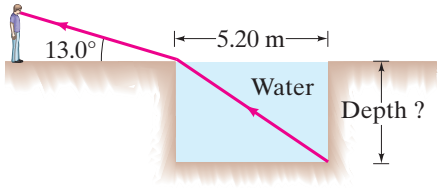

**FIGURE 32–61** Problem 71.

**72.** A 1.80-m-tall person stands 4.20 m from a convex mirror and notices that he looks precisely half as tall as he does in a plane mirror placed at the same distance. What is the radius of curvature of the convex mirror? (Assume that $\sin\theta \approx \theta$.) [*Hint*: The viewing *angle* is half.]

**73.** Each student in a physics lab is assigned to find the location where a bright object may be placed in order that a concave mirror, with radius of curvature $r = 54$ cm, will produce an image three times the size of the object. Two students complete the assignment at different times using identical equipment, but when they compare notes later, they discover that their answers for the object distance are not the same. Explain why they do not necessarily need to repeat the lab, and justify your response with a calculation.

**74.** A slab of thickness $D$, whose two faces are parallel, has index of refraction $n$. A ray of light incident from air onto one face of the slab at incident angle $\theta_1$ splits into two rays A and B. Ray A reflects directly back into the air, while B travels a total distance $\ell$ within the slab before reemerging from the slab's face a distance $d$ from its point of entry (Fig. 32–62). (*a*) Derive expressions for $\ell$ and $d$ in terms of $D$, $n$, and $\theta_1$. (*b*) For normal incidence (i.e., $\theta_1 = 0°$) show that your expressions yield the expected values for $\ell$ and $d$.

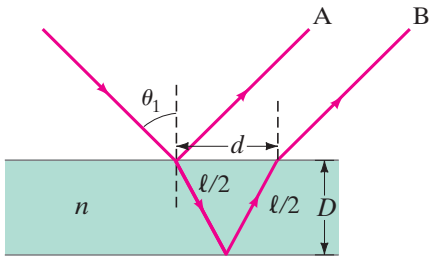

**FIGURE 32–62** Problem 74.

**75.** A kaleidoscope makes symmetric patterns with two plane mirrors having a 60° angle between them as shown in Fig. 32–63. Draw the location of the images (some of them images of images) of the object placed midway between the mirrors.

**FIGURE 32–63** Problem 75.

**76.** Sunlight is reflected off the Moon. How long does it take that light to reach us from the Moon?

**77.** The label on a laser says it produces light of wavelength 670 nm. The laser beam passes through a block of plastic for which $n = 1.57$. What is the wavelength of the light inside the plastic?

**78.** The index of refraction for a piece of plastic is 1.50 for light of wavelength 550 nm. A beam of white light strikes the plastic surface at a 45° incident angle. The angle between the violet light and the red light in the refracted beam is 0.24°. What is the percentage difference in the plastic's index of refraction from one end of the visible spectrum to the other?

**79.** When light passes through a prism, the angle that the refracted ray makes relative to the incident ray is called the deviation angle $\delta$, Fig. 32–64. Show that this angle is a minimum when the ray passes through the prism symmetrically, perpendicular to the bisector of the apex angle $\phi$, and show that the minimum deviation angle, $\delta_m$, is related to the prism's index of refraction $n$ by

$$n = \frac{\sin\frac{1}{2}(\phi + \delta_m)}{\sin\phi/2}.$$

[*Hint*: For $\theta$ in radians, $(d/d\theta)(\sin^{-1}\theta) = 1/\sqrt{1-\theta^2}$.]

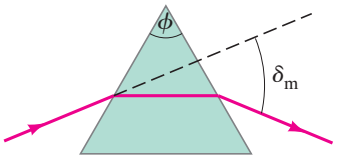

**FIGURE 32–64** Problems 79 and 80.

**80.** If the apex angle of a prism is $\phi = 68°$ (see Fig. 32–63), what is the minimum incident angle for a ray if it is to emerge from the opposite side (i.e., not be totally internally reflected), given $n = 1.58$?

**81.** **Fermat's principle** states that "light travels between two points along the path that requires the least time, as compared to other nearby paths." From Fermat's principle derive (*a*) the law of reflection $(\theta_i = \theta_r)$ and (*b*) the law of refraction (Snell's law). [*Hint*: Choose two appropriate points so that a ray between them can undergo reflection or refraction. Draw a rough path for a ray between these points, and write down an expression of the time required for light to travel the arbitrary path chosen. Then take the derivative to find the minimum.]

**82.** A ray of light with wavelength $\lambda$ is incident from air at precisely $60°$ $(=\theta)$ on a spherical water drop of radius $r$ and index of refraction $n$ (which depends on $\lambda$). When the ray reemerges into the air from the far side of the drop, it has been deflected an angle $\phi$ from its original direction as shown in Fig. 32–65. By how much does the value of $\phi$ for violet light $(n = 1.341)$ differ from the value for red light $(n = 1.330)$?

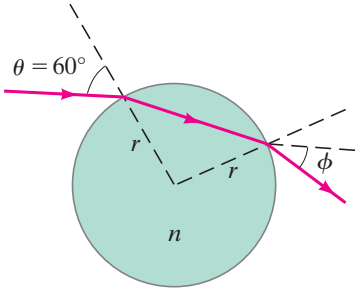

**FIGURE 32–65**
Problem 82.

**83.** A triangular prism made of crown glass $(n = 1.52)$ with base angles of 26.0° is surrounded by air. If parallel rays are incident normally on its base as shown in Fig. 32–66, what is the angle $\phi$ between the two emerging rays?

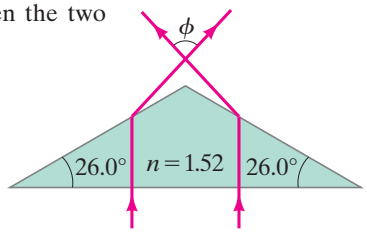

**FIGURE 32–66**
Problem 83.

**84.** Figure 32–67 shows a liquid-detecting prism device that might be used inside a washing machine. If no liquid covers the prism's hypotenuse, total internal reflection of the beam from the light source produces a large signal in the light sensor. If liquid covers the hypotenuse, some light escapes from the prism into the liquid and the light sensor's signal decreases. Thus a large signal from the light sensor indicates the absence of liquid in the reservoir. Determine the allowable range for the prism's index of refraction $n$.

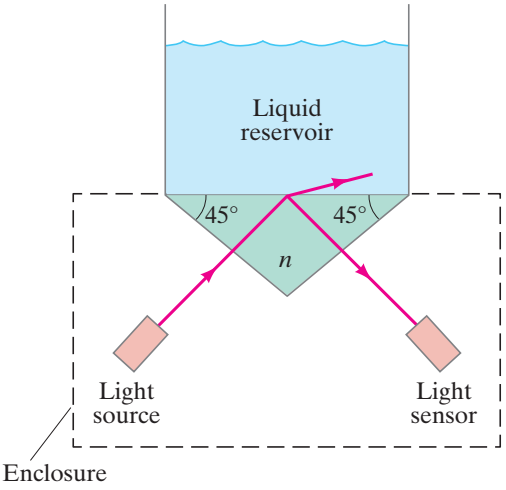

**FIGURE 32–67** Problem 84.

**85.** Light from a laser (in air) strikes the exact center of one face of a solid glass cube $(n = 1.40)$ at an angle $\theta$ relative to the normal. The refracted beam travels inside the glass until it strikes an adjacent face of the cube. The original angle of incidence $\theta$ is such that no light exits the cube where the beam strikes the second face. What is the maximum value $\theta$ can have?

**86.** An optical fiber is a long transparent cylinder of diameter $d$ and index of refraction $n$. If this fiber is bent sharply, some light hitting the side of the cylinder may escape rather than reflect back into the fiber (Fig. 32–68). What is the smallest radius $r$ at a short bent section for which total internal reflection will be assured for light initially travelling parallel to the axis of the fiber?

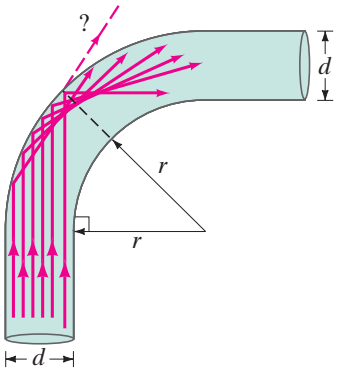

**FIGURE 32–68** Problem 86.

**87.** An object is placed 21 cm from a certain mirror. The image is half the height of the object, inverted, and real. How far is the image from the mirror, and what is the radius of curvature of the mirror?

**88.** The end faces of a cylindrical glass rod $(n = 1.51)$ are perpendicular to the sides. Show that a light ray entering an end face at any angle will be totally internally reflected inside the rod when it strikes the sides. Assume the rod is in air. What if it were in water?

**89.** The index of refraction, $n$, of crown flint glass at different wavelengths $(\lambda)$ of light are given in the Table below.

| $\lambda$ (nm) | 1060 | 546.1 | 365.0 | 312.5 |
|---|---|---|---|---|
| $n$ | 1.50586 | 1.51978 | 1.54251 | 1.5600 |

Make a graph of $n$ versus $\lambda$. The variation in index of refraction with wavelength is given by the Cauchy equation $n = A + B/\lambda^2$. Make another graph of $n$ versus $1/\lambda^2$ and determine the constants $A$ and $B$ for the glass by fitting the data with a straight line.

***90.** Suppose Fig. 32–37 shows a cylindrical rod whose end has a radius of curvature $R = 2.0$ cm, and the rod is immersed in water with index of refraction of 1.33. The rod has index of refraction 1.49. Find the location and height of the image of an object 2.0 mm high located 23 cm away from the rod.

**91.** A coin lies at the bottom of a 0.95-m-deep pool. If a viewer sees it at a 45° angle, where is the image of the coin, relative to the coin? [*Hint*: The image is found by tracing back to the intersection of two rays.]

**92.** Consider a ray of sunlight incident from air on a spherical raindrop of radius $r$ and index of refraction $n$. Defining $\theta$ to be its incident angle, the ray then follows the path shown in Fig. 32–69, exiting the drop at a "scattering angle" $\phi$ compared with its original incoming direction. (*a*) Show that $\phi = 180° + 2\theta - 4\sin^{-1}(\sin\theta/n)$. (*b*) The parallel rays of sunlight illuminate a raindrop with rays of all possible incident angles from 0° to 90°. Plot $\phi$ vs. $\theta$ in the range $0° \le \theta \le 90°$, in 0.5° steps, assuming $n = 1.33$ as is appropriate for water at visible-light wavelengths. (*c*) From your plot, you should find that a fairly large fraction of the incident angles have nearly the same scattering angle. Approximately what fraction of the possible incident angles is within roughly 1° of $\phi = 139°$? [This subset of incident rays is what creates the *rainbow*. Wavelength-dependent variations in $n$ cause the rainbow to form at slightly different $\phi$ for the various visible colors.]

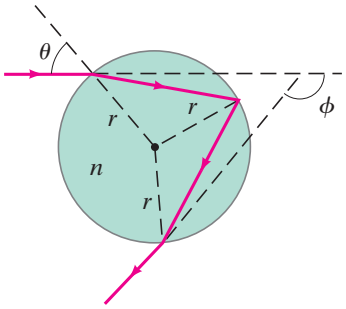

**FIGURE 32–69** Problem 92.

**93.** The paint used on highway signs often contains small transparent spheres which provide nighttime illumination of the sign's lettering by retro-reflecting vehicle headlight beams. Consider a light ray from air incident on one such sphere of radius $r$ and index of refraction $n$. Let $\theta$ be its incident angle, and let the ray follow the path shown in Fig. 32–70, so that the ray exits the sphere in the direction exactly antiparallel to its incoming direction. Considering only rays for which $\sin\theta$ can be approximated as $\theta$, determine the required value for $n$.

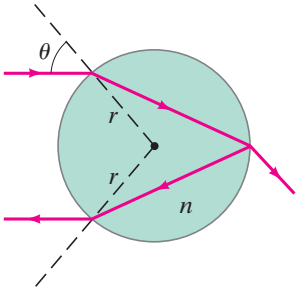

**FIGURE 32–70** Problem 93.

**94.** You hold a small flat mirror 0.50 m in front of you and can see your reflection twice in that mirror because there is a full-length mirror 1.0 m behind you (Fig. 32–71). Determine the distance of each image from you.

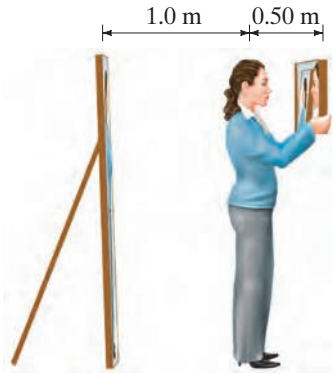

**FIGURE 32–71** Problem 94.

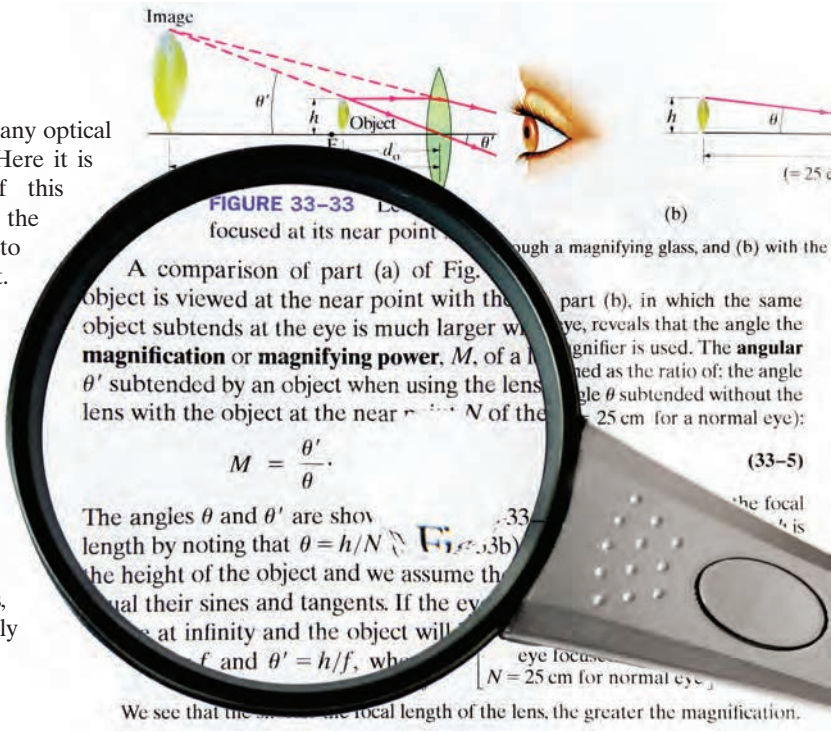
**95.** (*a*) Did the person we see in Fig. 32–72 shoot the picture we are looking at? We see her in three different mirrors. Describe (*b*) what type of mirror each is, and (*c*) her position relative to the focal point and center of curvature.

**FIGURE 32–72** Problem 95.



**96.** If the truck in Example 32–7 is viewed by the driver in the passenger side mirror (as in Fig. 32–20), $d_{\text{eye}}$ would be about 1.5 m. What then would the angular magnification be?

## ANSWERS TO EXERCISES

**A:** No.
**B:** (*b*).
**C:** Toward.
**D:** None.
**E:** The face of the watch becomes shiny. You can no longer see the numbers; total internal reflection.
**F:** No total internal reflection, $\theta_C > 45°$.

This magnifying glass is one of the many optical devices we discuss in this Chapter. Here it is magnifying part of page 979 of this Chapter, which describes how the magnifying glass works according to geometry and the ray model of light.

In this Chapter we examine thin lenses, seeing how they form images by refraction. We see how to determine image position as a function of object position and the focal length of the lens, using the ray model and geometry. We then examine optical devices including film and digital cameras, the human eye, eyeglasses, simple magnifiers, telescopes, microscopes, and finally optical aberrations.

33 – 9 Compound Microscope
33–10 Aberrations of Lenses and Mirrors

## CHAPTER-OPENING QUESTION—Guess now!

A converging lens, like the type used in a magnifying glass,

(a) always produces a magnified image (image taller than the object).
(b) can also produce an image smaller than the object.
(c) always produces an upright image.
(d) can also produce an inverted image (upside down).
(e) None of these statements are true.

The laws of reflection and refraction are the basis for explaining the operation of many optical instruments. We now discuss and analyze simple lenses using the ray model of optics as in the previous Chapter. We then analyze a number of optical instruments, from the magnifying glass and the human eye to telescopes and microscopes. The importance of lenses is that they form images of objects—see Fig. 33–1.

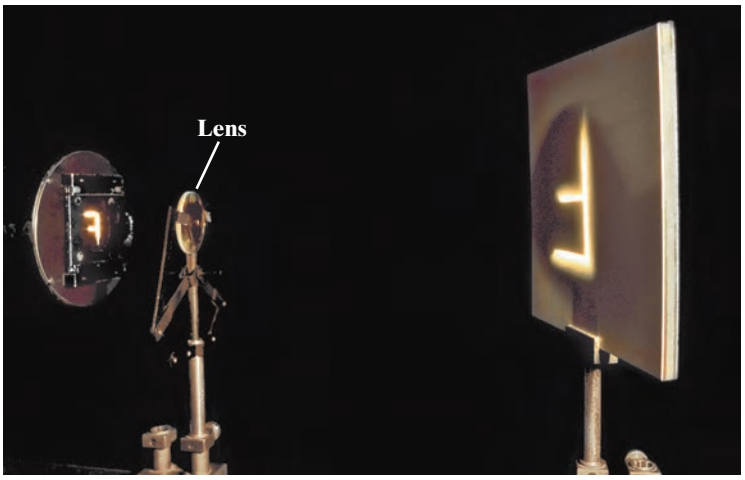

**FIGURE 33–1** Converging lens (in holder) forms an image (large "F" on screen at right) of a bright object (illuminated "F" at the left).

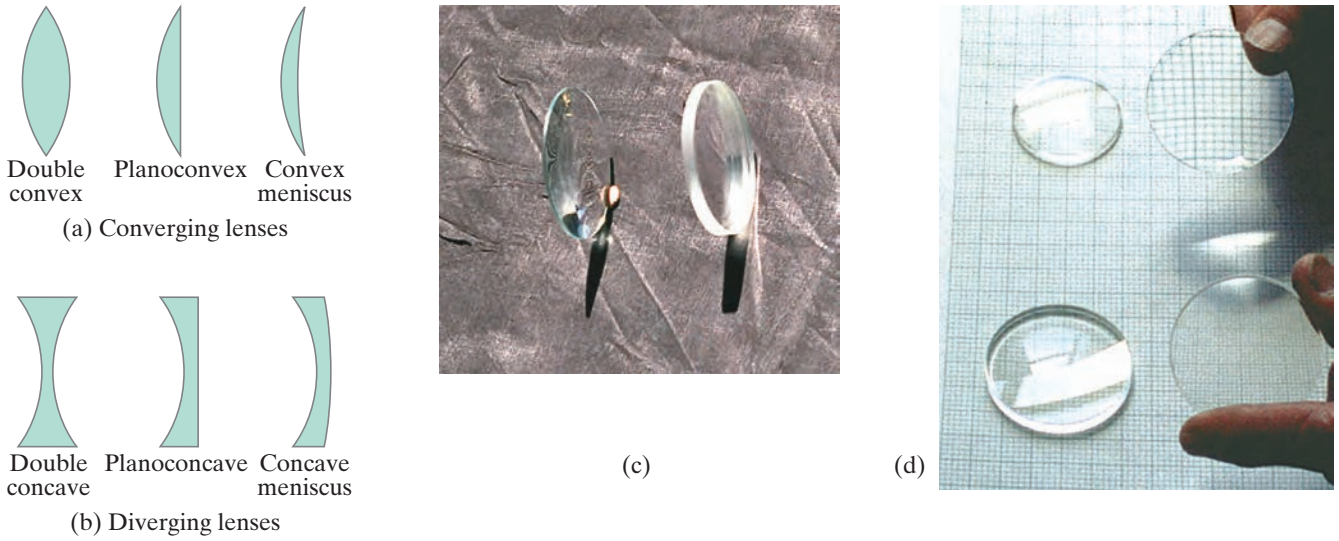

**FIGURE 33–2** (a) Converging lenses and (b) diverging lenses, shown in cross section. Converging lenses are thicker at the center whereas diverging lenses are thicker at the edges. (c) Photo of a converging lens (on the left) and a diverging lens (right). (d) Converging lenses (top), and diverging lenses (below), lying flat, and raised off the paper to form images.

# 33–1 Thin Lenses; Ray Tracing and Focal Length

The most important simple optical device is the thin lens. The development of optical devices using lenses dates to the sixteenth and seventeenth centuries, although the earliest record of eyeglasses dates from the late thirteenth century. Today we find lenses in eyeglasses, cameras, magnifying glasses, telescopes, binoculars, microscopes, and medical instruments. A thin lens is usually circular, and its two faces are portions of a sphere. (Cylindrical faces are also possible, but we will concentrate on spherical.) The two faces can be concave, convex, or plane. Several types are shown in Fig. 33–2a and b in cross section.

Consider parallel rays striking the double convex lens shown in cross section in Fig. 33–3a. We assume the lens is made of transparent material such as glass or transparent plastic, with index of refraction greater than that of the air outside. The **axis** of a lens is a straight line passing through the center of the lens and perpendicular to its two surfaces (Fig. 33–3). From Snell's law, we can see that each ray in Fig. 33–3a is bent toward the axis when the ray enters the lens and again when it leaves the lens at the back surface. (Note the dashed lines indicating the normals to each surface for the top ray.) If rays parallel to the axis fall on a thin lens, they will be focused to a point called the **focal point**, F. This will not be precisely true for a lens with spherical surfaces. But it will be very nearly true—that is, parallel rays will be focused to a tiny region that is nearly a point—if the diameter of the lens is small compared to the radii of curvature of the two lens surfaces. This criterion is satisfied by a **thin lens**, one that is very thin compared to its diameter, and we consider only thin lenses here.

The rays from a point on a distant object are essentially parallel—see Fig. 32–12. Therefore we can say that *the focal point is the image point for an object at infinity on the lens axis*, Fig. 33–3a. Thus, the focal point of a lens can be found by locating the point where the Sun's rays (or those from some other distant object) are brought to a sharp image, Fig. 33–4. The distance of the focal point from the center of the lens is called the **focal length**, $f$, Fig. 33–3a. A lens can be turned around so that light can pass through it from the opposite side. The *focal length is the same on both sides*, as we shall see later, even if the curvatures of the two lens surfaces are different. If parallel rays fall on a lens at an angle, as in Fig. 33–3b, they focus at a point $F_a$. The plane (or surface) containing all focus points, such as F and $F_a$ in Fig. 33–3b, is called the **focal plane** of the lens.

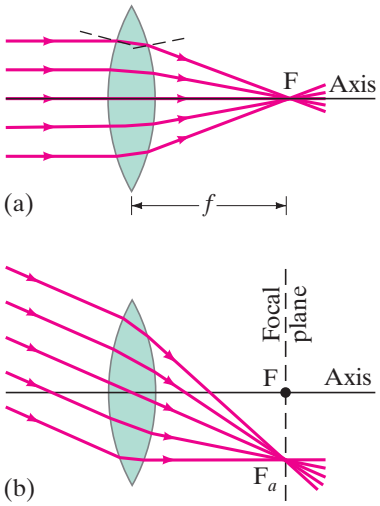

**FIGURE 33–3** Parallel rays are brought to a focus by a converging thin lens.

**FIGURE 33–4** Image of the Sun burning wood.

Any lens (in air) that is thicker in the center than at the edges will make parallel rays converge to a point, and is called a **converging lens** (see Fig. 33–2a). Lenses that are thinner in the center than at the edges (Fig. 33–2b) are called **diverging lenses** because they make parallel light diverge, as shown in Fig. 33–5.

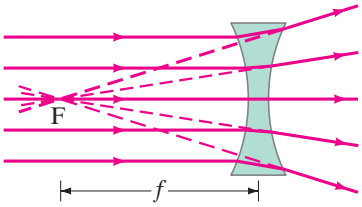

**FIGURE 33–5** Diverging lens.

The focal point, F, of a diverging lens is defined as that point from which refracted rays, originating from parallel incident rays, seem to emerge as shown in Fig. 33–5. And the distance from F to the center of the lens is called the **focal length**, $f$, just as for a converging lens.

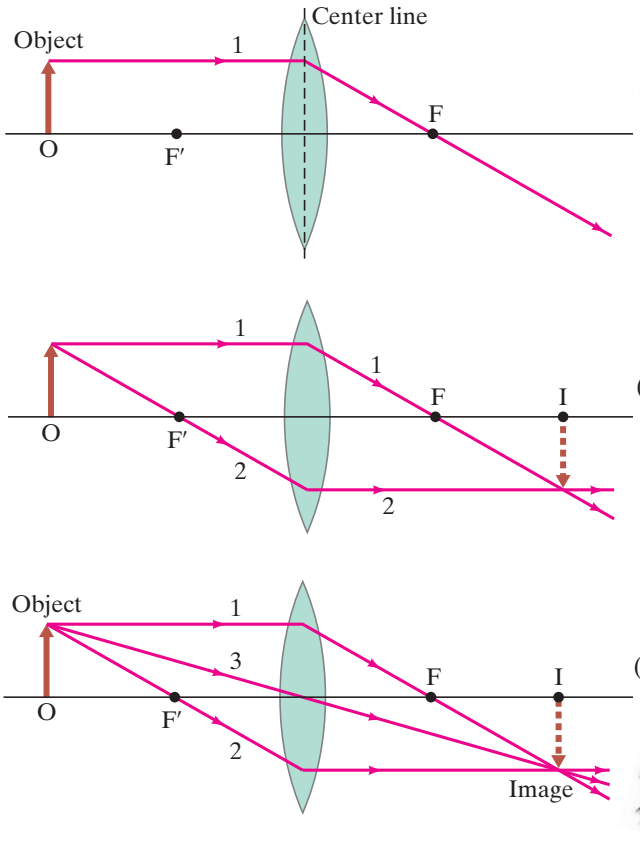
Optometrists and ophthalmologists, instead of using the focal length, use the reciprocal of the focal length to specify the strength of eyeglass (or contact) lenses. This is called the **power**, $P$, of a lens:

$$P = \frac{1}{f}. \qquad \textbf{(33–1)}$$

The unit for lens power is the **diopter** (D), which is an inverse meter: $1\,\text{D} = 1\,\text{m}^{-1}$. For example, a 20-cm-focal-length lens has a power $P = 1/(0.20\,\text{m}) = 5.0\,\text{D}$. We will mainly use the focal length, but we will refer again to the power of a lens when we discuss eyeglass lenses in Section 33–6.

The most important parameter of a lens is its focal length $f$, which is the same on both sides of the lens. For a converging lens, $f$ can be measured by finding the image point for the Sun or other distant objects. Once $f$ is known, the image position can be determined for any object. To find the image point by drawing rays would be difficult if we had to determine the refractive angles at the front surface of the lens and again at the back surface where the ray exits. We can save ourselves a lot of effort by making use of certain facts we already know, such as that a ray parallel to the axis of the lens passes (after refraction) through the focal point. To determine an image point, we can consider only the three rays indicated in Fig. 33–6, which uses an arrow (on the left) as the object, and a converging lens forming an image (dashed arrow) to the right. These rays, emanating from a single point on the object, are drawn as if the lens were infinitely thin, and we show only a single sharp bend at the center line of the lens instead of the refractions at each surface. These three rays are drawn as follows:

**RAY DIAGRAM**
*Finding the image position formed by a thin lens*



Ray 1 is drawn parallel to the axis, Fig. 33–6a; therefore it is refracted by the lens so that it passes along a line through the focal point F behind the lens. (See also Fig. 33–3a.)

Ray 2 is drawn to pass through the other focal point F′ (front side of lens in Fig. 33–6) and emerge from the lens parallel to the axis, Fig. 33–6b. (In reverse it would be a parallel ray going left and passing through F′.)

Ray 3 is directed toward the very center of the lens, where the two surfaces are essentially parallel to each other, Fig. 33–6c. This ray therefore emerges from the lens at the same angle as it entered. The ray would be displaced slightly to one side, as we saw in Example 32–8 (Fig. 32–24), but since we assume the lens is thin, we draw ray 3 straight through as shown.

The point where these three rays cross is the image point for that object point. Actually, any two of these rays will suffice to locate the image point, but drawing the third ray can serve as a check.

Using these three rays for one object point, we can find the image point for that point of the object (the top of the arrow in Fig. 33–6). The image points for all other points on the object can be found similarly to determine the complete

(a) Ray 1 leaves one point on object going parallel to the axis, then refracts through focal point behind the lens.

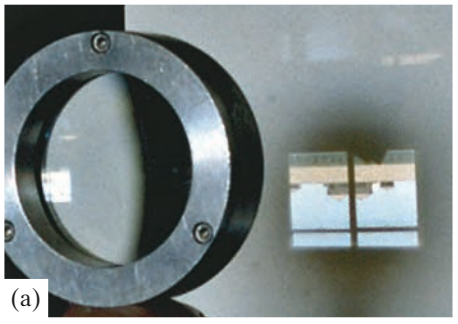
(b) Ray 2 passes through F′ in front of the lens; therefore it is parallel to the axis behind the lens.

(c) Ray 3 passes straight through the center of the lens (assumed very thin).

**FIGURE 33–6** Finding the image by ray tracing for a converging lens. Rays are shown leaving one point on the object (an arrow). Shown are the three most useful rays, leaving the tip of the object, for determining where the image of that point is formed. (Note that the focal points F and F′ on either side of the lens are the same distance $f$ from the center of the lens.)

image of the object. Because the rays actually pass through the image for the case shown in Fig. 33–6, it is a **real image** (see page 929). The image could be detected on film or by an electronic camera sensor, and actually be seen on a white surface or screen placed at the position of the image (Fig. 33–7).

**CONCEPTUAL EXAMPLE 33–1** **Half-blocked lens.** What happens to the image of an object if the top half of a lens is covered by a piece of cardboard?



**RESPONSE** Let us look at the rays in Fig. 33–6. If the top half (or any half of the lens) is blocked, you might think that half the image is blocked. But in Fig. 33–6c, we see how the rays used to create the "top" of the image pass through both the top and the bottom of the lens. Only three of many rays are shown—many more rays pass through the lens, and they can form the image. You don't lose the image. But covering part of the lens cuts down on the total light received and reduces the brightness of the image.

**NOTE** If the lens is partially blocked by your thumb, you may notice an out of focus image of part of that thumb.

## Seeing the Image

The image can also be seen directly by the eye when the eye is placed behind the image, as shown in Fig. 33–6c, so that some of the rays diverging from each point on the image can enter the eye. We can see a sharp image only for rays *diverging* from each point on the image, because we see normal objects when diverging rays from each point enter the eye, as shown in Fig. 32–1. A normal eye cannot focus converging rays; if your eye was positioned between points F and I in Fig. 33–6c, it would not see a clear image. (More about our eyes in Section 33–6.) Figure 33–7 shows an image seen (a) on a white surface and (b) directly by the eye (and a camera) placed behind the image. The eye can see both real and virtual images (see next page) as long as the eye is positioned so diverging rays enter it.

**FIGURE 33–7** (a) A converging lens can form a real image (here of a distant building, upside down) on a white wall. (b) That same real image is also directly visible to the eye. [Figure 33–2d shows images (graph paper) seen by the eye made by both diverging and converging lenses.]

(a)

(b)

### Diverging Lens

By drawing the same three rays emerging from a single object point, we can determine the image position formed by a diverging lens, as shown in Fig. 33–8. Note that ray 1 is drawn parallel to the axis, but does not pass through the focal point F′ behind the lens. Instead it seems to come (dashed line) from the focal point F in front of the lens. Ray 2 is directed toward F′ and is refracted parallel to the lens axis by the lens. Ray 3 passes directly through the center of the lens. The three refracted rays seem to emerge from a point on the left of the lens. This is the image point, I. Because the rays do not pass through the image, it is a **virtual image**. Note that the eye does not distinguish between real and virtual images—both are visible.

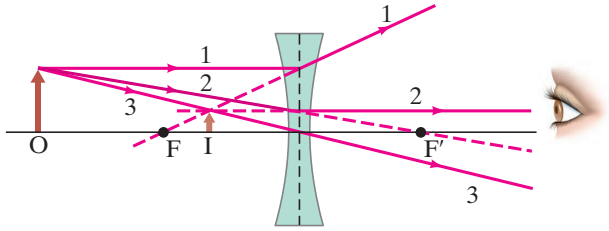


**FIGURE 33–8** Finding the image by ray tracing for a diverging lens.

## 33–2 The Thin Lens Equation

We now derive an equation that relates the image distance to the object distance and the focal length of a thin lens. This equation will make the determination of image position quicker and more accurate than doing ray tracing. Let $d_o$ be the object distance, the distance of the object from the center of the lens, and $d_i$ be the image distance, the distance of the image from the center of the lens.

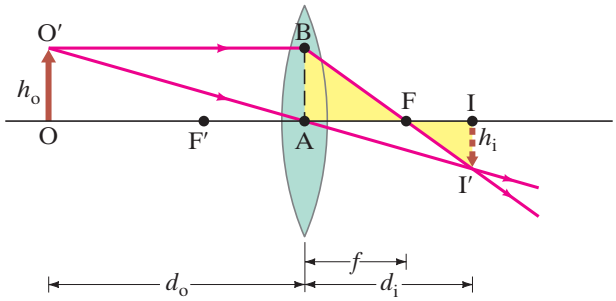

**FIGURE 33–9** Deriving the lens equation for a converging lens.

Let $h_o$ and $h_i$ refer to the heights of the object and image. Consider the two rays shown in Fig. 33–9 for a converging lens, assumed to be very thin. The right triangles FI′I and FBA (highlighted in yellow) are similar because angle AFB equals angle IFI′. Therefore

$$\frac{h_i}{h_o} = \frac{d_i - f}{f},$$

since length AB $= h_o$. Triangles OAO′ and IAI′ are similar as well. Therefore,

$$\frac{h_i}{h_o} = \frac{d_i}{d_o}.$$

We equate the right sides of these two equations (the left sides are the same), and divide by $d_i$ to obtain

$$\frac{1}{f} - \frac{1}{d_i} = \frac{1}{d_o}$$

or

*THIN LENS EQUATION*

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f}. \qquad \textbf{(33–2)}$$

This is called the **thin lens equation**. It relates the image distance $d_i$ to the object distance $d_o$ and the focal length $f$. It is the most useful equation in geometric optics. (Interestingly, it is exactly the same as the mirror equation, Eq. 32–2.)

If the object is at infinity, then $1/d_o = 0$ and Eq. 33–2 gives $d_i = f$. Thus the focal length is the image distance for an object at infinity, as mentioned earlier.

We can derive the lens equation for a diverging lens using Fig. 33–10. Triangles IAI′ and OAO′ are similar; and triangles IFI′ and AFB are similar. Thus (noting that length AB $= h_o$)

$$\frac{h_i}{h_o} = \frac{d_i}{d_o}$$

and

$$\frac{h_i}{h_o} = \frac{f - d_i}{f}.$$

When we equate the right sides of these two equations and simplify, we obtain

$$\frac{1}{d_o} - \frac{1}{d_i} = -\frac{1}{f}.$$

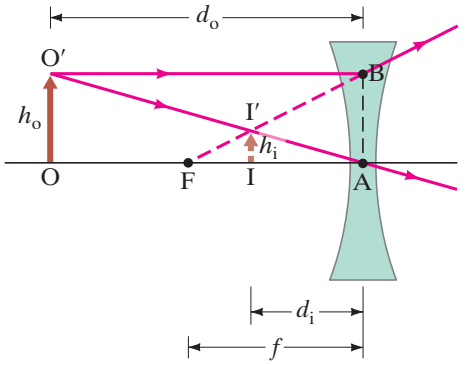

**FIGURE 33–10** Deriving the lens equation for a diverging lens.

This equation becomes the same as Eq. 33–2 if we make $f$ and $d_i$ negative. That is, we take $f$ to be *negative for a diverging lens*, and $d_i$ negative when the image is on the same side of the lens as the light comes from. Thus Eq. 33–2 will be valid for both converging and diverging lenses, and for *all* situations, if we use the following **sign conventions**:

**CAUTION**
*Focal length is negative for diverging lens*

**PROBLEM SOLVING**
*SIGN CONVENTIONS for lenses*

1. The focal length is positive for converging lenses and negative for diverging lenses.
2. The object distance is positive if the object is on the side of the lens from which the light is coming. This is always the case for real objects; but when lenses are used in combination, it might not be so (see Example 33–6, where the object distance for the diverging lens is negative, and the object is "virtual" and behind the lens).
3. The image distance is positive if the image is on the opposite side of the lens from where the light is coming; if it is on the same side, $d_i$ is negative. Equivalently, the image distance is positive for a real image (Fig. 33–9) and negative for a virtual image (Fig. 33–10).
4. The height of the image, $h_i$, is positive if the image is upright, and negative if the image is inverted relative to the object. ($h_o$ is always taken as upright and positive.)

The **lateral magnification**, $m$, of a lens is defined as the ratio of the image height to object height, $m = h_i/h_o$. From Figs. 33–9 and 33–10 and the conventions just stated (for which we will need a minus sign), we have

$$m = \frac{h_i}{h_o} = -\frac{d_i}{d_o}. \qquad \textbf{(33–3)}$$

For an upright image the magnification is positive (as in Fig. 33–10), and for an inverted image the magnification is negative (Fig. 33–9).

From sign convention 1, it follows that the power (Eq. 33–1) of a converging lens, in diopters, is positive, whereas the power of a diverging lens is negative. A converging lens is sometimes referred to as a **positive lens**, and a diverging lens as a **negative lens**.

Diverging lenses (see Fig. 33–10) always produce an upright virtual image for any real object, no matter where that object is. Converging lenses can produce real (inverted) images as in Fig. 33–9, or virtual (upright) images, depending on object position, as we shall see.

PROBLEM SOLVING

## Thin Lenses

1. Draw a **ray diagram**, as precise as possible, but even a rough one can serve as confirmation of analytic results. Choose one point on the object and draw at least two, or preferably three, of the easy-to-draw rays described in Figs. 33–6 and 33–8. The image point is where the rays intersect.
2. For analytic solutions, solve for unknowns in the **thin lens equation** (Eq. 33–2) and the **magnification equation** (Eq. 33–3). The thin lens equation involves reciprocals—don't forget to take the reciprocal.
3. Follow the **sign conventions** listed on page 963.
4. Check that your analytic answers are **consistent** with your ray diagram.

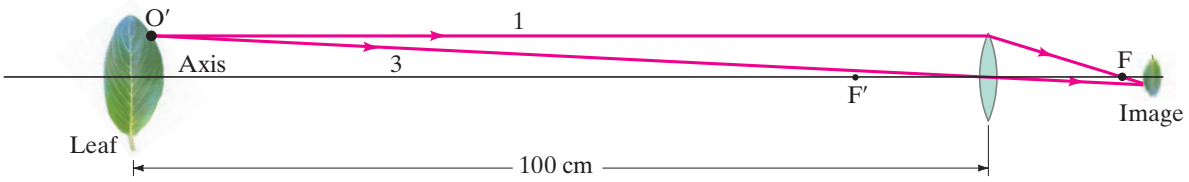

**FIGURE 33–11** Example 33–2. (Not to scale.)

**EXAMPLE 33–2** **Image formed by converging lens.** What is (*a*) the position, and (*b*) the size, of the image of a 7.6-cm-high leaf placed 1.00 m from a +50.0-mm-focal-length camera lens?

**APPROACH** We follow the steps of the Problem Solving Strategy explicitly.

**SOLUTION**

1. **Ray diagram**. Figure 33–11 is an approximate ray diagram, showing only rays 1 and 3 for a single point on the leaf. We see that the image ought to be a little behind the focal point F, to the right of the lens.
2. **Thin lens and magnification equations**. (*a*) We find the image position analytically using the thin lens equation, Eq. 33–2. The camera lens is converging, with $f = +5.00\,\text{cm}$, and $d_o = 100\,\text{cm}$, and so the thin lens equation gives
$$\frac{1}{d_i} = \frac{1}{f} - \frac{1}{d_o} = \frac{1}{5.00\,\text{cm}} - \frac{1}{100\,\text{cm}} = \frac{20.0 - 1.0}{100\,\text{cm}} = \frac{19.0}{100\,\text{cm}}.$$
Then, taking the reciprocal,
$$d_i = \frac{100\,\text{cm}}{19.0} = 5.26\,\text{cm},$$
or 52.6 mm behind the lens.
(*b*) The magnification is
$$m = -\frac{d_i}{d_o} = -\frac{5.26\,\text{cm}}{100\,\text{cm}} = -0.0526,$$
so
$$h_i = mh_o = (-0.0526)(7.6\,\text{cm}) = -0.40\,\text{cm}.$$
The image is 4.0 mm high.
3. **Sign conventions**. The image distance $d_i$ came out positive, so the image is behind the lens. The image height is $h_i = -0.40\,\text{cm}$; the minus sign means the image is inverted.
4. **Consistency**. The analytic results of steps 2 and 3 are consistent with the ray diagram, Fig. 33–11: the image is behind the lens and inverted.

**NOTE** Part (*a*) tells us that the image is 2.6 mm farther from the lens than the image for an object at infinity, which would equal the focal length, 50.0 mm. Indeed, when focusing a camera lens, the closer the object is to the camera, the farther the lens must be from the sensor or film.

**EXERCISE A** If the leaf (object) of Example 33–2 is moved farther from the lens, does the image move closer to or farther from the lens? (Don't calculate!)

**EXAMPLE 33–3** **Object close to converging lens.** An object is placed 10 cm from a 15-cm-focal-length converging lens. Determine the image position and size (*a*) analytically, and (*b*) using a ray diagram.

**APPROACH** The object is within the focal point—closer to the lens than the focal point F as $d_o < f$. We first use Eqs. 33–2 and 33–3 to obtain an analytic solution, and then confirm with a ray diagram using the special rays 1, 2, and 3 for a single object point.

**SOLUTION** (*a*) Given $f = 15\,\text{cm}$ and $d_o = 10\,\text{cm}$, then

$$\frac{1}{d_i} = \frac{1}{15\,\text{cm}} - \frac{1}{10\,\text{cm}} = \frac{2-3}{30\,\text{cm}} = -\frac{1}{30\,\text{cm}},$$

and $d_i = -30\,\text{cm}$. (Remember to take the reciprocal!) Because $d_i$ is negative, the image must be virtual and on the same side of the lens as the object (sign convention 3, page 963). The magnification

$$m = -\frac{d_i}{d_o} = -\frac{-30\,\text{cm}}{10\,\text{cm}} = 3.0.$$

The image is three times as large as the object and is upright. This lens is being used as a magnifying glass, which we discuss in more detail in Section 33–7.

(*b*) The ray diagram is shown in Fig. 33–12 and in accord with the results in part (*a*). We choose point O′ on the top of the object and draw ray 1. Ray 2, however, may take some thought: if we draw it heading toward F′, it is going the wrong way—so we have to draw it as if coming from F′ (and so dashed), striking the lens, and then going out parallel to the lens axis. We project it backward, with a dashed line, as we must do also for ray 1, in order to find where they cross. Ray 3 is drawn through the lens center, and it crosses the other two rays at the image point, I′.

**NOTE** From Fig. 33–12 we can see that, when an object is placed between a converging lens and its focal point, the image is virtual.

**CAUTION**
*Don't forget to take the reciprocal*

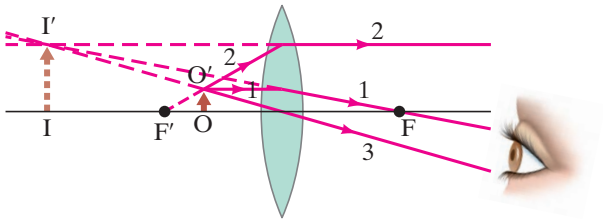

**FIGURE 33–12** An object placed within the focal point of a converging lens produces a virtual image. Example 33–3.

**EXERCISE B** Return to the Chapter-Opening Question, page 958, and answer it again now. Try to explain why you may have answered differently the first time.

**EXAMPLE 33–4** **Diverging lens.** Where must a small insect be placed if a 25-cm-focal-length diverging lens is to form a virtual image 20 cm from the lens, on the same side as the object?

**APPROACH** The ray diagram is basically that of Fig. 33–10 because our lens here is diverging and our image is given as in front of the lens within the focal distance. (It would be a valuable exercise to draw the ray diagram to scale, precisely, now.) The insect's distance, $d_o$, can be calculated using the thin lens equation.

**SOLUTION** The lens is diverging, so $f$ is negative: $f = -25\,\text{cm}$. The image distance must be negative too because the image is in front of the lens (sign conventions), so $d_i = -20\,\text{cm}$. The lens equation, Eq. 33–2, gives

$$\frac{1}{d_o} = \frac{1}{f} - \frac{1}{d_i} = -\frac{1}{25\,\text{cm}} + \frac{1}{20\,\text{cm}} = \frac{-4+5}{100\,\text{cm}} = \frac{1}{100\,\text{cm}}.$$

So the object must be 100 cm in front of the lens.

## 33–3 Combinations of Lenses

Many optical instruments use lenses in combination. When light passes through more than one lens, we can start the analysis by finding the image formed by the first lens as if it were alone. Then that image becomes the *object* for the second lens. Next we find the image formed by this second lens using the first image as object. This second image is the final image if there are only two lenses. The total magnification will be the product of the separate magnifications of each lens. Even if the second lens intercepts the light from the first lens before it forms an image, this technique still works.

**EXAMPLE 33–5** **A two-lens system.** Two converging lenses, A and B, with focal lengths $f_A = 20.0\,\text{cm}$ and $f_B = 25.0\,\text{cm}$, are placed 80.0 cm apart, as shown in Fig. 33–13a. An object is placed 60.0 cm in front of the first lens as shown in Fig. 33–13b. Determine (*a*) the position, and (*b*) the magnification, of the final image formed by the combination of the two lenses.

**APPROACH** Starting at the tip of our object O, we draw rays 1, 2, and 3 for the first lens, A, and also a ray 4 which, after passing through lens A, acts for the second lens, B, as ray 3′ (through the center). We use primes now for the standard rays relative to lens B. Ray 2 for lens A exits parallel, and so is ray 1′ for lens B. To determine the position of the image $I_A$ formed by lens A, we use Eq. 33–2 with $f_A = 20.0\,\text{cm}$ and $d_{oA} = 60.0\,\text{cm}$. The distance of $I_A$ (lens A's image) from lens B is the object distance $d_{oB}$ for lens B. The final image is found using the thin lens equation, this time with all distances relative to lens B. For (*b*) the magnifications are found from Eq. 33–3 for each lens in turn.

**SOLUTION** (*a*) The object is a distance $d_{oA} = +60.0\,\text{cm}$ from the first lens, A, and this lens forms an image whose position can be calculated using the thin lens equation:

$$\frac{1}{d_{iA}} = \frac{1}{f_A} - \frac{1}{d_{oA}} = \frac{1}{20.0\,\text{cm}} - \frac{1}{60.0\,\text{cm}} = \frac{3-1}{60.0\,\text{cm}} = \frac{1}{30.0\,\text{cm}}.$$

**CAUTION**
*Object distance for second lens is* **not** *equal to the image distance for first lens*

So the first image $I_A$ is at $d_{iA} = 30.0\,\text{cm}$ behind the first lens. This image becomes the object for the second lens, B. It is a distance $d_{oB} = 80.0\,\text{cm} - 30.0\,\text{cm} = 50.0\,\text{cm}$ in front of lens B (Fig. 33–13b). The image formed by lens B, again using the thin lens equation, is at a distance $d_{iB}$ from the lens B:

$$\frac{1}{d_{iB}} = \frac{1}{f_B} - \frac{1}{d_{oB}} = \frac{1}{25.0\,\text{cm}} - \frac{1}{50.0\,\text{cm}} = \frac{2-1}{50.0\,\text{cm}} = \frac{1}{50.0\,\text{cm}}.$$

Hence $d_{iB} = 50.0\,\text{cm}$ behind lens B. This is the final image—see Fig. 33–13b.

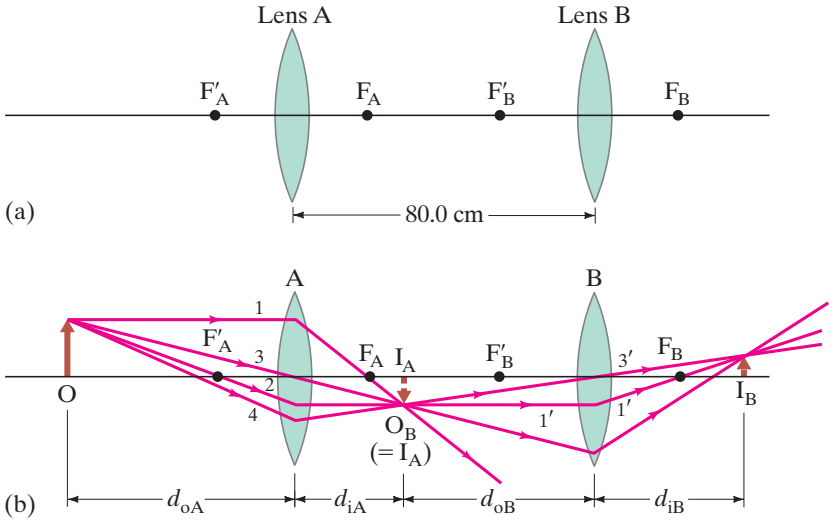

**FIGURE 33–13** Two lenses, A and B, used in combination, Example 33–5. The small numbers refer to the easily drawn rays; those numbers have a prime (′) when referring to lens B.

(*b*) Lens A has a magnification (Eq. 33–3)

$$m_A = -\frac{d_{iA}}{d_{oA}} = -\frac{30.0\,\text{cm}}{60.0\,\text{cm}} = -0.500.$$

Thus, the first image is inverted and is half as high as the object (again Eq. 33–3):

$$h_{iA} = m_A h_{oA} = -0.500 h_{oA}.$$

Lens B takes this first image as object and changes its height by a factor

$$m_B = -\frac{d_{iB}}{d_{oB}} = -\frac{50.0\,\text{cm}}{50.0\,\text{cm}} = -1.000.$$

The second lens reinverts the image (the minus sign) but doesn't change its size. The final image height is (remember $h_{oB}$ is the same as $h_{iA}$)

$$h_{iB} = m_B h_{oB} = m_B h_{iA} = m_B m_A h_{oA} = (m_{\text{total}}) h_{oA}.$$

The total magnification is the product of $m_A$ and $m_B$, which here equals $m_{\text{total}} = m_B m_A = (-1.000)(-0.500) = +0.500$, or half the original height, and the final image is upright.

**PROBLEM SOLVING**
*Total magnification is* $m_{\text{total}} = m_A m_B$

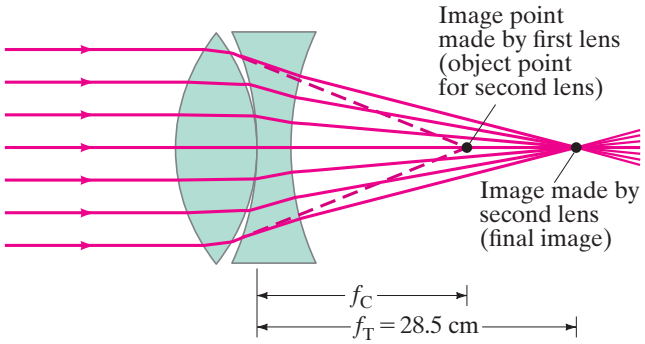

**FIGURE 33–14** Determining the focal length of a diverging lens. Example 33–6.

**EXAMPLE 33–6** **Measuring *f* for a diverging lens.** To measure the focal length of a diverging lens, a converging lens is placed in contact with it, as shown in Fig. 33–14. The Sun's rays are focused by this combination at a point 28.5 cm behind the lenses as shown. If the converging lens has a focal length $f_C$ of 16.0 cm, what is the focal length $f_D$ of the diverging lens? Assume both lenses are thin and the space between them is negligible.

**APPROACH** The image distance for the first lens equals its focal length (16.0 cm) since the object distance is infinity ($\infty$). The position of this image, even though it is never actually formed, acts as the object for the second (diverging) lens. We apply the thin lens equation to the diverging lens to find its focal length, given that the final image is at $d_i = 28.5$ cm.

**SOLUTION** Rays from the Sun are focused 28.5 cm behind the combination, so the focal length of the total combination is $f_T = 28.5$ cm. If the diverging lens was absent, the converging lens would form the image at its focal point—that is, at a distance $f_C = 16.0$ cm behind it (dashed lines in Fig. 33–14). When the diverging lens is placed next to the converging lens, we treat the image formed by the first lens as the *object* for the second lens. Since this object lies to the right of the diverging lens, this is a situation where $d_o$ is negative (see the sign conventions, page 963). Thus, for the diverging lens, the object is virtual and $d_o = -16.0$ cm. The diverging lens forms the image of this virtual object at a distance $d_i = 28.5$ cm (given). Thus,

**CAUTION**
$d_o < 0$

$$\frac{1}{f_D} = \frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{-16.0\,\text{cm}} + \frac{1}{28.5\,\text{cm}} = -0.0274\,\text{cm}^{-1}.$$

We take the reciprocal to find $f_D = -1/(0.0274\,\text{cm}^{-1}) = -36.5$ cm.

**NOTE** If this technique is to work, the converging lens must be "stronger" than the diverging lens—that is, it must have a focal length whose magnitude is less than that of the diverging lens.

## 33–4 Lensmaker's Equation

A useful equation, called the **lensmaker's equation**, relates the focal length of a lens (in air) to the radii of curvature $R_1$ and $R_2$ of its two surfaces and its index of refraction $n$:

$$\frac{1}{f} = (n - 1)\left(\frac{1}{R_1} + \frac{1}{R_2}\right). \qquad \textbf{(33–4)}$$

**CAUTION**
*Sign conventions*

If both surfaces are convex, $R_1$ and $R_2$ are considered positive.† For a concave surface, the radius must be considered *negative*.

Notice that Eq. 33–4 is *symmetrical* in $R_1$ and $R_2$. Thus, if a lens is turned around so that light impinges on the other surface, the focal length is the same even if the two lens surfaces are different. This confirms what we said earlier: a lens' focal length is the same on both sides of the lens.

**EXAMPLE 33–7** **Calculating $f$ for a converging lens.** A convex meniscus lens (Figs. 33–2a and 33–15) is made from glass with $n = 1.50$. The radius of curvature of the convex surface is 22.4 cm and that of the concave surface is 46.2 cm. (*a*) What is the focal length? (*b*) Where will the image be for an object 2.00 m away?

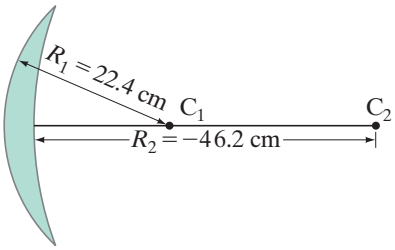

**FIGURE 33–15** Example 33–7.

**APPROACH** We use Eq. 33–4, noting that $R_2$ is negative because it refers to the concave surface.

**SOLUTION** (*a*) $R_1 = 22.4\,\text{cm}$ and $R_2 = -46.2\,\text{cm}$.
Then

$$\frac{1}{f} = (1.50 - 1.00)\left(\frac{1}{22.4\,\text{cm}} - \frac{1}{46.2\,\text{cm}}\right) = 0.0115\,\text{cm}^{-1}.$$

So

$$f = \frac{1}{0.0115\,\text{cm}^{-1}} = 87.0\,\text{cm}$$

and the lens is converging. Notice that if we turn the lens around so that $R_1 = -46.2\,\text{cm}$ and $R_2 = +22.4\,\text{cm}$, we get the same result.

(*b*) From the lens equation, with $f = 0.870\,\text{m}$ and $d_o = 2.00\,\text{m}$, we have

$$\frac{1}{d_i} = \frac{1}{f} - \frac{1}{d_o} = \frac{1}{0.870\,\text{m}} - \frac{1}{2.00\,\text{m}} = 0.649\,\text{m}^{-1},$$

so $d_i = 1/0.649\,\text{m}^{-1} = 1.54\,\text{m}$.

**EXERCISE C** A Lucite planoconcave lens (see Fig. 33–2b) has one flat surface and the other has $R = -18.4\,\text{cm}$. What is the focal length? Is the lens converging or diverging?

### *Derivation of the Lensmaker's Equation

Now we show that parallel rays are brought to a focus at a single point for a thin lens, and also derive the lensmaker's equation, Eq. 33–4.

In Fig. 33–16, a ray parallel to the axis of a lens (in air) is refracted at the front surface of the lens at point $A_1$ and is refracted at the back surface at point $A_2$. This ray then passes through point F, which we call the focal point for this ray. Point $A_1$ is a height $h_1$ above the axis, and point $A_2$ is height $h_2$ above the axis. $C_1$ and $C_2$ are the centers of curvature of the two lens surfaces; so the length $C_1A_1 = R_1$, the radius of curvature of the front surface, and $C_2A_2 = R_2$ is the radius of the second surface. We consider a double convex lens and by convention choose the radii of both lens surfaces as positive. The thickness of the lens has been grossly exaggerated so that the various angles would be clear. But we will assume that the lens is actually very thin and that angles between the rays and the axis are small. In this approximation, the sines and tangents of all the angles will be equal to the angles themselves in radians. For example, $\sin\theta_1 \approx \tan\theta_1 \approx \theta_1$ (radians).

†Some books use a different convention: $R_1$ and $R_2$ may be considered positive if their centers of curvature are to the right of the lens; then a minus sign appears in their version of Eq. 33–4, in place of our + sign.

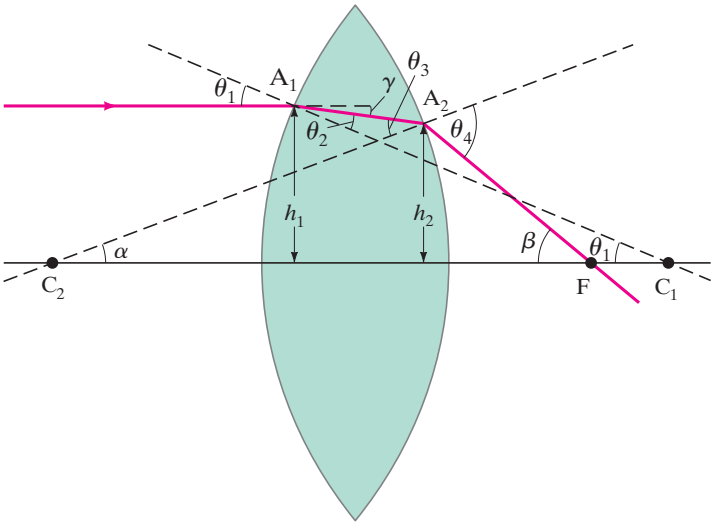

**FIGURE 33–16** Diagram of a ray passing through a lens for derivation of the lensmaker's equation.

To this approximation, then, Snell's law tells us that

$$\theta_1 = n\theta_2$$
$$\theta_4 = n\theta_3$$

where $n$ is the index of refraction of the lens, and we assume that the lens is surrounded by air $(n = 1)$. Notice also in Fig. 33–16 that

$$\theta_1 \approx \sin\theta_1 = \frac{h_1}{R_1}$$
$$\alpha \approx \frac{h_2}{R_2}$$
$$\beta \approx \frac{h_2}{f}.$$

The last follows because the distance from F to the lens (assumed very thin) is $f$. From the diagram, the angle $\gamma$ is

$$\gamma = \theta_1 - \theta_2.$$

A careful examination of Fig. 33–16 shows also that

$$\alpha = \theta_3 - \gamma.$$

This can be seen by drawing a horizontal line to the left from point $A_2$, which divides the angle $\theta_3$ into two parts. The upper part equals $\gamma$ and the lower part equals $\alpha$. (The opposite angles between an oblique line and two parallel lines are equal, Fig. A–1 in Appendix A.) Thus, $\theta_3 = \gamma + \alpha$. Furthermore, by drawing a horizontal line to the right from point $A_2$, we divide $\theta_4$ into two parts. The upper part is $\alpha$ and the lower is $\beta$. Thus

$$\theta_4 = \alpha + \beta.$$

We now combine all these equations:

$$\alpha = \theta_3 - \gamma = \frac{\theta_4}{n} - (\theta_1 - \theta_2) = \frac{\alpha}{n} + \frac{\beta}{n} - \theta_1 + \theta_2,$$

or

$$\frac{h_2}{R_2} = \frac{h_2}{nR_2} + \frac{h_2}{nf} - \frac{h_1}{R_1} + \frac{h_1}{nR_1}.$$

Because the lens is thin, $h_1 \approx h_2$ and all $h$'s can be canceled from all the numerators. We then multiply through by $n$ and rearrange to find that

$$\frac{1}{f} = (n - 1)\left(\frac{1}{R_1} + \frac{1}{R_2}\right),$$

which is Eq. 33–4, the **lensmaker's equation**. Notice that $f$ for a thin lens does not depend on $h_1$ or $h_2$. Thus the position of the point F does not depend on where the ray strikes the lens. Hence, all rays parallel to the axis of a thin lens will pass through the same point F, which we wished to show.

In this derivation of the lensmaker's equation, both surfaces are convex and $R_1$ and $R_2$ are considered positive. Equation 33–4 also works for lenses with one or both surfaces concave; but for a concave surface, the radius must be considered *negative* (see page 968, first paragraph).

[The lensmaker's equation, and our derivation of it, assume the lens is in air or vacuum. If the lens, of index of refraction $n_2$, is submerged in water or other liquid with index $n_1$, then our Snell's laws equations become

$$n_1\theta_1 = n_2\theta_2 \quad \text{and} \quad n_2\theta_3 = n_1\theta_4.$$

In our final result, Eq. 33–4, we would need to substitute $n$ with $(n_2/n_1)$. See Problem 31.]

# 33–5 Cameras: Film and Digital

The basic elements of a **camera** are a lens, a light-tight box, a shutter (that "clicks") to let light pass through the lens only briefly, and an electronic sensor in a digital camera or a piece of film in a traditional camera (Fig. 33–17). When the shutter is opened for a brief "exposure," light from external objects in the field of view is focused by the lens as an image on the sensor or film.

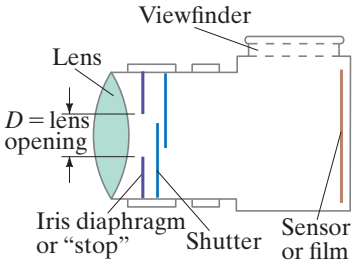

**FIGURE 33–17** A simple camera.

You can see the image yourself if you are able to remove the back of a conventional camera, keeping the shutter open, and view through a piece of tissue paper (on which an image can form) placed where the film should be.

Film contains a thin **emulsion** (= a coating) with light-sensitive chemicals that change when light strikes them. The film is then developed by chemicals dissolved in water, which causes the most changed areas (brightest light) to turn opaque, so the image is recorded on the film.[†] We might call film "chemical photography" as compared to digital, which is electronic.

**PHYSICS APPLIED**
*Cameras, film and digital*

## Digital Cameras, Electronic Sensors (CCD, CMOS)

In a **digital camera**, the film is replaced by a *semiconductor* sensor. Two types are common: **CCD** (*charge-coupled device*) and **CMOS** (*complementary metal oxide semiconductor*). Either sensor is made up of millions of tiny semiconductor **pixels** ("picture elements")—see Figs. 33–18 and 34–36. A 12-MP (12-megapixel) sensor might contain about 4000 pixels horizontally by 3000 pixels vertically over an area of perhaps $16 \times 12$ mm, and preferably larger such as $36 \times 24$ mm like 35-mm film. Light reaching any pixel liberates electrons within its semiconductor,[‡] which is itself attached to a tiny metal "gate" electrode (this combination is called a "photodiode"). The gate has a positive voltage applied to it and attracts the liberated electrons. The more intense the light, the more electrons are emitted and more charge accumulates during the brief exposure time. After exposure, the charge on each pixel has to be "read" (measured) and stored. In a CCD sensor, a reader-circuit at the end of each pixel row or column reads the charge on the pixel nearest it. To do so, it attracts the charge $Q$ that was collected on "pixel-1" by being given a higher voltage itself than pixel-1. Immediately after, the charge on pixel-2 is attracted in to be measured ("read") and so on. All this information (the brightness of each pixel) goes to a central processor that stores it digitally (analog-to-digital converter) and allows re-formation of the image later onto the camera's screen, or a computer screen, or a printer. After all the pixel charge information is transferred to memory (Section 29–8), a new picture can be taken.

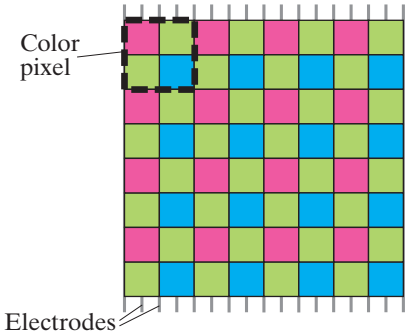

**FIGURE 33–18** Portion of a typical Bayer array sensor. A square group of four pixels $\begin{matrix}\text{RG}\\\text{GB}\end{matrix}$ is sometimes called a "color pixel." (R is red, G green, B blue.)

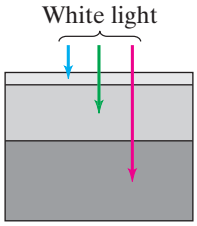
[†]This is called a *negative*, because the black areas correspond to bright objects and vice versa. The same process occurs during printing to produce a black-and-white "positive" picture from the negative. Color film has three emulsion layers (or dyes) corresponding to the three primary colors.

[‡]Specifically, photons of light knock electrons in the valence band up to the conduction band (Chapter 40). It is sometimes said that the electrons liberated by incoming photons (a particle of light as we will see in Chapter 37) and attracted to a pixel gate are contained in a "well" of finite depth. This is *not* a physical well. It is a minimum in a *potential energy diagram* (as in Fig. 8–23, Section 8–9), and such a potential well (Section 38–8 and 38–9) can hold only a limited number of electrons because of quantum theory's exclusion principle (Section 39–4). If a "well" overflows, the charge enters neighboring pixels, referred to as "cross-talk" or "blooming", which blurs the picture.

A CMOS sensor also uses a silicon semiconductor, but incorporates transistor electronics within each pixel so each pixel charge can be read directly, somewhat like the similar MOSFET array that was shown in Fig. 29–31. CMOS costs less to manufacture, but for scientific work (such as astronomical telescopes) CCDs are usually used because they provide greater precision.

Sensor sizes are typically in the ratio 4:3 or 3:2. A larger sensor is better because it can hold more pixels, and/or each pixel can be larger and hold more charge (free electrons) to provide a wider range of brightness, better color accuracy, and better sensitivity in low-light conditions.

In the most common array of pixels, referred to as a **Bayer mosaic**, color is achieved by red, green, and blue filters over alternating pixels as shown in Fig. 33–18, similar to what a color LCD TV screen does (Sections 23–10 and 34–8). The sensor type shown in Fig. 33–18 contains twice as many green pixels as red or blue, because green seems to have a stronger influence on the human eye's sensation of sharpness.



The output image from a camera provides a computer-analyzed color at many pixels, often an average with nearest-neighbor colors to reduce memory size (= compression, see Section 23–9). That is, the output image of a 12 MP camera is 12 million dots or squares, each a (computer) mixed color, not the individual colors of Fig. 33–18.

Each different color of pixel in a Bayer array is counted as a *separate* pixel. In contrast, in an LCD screen (Sections 23–10 and 34–8), a group of three subpixels is counted as one pixel, a more conservative count.

**CAUTION**
*Camera and TV pixels are counted differently*

An alternative technology, called "Foveon," uses a semiconductor layer system. Different wavelengths of light penetrate silicon to different depths, as shown in Fig. 33–19: the top layer is designed to absorb blue wavelengths, allowing green and red light to pass through. Longer wavelengths (green) are absorbed in the second layer, and the bottom layer detects the longest wavelengths (red). All three colors are detected by each "tri-pixel" site, resulting in better color resolution and fewer artifacts.

**FIGURE 33–19** A layered or "Foveon" tri-pixel that includes all three colors, arranged vertically so light can pass through all three subpixels.

## Digital Artifacts

Digital cameras can produce image artifacts (artificial effects in the image not present in the original) resulting from the electronic sensing of the image. One example using the Bayer mosaic of pixels (Fig. 33–18) is described in Fig. 33–20.

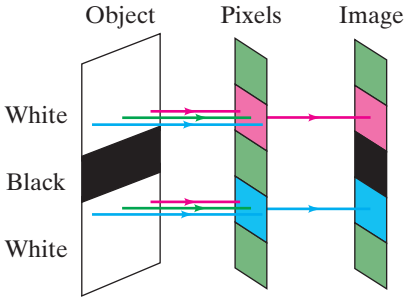


**FIGURE 33–20** Suppose we take a picture that includes a black line (our object) on a white background. The *image* of this black line on a Bayer sensor has a colored halo (red above, blue below) due to the mosaic arrangement of color filter pixels, as shown here by the colors transmitted to the image plane. Computer averaging minimizes such color problems as this (the green at top and bottom of the image may average with nearby pixels to give white or nearly so) but the image is consequently "softened" or blurred.

## Camera Adjustments

There are four main adjustments on good-quality cameras: shutter speed, *f*-stop, sensor or film sensitivity (ISO), and focusing. Although most cameras today make these adjustments automatically, it is valuable to understand these adjustments to use a camera effectively. For special or top-quality work, a manual camera is indispensable (Fig. 33–21).

**FIGURE 33–21** On this camera, the *f*-stops and the focusing ring are on the camera lens. Shutter speeds are selected on the small wheel on top of the camera body.

**Exposure time or shutter speed** This refers to how long the shutter of a camera is open and the film or sensor is exposed. It could vary from a second or more ("time exposures") to $\frac{1}{1000}$ s or faster. To avoid blurring from camera movement, exposure times shorter than $\frac{1}{100}$ s are normally needed. If the object is moving, even shorter exposure times are needed to "stop" the action ($\frac{1}{1000}$ s or less). If the exposure time is not short enough, the image will be blurred by camera shake or because objects have time to move. Blurring in low light conditions is more of a problem with cheap (or most cell-phone) cameras whose inexpensive sensors need to have the shutter open longer to collect enough light. Digital still cameras or cell phones that take short videos must have a fast enough "sampling" time and fast "clearing" (of the charge) so as to take pictures at least 15 frames per second; preferable is 24 fps (like movies) or 30, 60, or 120 fps like TV refresh rates (25, 50, or 100 in areas like Europe where 50 Hz is the normal line voltage frequency).

***f*-stop and exposure** The amount of light reaching the sensor or film depends on the area of the **lens opening** as well as shutter speed, and must be carefully controlled to avoid **underexposure** (too little light so the picture is dark and only the brightest objects show up) or **overexposure** (too much light, so that bright objects have a lack of contrast and "washed-out" appearance). A good camera may control the exposure with a "stop" or iris diaphragm, whose opening is of variable diameter, placed behind the lens (Fig. 33–17). The lens opening is controlled (automatically or manually) to compensate for bright or dark lighting conditions, the sensitivity of the sensor or film (ISO), and for different shutter speeds. The size of the opening is specified by the ***f*-stop** or ***f*-number**, defined as

$$f\text{-stop} = \frac{f}{D},$$

where $f$ is the focal length of the lens and $D$ is the diameter of the lens opening (see Fig. 33–17). For example, when a 50-mm-focal-length lens has an opening $D = 25\,\text{mm}$, then $f/D = 50\,\text{mm}/25\,\text{mm} = 2$, so we say it is set at $f/2$. When this lens is set at $f/5.6$, the opening is only $9\,\text{mm}\ (50/9 = 5.6)$. For faster shutter speeds, or low light conditions, a wider lens opening must be used to get a proper exposure, which corresponds to a smaller $f$-stop number. The smaller the $f$-stop number, the larger the opening and the more light passes through the lens to the sensor or film. The smallest $f$-number of a lens (largest opening) is referred to as the *speed* of the lens.[†] The best lenses may have a speed of $f/2.0$, or even faster. The advantage of a fast lens is that it lets more light in to take pictures under poor lighting conditions. Standard $f$-stops are

$$1.0,\ 1.4,\ 2.0,\ 2.8,\ 4.0,\ 5.6,\ 8,\ 11,\ 16,\ 22,\ \text{and}\ 32$$

(see Fig. 33–21, which only goes to $f/16$). Each of these stops corresponds to a diameter reduction by a factor of $\sqrt{2} \approx 1.4$. Because the amount of light reaching the film is proportional to the *area* of the opening, and therefore proportional to the diameter squared, each standard $f$-stop corresponds to a factor of 2 change in light intensity reaching the film. If you change the shutter speed by a factor of 2, say 1/250 to 1/500 of a second, half as much light comes in so you need to open the lens by one stop (such as $f11$ to $f8$) to get the same exposure.

**ISO** Good quality cameras have an adjustment for the sensitivity to light of the sensor or film, called the ISO number (once called ASA). On many digital cameras, you can adjust the ISO. Film, on the other hand, is manufactured to be "fast" (high ISO) or "slow" (low ISO) and you set your camera for the film chosen. For normal bright days you might prefer ISO of 100 or 200. But at night or with low light conditions, you may want a high ISO, maybe 1600 or 3200 or even higher, in order to get a good exposure. ISO is a bit like shutter speed: if you double it (say from 200 to 400) you can use one $f$-stop smaller, or double the shutter speed, and get the same exposure. To get a good exposure, you or the camera needs an "exposure meter" to measure the amount of light available. And there are trade-offs. In low light, you can: (1) slow the shutter speed, but if too slow any motion is blurred; (2) use a wider lens opening, but that will reduce depth-of-field and perhaps reduce sharpness (lens aberrations); or (3) increase the ISO (inconvenient film replacement for a film camera). A high ISO has disadvantages too: pictures are grainier or "noisier" and less sharp, and have poorer color rendition. High ISO works better for very high quality sensors whose pixels have greater "depth", meaning holding more electrons for any given light level.

**Focusing** Focusing is the operation of placing the lens at the correct position relative to the sensor or film for the sharpest image. The image distance is smallest for objects at infinity (the symbol $\infty$ is used for infinity—see Fig. 33–21) and is equal to the focal length, as we saw in Section 33–1. For closer objects, the image distance is greater than the focal length, as can be seen from the lens equation, $1/f = 1/d_o + 1/d_i$ (Eq. 33–2). To focus on nearby objects, the lens must therefore be moved away from the sensor or film (by turning a ring on the lens for a manual camera).

[†]Lens apertures and film are referred to as "fast" because they allow for faster shutter speeds.

If the lens is focused on a nearby object, a sharp image of it will be formed (a point will be a point of the image), but the image of distant objects may be blurry (Fig. 33–22). The rays from a point on the distant object will be out of focus—instead of a point, they will form a circle on the sensor or film as shown (exaggerated) in Fig. 33–23. The distant object will thus produce an image consisting of overlapping circles and will be blurred. These circles are called **circles of confusion**. To have near and distant objects sharp in the same photo, you (or the camera) can try setting the lens focus at an intermediate position. For a given distance setting, there is a range of distances over which the circles of confusion will be small enough that the images will be reasonably sharp. This is called the **depth of field**. For a sensor or film width of 36 mm (including 35-mm film cameras), the depth of field is usually based on a maximum circle of confusion diameter of 0.030 mm, even 0.02 mm or 0.01 mm for critical work or very large photographs. The depth of field varies with the lens opening. If the lens opening is smaller, only rays through the central part of the lens pass through, and these form smaller circles of confusion for a given object distance. Hence, at smaller lens openings, a greater range of object distances will fit within the circle of confusion criterion, so the depth of field is greater. Smaller lens openings, however, result in reduced resolution due to diffraction (discussed in Chapter 35). Best resolution is typically found around $f/5.6$ or $f/8$.

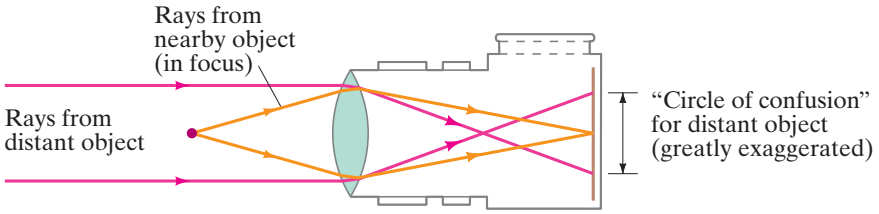

**FIGURE 33–23** When the lens is positioned to focus on a nearby object, points on a distant object produce circles and are therefore blurred. (The effect is shown greatly exaggerated.)

**CONCEPTUAL EXAMPLE 33–8** **Shutter speed.** To improve the depth of field, you "stop down" your camera lens by two *f*-stops from $f/4$ to $f/8$. What should you do to the shutter speed to maintain the same exposure?

**RESPONSE** The amount of light admitted by the lens is proportional to the area of the lens opening. Reducing the lens opening by two *f*-stops reduces the diameter by a factor of 2, and the area by a factor of $2^2 = 4$. To maintain the same exposure, the shutter must be open four times as long. If the shutter speed had been $\frac{1}{500}$ s, you would have to increase the exposure time to $\frac{1}{125}$ s.

## Picture Sharpness

The sharpness of a picture depends not only on accurate focusing and short exposure times, but also on the graininess of the film, or number of pixels on a digital sensor. Fine-grained films and tiny pixels are "slower," meaning they require longer exposures for a given light level. All pixels are rarely used because digital cameras have averaging (or "compression") programs, such as JPEG, which reduce memory size by averaging over pixels where little contrast is detected. But some detail is inevitably lost. For example, a small blue lake may seem uniform, and coding 600 pixels as identical takes less memory than specifying all 600. Any slight variation of the water surface is lost. Full "RAW" data uses more memory. Film has the advantage that it always records everything (down to its grain size) with no computer averaging. So does RAW if your camera offers it. The processor also averages over pixels in low light conditions, resulting in a less sharp photo.

The quality of the lens strongly affects the image quality, and we discuss lens resolution and diffraction effects in Sections 33–10 and 35–4. The sharpness, or **resolution**, of a lens is often given as so many lines per millimeter, measured by photographing a standard set of parallel black lines on a white background (sometimes said as "line pairs/mm") on fine-grain film or high-quality sensor, or as so many dots per inch (dpi).

**FIGURE 33–22** Photos taken with a camera lens (a) focused on a nearby object with distant object blurry, and (b) focused on a more distant object with nearby object blurry.

(a)

(b)

The minimum spacing of distinguishable lines or dots on sensor or film at the focal point gives the lens resolution. A lens that can give 50 lines/mm is reasonable, 100 lines/mm is very good (= 100 dots/mm ≈ 2500 dpi). Electronic sensors also have a resolution and it is sometimes given as line pairs across the full sensor width.

A "full" Bayer pixel (upper left in Fig. 33–18) is 4 regular pixels: for example, to make a white dot as part of a white line (between two black lines when determining lens resolution), all 4 Bayer pixels (RGGB) would have to be bright. For a Foveon, all three colors of one pixel need to be bright to produce a white dot.[†]

**EXAMPLE 33–9** **Pixels and resolution.** A 12-MP digital camera offers a maximum resolution of $4000 \times 3000$ pixels on a 32-mm × 24-mm sensor. How sharp should the lens be to make use of this resolution in RAW?

**APPROACH** We find the number of pixels per millimeter and require the lens to be at least that good.

**SOLUTION** We can take either the image height (3000 pixels in 24 mm) or the width (4000 pixels in 32 mm):

$$\frac{3000 \text{ pixels}}{24 \text{ mm}} = 125 \text{ pixels/mm}.$$

We would like the lens to match this resolution of 125 lines or dots per mm, which would be quite a good lens. If the lens is not this good, fewer pixels and less memory could be used.

**NOTE** Increasing lens resolution is a tougher problem today than is squeezing more pixels on a CCD or CMOS sensor. The sensor for high-quality cameras must also be physically larger for better image accuracy (more brightness levels, more colors, etc.) and greater light sensitivity in low light conditions.

**PHYSICS APPLIED**
*When is a photo sharp?*

**EXAMPLE 33–10** **Blown-up photograph.** A photograph looks sharp at normal viewing distances if the dots or lines are resolved to perhaps 10 dots/mm (or 250 dots/inch since 1 inch = 25 mm). Would an 8 × 10-inch enlargement of a photo taken by the camera in Example 33–9 seem sharp?

**APPROACH** We assume the image is $4000 \times 3000$ pixels on a $32 \times 24$-mm sensor as in Example 33–9, or 125 pixels/mm. We make an enlarged photo $8 \times 10$ in. = 20 cm × 25 cm.

**SOLUTION** The short side of the sensor is 24 mm = 2.4 cm long, and that side of the $8 \times 10$ inch photograph is 8 inches or 20 cm. Thus the size is increased by a factor of 20 cm/2.4 cm ≈ 8× (or 25 cm/3.2 cm ≈ 8×). To fill the 8 × 10-in. paper, we assume the enlargement is 8×. The pixels are thus enlarged 8×. So the given sensor resolution of 125 dots/mm becomes 125/8 = 15 dots/mm on the print. Hence an 8 × 10-inch print would be a sharp photograph. We could go 50% larger, $11 \times 14$ inch or even $12 \times 18$.

***Alternate Solution*** When the $24 \times 32$-mm sensor image is enlarged, the 3000 pixel side fills the short 8-inch (= 200 mm) side of the print. The resolution is 3000 dots/200 mm = 15 dots/ mm (or 375 dpi). Similar for the long side, 4000 dots/10 in. = 400 dpi.

In order to make very large photographic prints, large-format cameras are used such as 6 cm × 6 cm ($2\frac{1}{4}$ inch square)—either film or sensor—and even 4 × 5 inch and 8 × 10 inch (using sheet film or glass plates).

**EXERCISE D** The criterion of 0.030 mm as the diameter of a circle of confusion as acceptable sharpness is how many dots per mm on the camera sensor?

[†]Consider a $4000 \times 3000$-pixel array. For a Foveon, each "full pixel" (Fig. 33–19) has all 3 colors, each of which can be counted as a pixel, so it may be considered as $4000 \times 3000 \times 3 = 36$ MP. For a Bayer sensor, Fig. 33–18, $4000 \times 3000$ is 12 MP (6 MP of green, 3 MP each of red and blue). There are more green pixels because they are most important in our eyes' ability to note resolution. So the distance between green pixels is a rough guide to the sharpness of a Bayer. To match a $4000 \times 3000$ Foveon (36 MP, or 12 MP of tri-pixel sites), a Bayer would need to have about 24 MP (because it would then have 12 MP of green). This "equivalence" is only a rough approximation.

### Telephotos and Wide-Angle Lenses

Camera lenses are categorized into normal, telephoto, and wide angle, according to focal length and film size. A **normal lens** covers the sensor or film with a field of view that corresponds approximately to that of normal vision. A "normal" lens for 35-mm film has a focal length of 50 mm. The best digital cameras aim for a sensor of the same size[†] (24 mm × 36 mm). (If the sensor is smaller, digital cameras sometimes specify focal lengths to correspond with classic 35-mm cameras.) **Telephoto lenses** act like telescopes to magnify images. They have longer focal lengths than a normal lens: as we saw in Section 33–2 (Eq. 33–3), the height of the image for a given object distance is proportional to the image distance, and the image distance will be greater for a lens with longer focal length. For distant objects, the image height is very nearly proportional to the focal length. Thus a 200-mm telephoto lens for use with a 35-mm camera gives a 4× magnification over the normal 50-mm lens. A **wide-angle lens** has a shorter focal length than normal: a wider field of view is observed, and objects appear smaller. A **zoom lens** is one whose focal length can be changed (by changing the distance between the thin lenses that make up the compound lens, Section 33–10) so that you seem to zoom up to, or away from, the subject as you change the focal length.

Digital cameras may have an **optical zoom** meaning the lens can change focal length and maintain resolution. But an "electronic" or **digital zoom** just enlarges the dots (pixels) with loss of sharpness.

Different types of viewing systems are used in cameras. In some cameras, you view through a small window just above the lens as in Fig. 33–17. In a **single-lens reflex** camera (SLR or DSLR were D means digital), you actually view through the lens with the use of prisms and mirrors (Fig. 33–24). A mirror hangs at a 45° angle behind the lens and flips up out of the way just before the shutter opens. SLRs have the advantage that you can see almost exactly what you will get. Digital cameras use an electronic LCD display on the back. Some mirrorless DSLRs have a tiny electronic LCD display in the viewfinder, and it too can show what you will get on the photo if it is carefully designed.

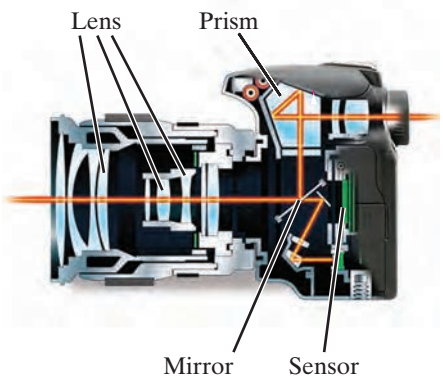

**FIGURE 33–24** Single-lens reflex (SLR) camera, showing how the image is viewed through the lens with the help of a movable mirror and prism. The ray entering the camera is split, part going through the prism to be viewed directly, part to a sensor to display on a screen on the camera back.

## 33–6 The Human Eye; Corrective Lenses

The human eye resembles a camera in its basic structure (Fig. 33–25), but is far more sophisticated. The interior of the eye is filled with a transparent gel-like substance called the *vitreous humor* with index of refraction $n = 1.337$. Light enters this enclosed volume through the cornea and lens. Between the cornea and lens is a watery fluid, the aqueous humor (*aqua* is "water" in Latin) with $n = 1.336$. A diaphragm, called the **iris** (the colored part of your eye), adjusts automatically to control the amount of light entering the eye, similar to a camera. The hole in the iris through which light passes (the **pupil**) is black because no light is reflected from it (it's a hole), and very little light is reflected back out from the interior of the eye. The **retina**, which plays the role of the film or sensor in a camera, is on the curved rear surface of the eye. The retina consists of a complex array of nerves and receptors known as *rods* and *cones* which act to change light energy into electrical signals that travel along the nerves. The reconstruction of the image from all these tiny receptors is done mainly in the brain, although some analysis may also be done in the complex interconnected nerve network at the retina itself. At the center of the retina is a small area called the **fovea**, about 0.25 mm in diameter, where the cones are very closely packed and the sharpest image and best color discrimination are found.

**PHYSICS APPLIED**
*The eye*

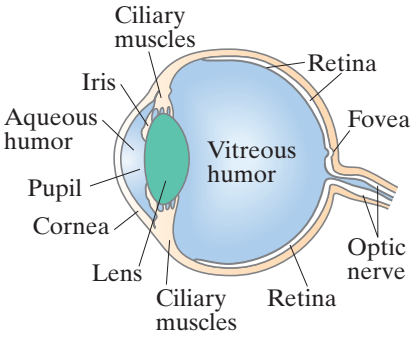

**FIGURE 33–25** Diagram of a human eye.

[†]A "35-mm camera" uses film that is physically 35 mm wide; that 35 mm is not to be confused with a focal length. 35-mm film has sprocket holes (for making and showing movies), so only 24 mm of its height is used for the photo; the width is usually 36 mm for stills. Thus one frame is 36 mm × 24 mm. Movie frames on 35-mm film are 24 mm × 18 mm.

Unlike a camera, the eye contains no shutter. The equivalent operation is carried out by the nervous system, which analyzes the signals to form images at the rate of about 30 per second. This can be compared to motion picture or television cameras, which operate by taking a series of still pictures at a rate of 24 (movies) and 60 or 30 (U.S. television) per second. Their rapid projection on the screen gives the appearance of motion.

The lens of the eye ($n = 1.386$ to 1.406) does little of the bending of the light rays. Most of the refraction is done at the front surface of the **cornea** ($n = 1.376$) at its interface with air ($n = 1.0$). The lens acts as a fine adjustment for focusing at different distances. This is accomplished by the ciliary muscles (Fig. 33–25), which change the curvature of the lens so that its focal length is changed. To focus on a distant object, the ciliary muscles of the eye are relaxed and the lens is thin, as shown in Fig. 33–26a, and parallel rays focus at the focal point (on the retina). The retina–lens distance in the eye is fixed. So, unlike a camera, the image distance in the eye is fixed. To focus on a nearby object, the ciliary muscles contract, causing the center of the lens to thicken, Fig. 33–26b, thus shortening the focal length so that images of nearby objects can be focused on the retina, behind the new focal point. This focusing adjustment is called **accommodation**.

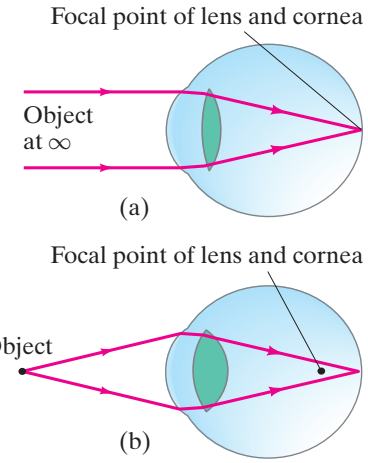

**FIGURE 33–26** Accommodation by a normal eye: (a) lens relaxed, focused at infinity; (b) lens thickened, focused on a nearby object.

The closest distance at which the eye can focus clearly is called the **near point** of the eye. For young adults it is typically 25 cm, although younger children can often focus on objects as close as 10 cm. As people grow older, the ability to accommodate is reduced and the near point increases. A given person's **far point** is the farthest distance at which an object can be seen clearly. For some purposes it is useful to speak of a **normal eye** (a sort of average over the population), defined as an eye having a near point of 25 cm and a far point of infinity. To check your own near point, place this book close to your eye and slowly move it away until the letters are sharp. If you cannot focus on this page unless it is, let's say, 55 cm away, then your near point is 55 cm; but at that distance, the letters may appear too small to read, so you need reading glasses (see below).

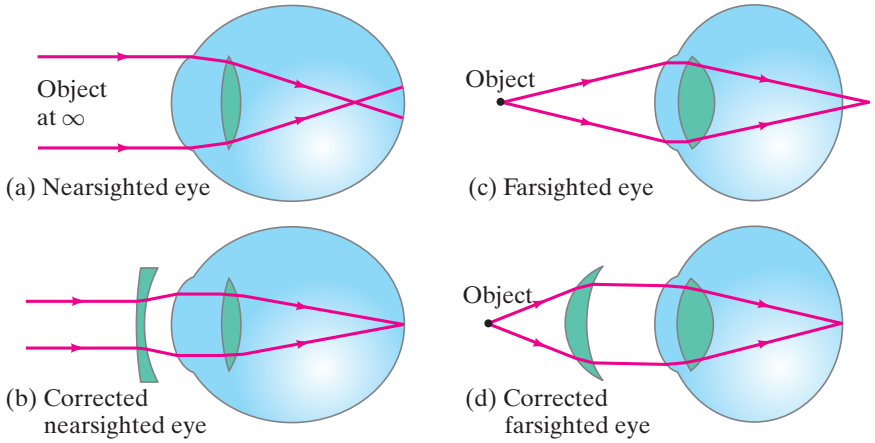
**PROBLEM SOLVING**
*Eye near point = 25 cm.*
*Far point = ∞. (Average)*

The "normal" eye is sort of an ideal. Many people have eyes that do not accommodate within the "normal" range of 25 cm to infinity, or have some other defect. Two common defects are nearsightedness and farsightedness. Both can be corrected to a large extent with lenses—either eyeglasses or contact lenses.

In **nearsightedness**, or **myopia**, the human eye can focus only on nearby objects. The far point is not infinity but some shorter distance, so distant objects are not seen clearly. Nearsightedness is usually caused by an eyeball that is too long, although sometimes it is the curvature of the cornea that is too great. In either case, images of distant objects are focused in front of the retina. A diverging lens, because it causes parallel rays to diverge, allows the rays to be focused at the retina (Figs. 33–27a and b) and thus can correct nearsightedness.

**PHYSICS APPLIED**
*Corrective lenses*

In **farsightedness**, or *hyperopia*, the eye cannot focus on nearby objects. Although distant objects are usually seen clearly, the near point is somewhat



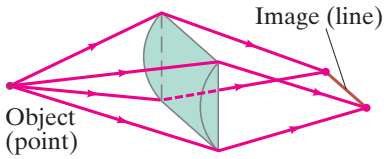


**FIGURE 33–27** Correcting eye defects with lenses. (a) A nearsighted eye, which cannot focus clearly on distant objects (focal point is in front of retina), can be corrected (b) by use of a diverging lens. (c) A farsighted eye, which cannot focus clearly on nearby objects (image point behind retina), can be corrected (d) by use of a converging lens.

greater than the "normal" 25 cm, which makes reading difficult. This defect is caused by an eyeball that is too short or (less often) by a cornea that is not sufficiently curved. It is corrected by a converging lens, Figs. 33–27c and d. Similar to hyperopia is *presbyopia*, which is the lessening ability of the eye to accommodate as a person ages, and the near point moves out. Converging lenses also compensate for this, and serve as "reading glasses" for many people.

**Astigmatism** is usually caused by an out-of-round cornea or lens so that point objects are focused as short lines, which blurs the image. It is as if the cornea was partly spherical with a cylindrical section superimposed. As shown in Fig. 33–28, a cylindrical lens focuses a point into a line parallel to its axis. An astigmatic eye may focus rays in one plane, such as the vertical plane, at a shorter distance than it does for rays in a horizontal plane. Astigmatism is corrected with the use of a compensating cylindrical lens. Lenses for eyes that are nearsighted or farsighted as well as astigmatic are ground with superimposed spherical and cylindrical surfaces, so that the radius of curvature of the correcting lens is different in different planes.

**FIGURE 33–28** A cylindrical lens forms a line image of a point object because it is converging in one plane only.

**EXAMPLE 33–11** **Farsighted eye.** A farsighted eye has a near point of 100 cm. Reading glasses must have what lens power so that a newspaper can be read at a distance of 25 cm? Assume the lens is very close to the eye.

**APPROACH** When the object is placed 25 cm from the lens ($= d_o$), we want the image to be 100 cm away on the *same* side of the lens (so the eye can focus on it), and so the image is virtual, as shown in Fig. 33–29, and $d_i = -100\,\text{cm}$ will be negative. We use the thin lens equation (Eq. 33–2) to determine the needed focal length. Optometrists' prescriptions specify the power ($P = 1/f$, Eq. 33–1) given in diopters ($1\,\text{D} = 1\,\text{m}^{-1}$).

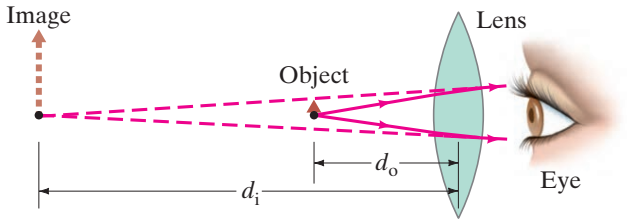

**FIGURE 33–29** Lens of reading glasses (Example 33–11).

**SOLUTION** Given that $d_o = 25\,\text{cm}$ and $d_i = -100\,\text{cm}$, the thin lens equation gives

$$\frac{1}{f} = \frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{25\,\text{cm}} + \frac{1}{-100\,\text{cm}} = \frac{4-1}{100\,\text{cm}} = \frac{1}{33\,\text{cm}}.$$

So $f = 33\,\text{cm} = 0.33\,\text{m}$. The power $P$ of the lens is $P = 1/f = +3.0\,\text{D}$. The plus sign indicates that it is a converging lens.

**NOTE** We chose the image position to be where the eye can actually focus. The lens needs to put the image there, given the desired placement of the object (newspaper).

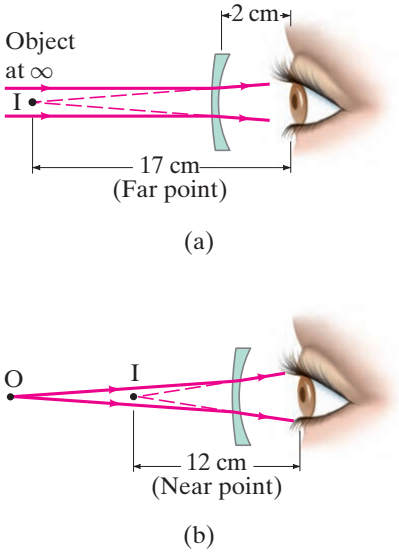

**FIGURE 33–30** Example 33–12.

**EXAMPLE 33–12** **Nearsighted eye.** A nearsighted eye has near and far points of 12 cm and 17 cm, respectively. (*a*) What lens power is needed for this person to see distant objects clearly, and (*b*) what then will be the near point? Assume that the eyeglass lens is 2.0 cm from the eye (which is typical).

**APPROACH** For a distant object $(d_o = \infty)$, the lens must put the image at the far point of the eye as shown in Fig. 33–30a, 17 cm in front of the eye. We can use the thin lens equation to find the focal length of the lens, and from this its lens power. The new near point (as shown in Fig. 33–30b) can be calculated for the lens by again using the thin lens equation.

**SOLUTION** (*a*) For an object at infinity $(d_o = \infty)$, the image must be in front of the lens 17 cm from the eye or $(17\text{ cm} - 2\text{ cm}) = 15\text{ cm}$ from the lens; hence $d_i = -15\text{ cm}$. We use the thin lens equation to solve for the focal length of the needed lens:

$$\frac{1}{f} = \frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{\infty} + \frac{1}{-15\text{ cm}} = -\frac{1}{15\text{ cm}}.$$

So $f = -15\text{ cm} = -0.15\text{ m}$ or $P = 1/f = -6.7\text{ D}$. The minus sign indicates that it must be a diverging lens for the myopic eye.

(*b*) The near point when glasses are worn is where an object is placed $(d_o)$ so that the lens forms an image at the "near point of the naked eye," namely 12 cm from the eye. That image point is $(12\text{ cm} - 2\text{ cm}) = 10\text{ cm}$ in front of the lens, so $d_i = -0.10\text{ m}$ and the thin lens equation gives

$$\frac{1}{d_o} = \frac{1}{f} - \frac{1}{d_i} = -\frac{1}{0.15\text{ m}} + \frac{1}{0.10\text{ m}} = \frac{-2 + 3}{0.30\text{ m}} = \frac{1}{0.30\text{ m}}.$$

So $d_o = 30\text{ cm}$, which means the near point when the person is wearing glasses is 30 cm in front of the lens, or 32 cm from the eye.

## Contact Lenses

**PHYSICS APPLIED**
*Contact lenses—different f and P*

Suppose contact lenses are used to correct the eye in Example 33–12. Since contacts are placed directly on the cornea, we would not subtract out the 2.0 cm for the image distances. That is, for distant objects $d_i = f = -17\text{ cm}$, so $P = 1/f = -5.9\text{ D}$. The new near point would be 41 cm $(1/d_o = -1/0.17\text{ m} + 1/0.12\text{ m} = 2.45\text{ m}^{-1})$. Thus we see that a contact lens and an eyeglass lens will require slightly different powers, or focal lengths, for the same eye because of their different placements relative to the eye. We also see that glasses in this case give a better near point than contacts.

**PHYSICS APPLIED**
*Glasses give closer near point than contact lenses*

**EXERCISE E** What power of contact lens is needed for an eye to see distant objects if its far point is 25 cm?

## Underwater Vision

**PHYSICS APPLIED**
*Underwater vision*

When your eyes are under water, distant underwater objects look blurry because at the water–cornea interface, the difference in indices of refraction is very small: $n = 1.33$ for water, 1.376 for the cornea. Hence light rays are bent very little and are focused far behind the retina, Fig. 33–31a. If you wear goggles or a face mask, you restore an air–cornea interface ($n = 1.0$ and 1.376, respectively) and the rays can be focused, Fig. 33–31b.

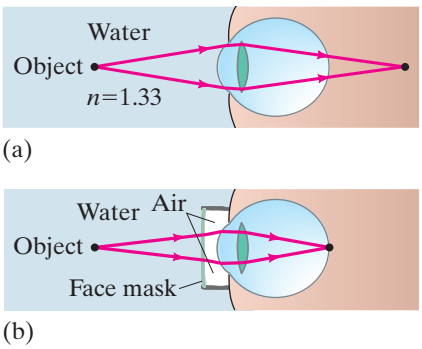

**FIGURE 33–31** (a) Under water, we see a blurry image because light rays are bent much less than in air. (b) If we wear goggles, we again have an air–cornea interface and can see clearly.

# 33–7 Magnifying Glass

Much of the remainder of this Chapter will deal with optical devices that are used to produce magnified images of objects. We first discuss the **simple magnifier**, or **magnifying glass**, which is simply a converging lens (see Chapter-Opening Photo, page 958).

How large an object appears, and how much detail we can see on it, depends on the size of the image it makes on the retina. This, in turn, depends on the angle subtended by the object at the eye. For example, a penny held 30 cm from the eye looks twice as tall as one held 60 cm away because the angle it subtends is twice as great (Fig. 33–32). When we want to examine detail on an object, we bring it up close to our eyes so that it subtends a greater angle. However, our eyes can accommodate only up to a point (the near point), and we will assume a standard distance of $N = 25\text{ cm}$ as the near point in what follows.

A magnifying glass allows us to place the object closer to our eye so that it subtends a greater angle. As shown in Fig. 33–33a, the object is placed at the focal point or just within it. Then the converging lens produces a virtual image, which must be at least 25 cm from the eye if the eye is to focus on it. If the eye is relaxed, the image will be at infinity, and in this case the object is exactly at the focal point. (You make this slight adjustment yourself when you "focus" on the object by moving the magnifying glass.)

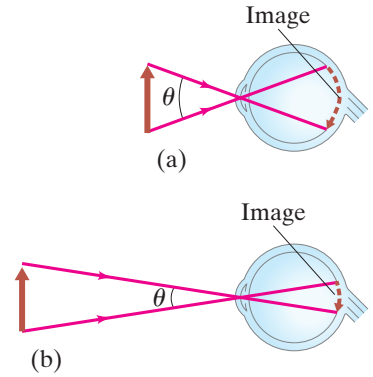

**FIGURE 33–32** When the same object is viewed at a shorter distance, the image on the retina is greater, so the object appears larger and more detail can be seen. The angle $\theta$ that the object subtends in (a) is greater than in (b). *Note*: This is not a normal ray diagram because we are showing only one ray from each point.

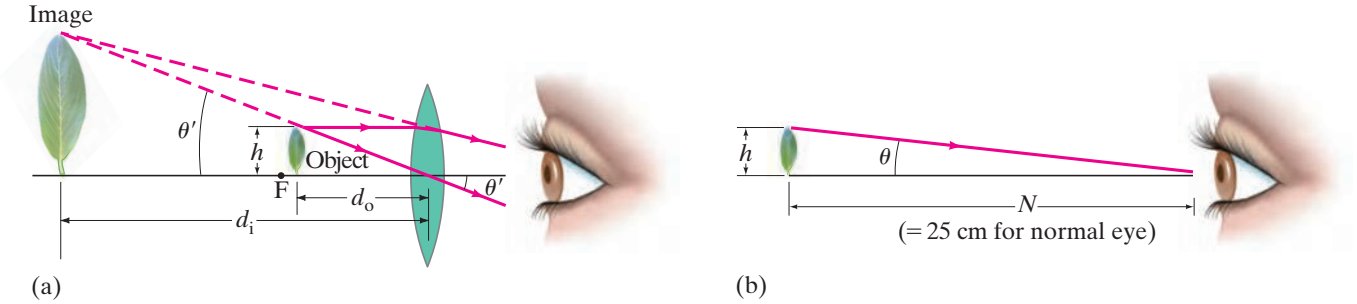

**FIGURE 33–33** Leaf viewed (a) through a magnifying glass, and (b) with the unaided eye. The eye is focused at its near point in both cases.

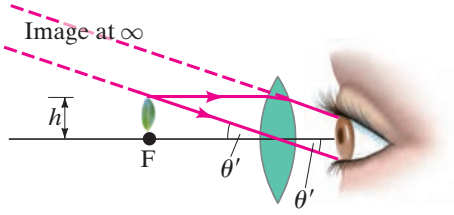
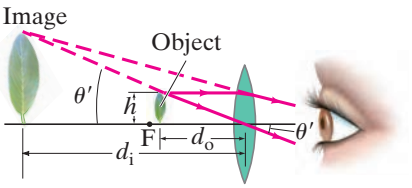
A comparison of part (a) of Fig. 33–33 with part (b), in which the same object is viewed at the near point with the unaided eye, reveals that the angle the object subtends at the eye is much larger when the magnifier is used. The **angular magnification** or **magnifying power**, $M$, of a lens is defined as the ratio of: the angle $\theta'$ subtended by an object when using the lens, to the angle $\theta$ subtended without the lens with the object at the near point $N$ of the eye ($N = 25\text{ cm}$ for a normal eye):

$$M = \frac{\theta'}{\theta}. \qquad \textbf{(33–5)}$$

The angles $\theta$ and $\theta'$ are shown in Fig. 33–33. We can write $M$ in terms of the focal length by noting that $\theta = h/N$ (Fig. 33–33b) and $\theta' = h/d_o$ (Fig. 33–33a), where $h$ is the height of the object and we assume the angles are small so $\theta$ and $\theta'$ (in radians) equal their sines and tangents. If the eye is relaxed (for least eye strain), the image will be at infinity and the object will be precisely at the focal point; see Fig. 33–34. Then $d_o = f$ and $\theta' = h/f$, whereas $\theta = h/N$ as before (Fig. 33–33b). Thus



$$M = \frac{\theta'}{\theta} = \frac{h/f}{h/N} = \frac{N}{f}. \quad \left[\begin{array}{c}\text{eye focused at } \infty;\\ N = 25\text{ cm for normal eye}\end{array}\right] \qquad \textbf{(33–6a)}$$



We see that the shorter the focal length of the lens, the greater the magnification.†

We use capital $M$ here for angular magnification, which is essentially the same $M$ we used in Chapter 32, Fig. 32–18. We need to distinguish it from lateral magnification $m$ (Eq. 33–3), which relates the image height as made by a lens or mirror to the original object height. Here, with $M$ of a magnifying glass, the human eye is involved, as it was in Sections 32–4 and 5.

†Note: Simple single-lens magnifiers are usually only 3 or 4× because of distortion due to spherical and other aberrations (Section 33–10).

**FIGURE 33–34** With the eye relaxed, the object is placed at the focal point, and the image is at infinity. Compare to Fig. 33–33a where the image is at the eye's near point.

(a)

**FIGURE 33–33a** (Repeated.)

The magnification of a given lens can be increased a bit by moving the lens and adjusting your eye so it focuses on the image at the eye's near point. In this case, $d_i = -N$ (as in Fig. 33–33a) if your eye is very near the magnifier. Then the object distance $d_o$ is given by

$$\frac{1}{d_o} = \frac{1}{f} - \frac{1}{d_i} = \frac{1}{f} + \frac{1}{N}.$$

We see from this equation that $d_o = fN/(f + N) < f$, as shown in Fig. 33–33a, since $N/(f + N)$ must be less than 1. With $\theta' = h/d_o$ the magnification is

$$M = \frac{\theta'}{\theta} = \frac{h/d_o}{h/N} = N\left(\frac{1}{d_o}\right) = N\left(\frac{1}{f} + \frac{1}{N}\right)$$

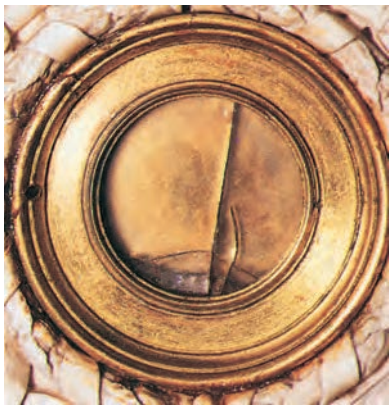
or

$$M = \frac{N}{f} + 1. \qquad \left[\begin{array}{c}\text{eye focused at near point, } N;\\ N = 25\text{ cm for normal eye;}\\ \text{magnifier near eye}\end{array}\right] \qquad \textbf{(33–6b)}$$

We see that the magnification is greater when the eye is focused at its near point, as compared to when it is relaxed. Equation 33–6b is valid only if the magnifier is near the eye. $M$ decreases if the magnifier is moved away from your eye. But Eq. 33–6a is valid even if the magnifier is not close to the eye (relaxed eye—see Fig. 33–34) as long as the object is at the focal point of the magnifier.

**EXAMPLE 33–13** ESTIMATE **A jeweler's "loupe."** An 8-cm-focal-length converging lens is used as a "jeweler's loupe," which is a magnifying glass. Estimate (*a*) the magnification when the eye is relaxed, and (*b*) the magnification if the eye is focused at its near point $N = 25$ cm.

**APPROACH** The magnification when the eye is relaxed is given by Eq. 33–6a. When the eye is focused at its near point, we use Eq. 33–6b and we assume the lens is near the eye.



**SOLUTION** (*a*) With the relaxed eye focused at infinity,

$$M = \frac{N}{f} = \frac{25\text{ cm}}{8\text{ cm}} \approx 3\times.$$

(*b*) The magnification when the eye is focused at its near point ($N = 25$ cm), and the lens is near the eye, is

$$M = 1 + \frac{N}{f} = 1 + \frac{25}{8} \approx 4\times.$$

**FIGURE 33–35** (a) Objective lens (mounted now in an ivory frame) from the telescope with which Galileo made his world-shaking discoveries, including the moons of Jupiter. (b) Telescopes made by Galileo (1609).

(a)

(b)

## 33–8 Telescopes

A telescope is used to magnify objects that are very far away. In most cases, the object can be considered to be at infinity.

Galileo, although he did not invent it,[†] developed the telescope into a usable and important instrument. He was the first to examine the heavens with the telescope (Fig. 33–35), and he made world-shaking discoveries, including the moons of Jupiter, the phases of Venus, sunspots, the structure of the Moon's surface, and that the Milky Way is made up of a huge number of individual stars.

Several types of **astronomical telescope** exist. The common **refracting** type, sometimes called **Keplerian**, contains two converging lenses located at opposite

[†]Galileo built his first telescope in 1609 after having heard of such an instrument existing in Holland. The first telescopes magnified only three to four times, but Galileo soon made a 30-power instrument. The first Dutch telescopes date from about 1604 and probably were copies of an Italian telescope built around 1590. Kepler (see Chapter 6) gave a ray description (in 1611) of the Keplerian telescope, which is named for him because he first described it, although he did not build it.

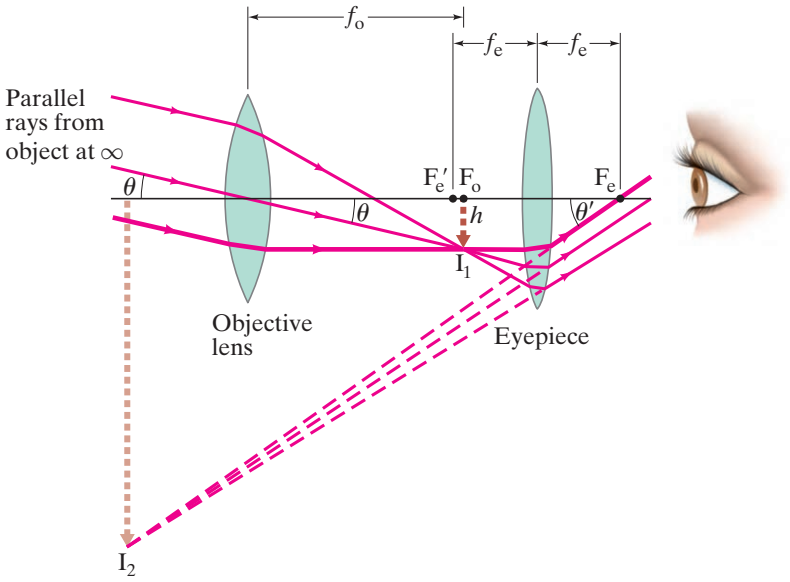


**FIGURE 33–36** Astronomical telescope (refracting). Parallel light from one point on a distant object $(d_o = \infty)$ is brought to a focus by the objective lens in its focal plane. This image $(I_1)$ is magnified by the eyepiece to form the final image $I_2$, which is inverted (and not much use for viewing objects on Earth). Only two of the rays shown entering the objective lens are standard rays (2 and 3) as described in Fig. 33–6.

ends of a long tube, as illustrated in Fig. 33–36. The lens closest to the object is called the **objective lens** (focal length $f_o$) and forms a real image $I_1$ of the distant object in the plane of its focal point $F_o$ (or near it if the object is not at infinity). The second lens, called the **eyepiece** (focal length $f_e$), acts as a magnifier. That is, the eyepiece magnifies the image $I_1$ formed by the objective lens to produce a second, greatly magnified image, $I_2$, which is virtual and inverted. (Because the image is upside-down, this type of telescope is useful only for astronomical objects.) If the viewing eye is relaxed, the eyepiece is adjusted so the image $I_2$ is at infinity. Then the real image $I_1$ is at the focal point $F_e'$ of the eyepiece, and the distance between the lenses is $f_o + f_e$ for an object at infinity.

**PROBLEM SOLVING**
*Distance between lenses = $f_o + f_e$ for relaxed eye*

To find the total angular magnification of this telescope, we note that the angle an object subtends as viewed by the unaided eye is just the angle $\theta$ subtended at the telescope objective. From Fig. 33–36 we can see that $\theta \approx h/f_o$, where $h$ is the height of the image $I_1$ and we assume $\theta$ is small so that $\tan\theta \approx \theta$. Note, too, that the thickest of the three rays drawn in Fig. 33–36 is parallel to the axis before it strikes the eyepiece and therefore is refracted through the eyepiece focal point $F_e$ on the far side of the eyepiece. Thus, $\theta' \approx h/f_e$ and the **total magnifying power** (that is, angular magnification, which is what is always quoted) of this telescope is

$$M = \frac{\theta'}{\theta} = \frac{(h/f_e)}{(h/f_o)} = -\frac{f_o}{f_e}, \qquad \left[\begin{matrix}\text{telescope}\\ \text{magnification}\end{matrix}\right] \quad \textbf{(33–7)}$$

where we used Eq. 33–5 and we inserted a minus sign to indicate that the image is inverted. To achieve a large magnification, the objective lens should have a long focal length and the eyepiece a short focal length.

In high-quality telescopes the eyepiece and objective are compound lenses, each consisting of several simple lenses to reduce aberrations (Section 33–10).

**FIGURE 33–37** This large refracting telescope was built in 1897 and is housed at Yerkes Observatory in Wisconsin. The objective lens is 102 cm (40 inches) in diameter, and the telescope tube is about 19 m long. Example 33–14.

**EXAMPLE 33–14** **Telescope magnification.** The largest optical refracting telescope in the world is located at the Yerkes Observatory in Wisconsin, Fig. 33–37. It is referred to as a "40-inch" telescope, meaning that the diameter of the objective is 40 in., or 102 cm. The objective lens has a focal length of 19 m, and the eyepiece has a focal length of 10 cm. (*a*) Calculate the total magnifying power of this telescope. (*b*) Estimate the length of the telescope.

**APPROACH** Equation 33–7 gives the magnification. The length of the telescope is the distance between the two lenses.

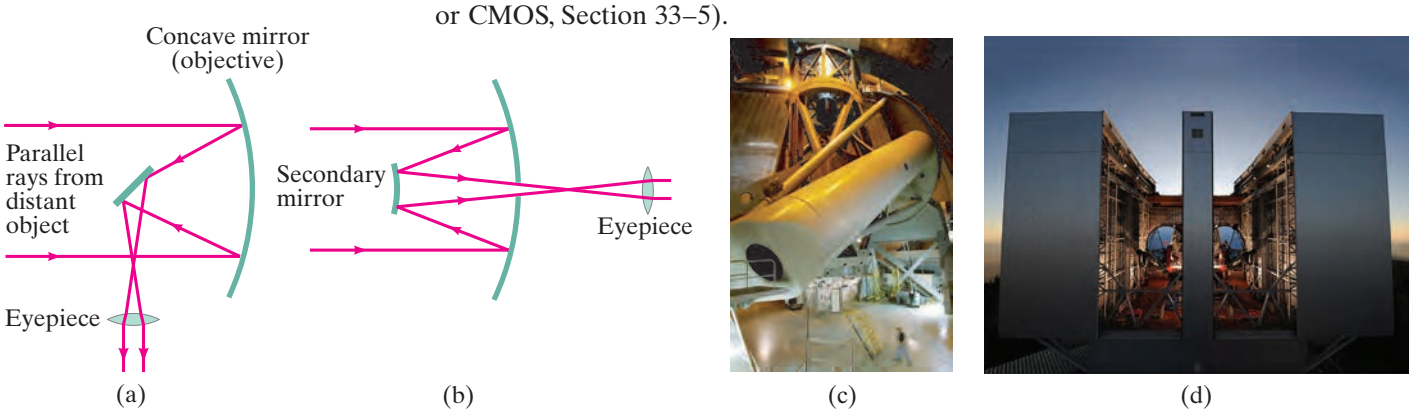
**SOLUTION** (*a*) From Eq. 33–7 we find

$$M = -\frac{f_o}{f_e} = -\frac{19\text{ m}}{0.10\text{ m}} = -190\times.$$

(*b*) For a relaxed eye, the image $I_1$ is at the focal point of both the eyepiece and the objective lenses. The distance between the two lenses is thus $f_o + f_e \approx 19$ m, which is essentially the length of the telescope.

**EXERCISE F** A 40× telescope has a 1.2-cm focal length eyepiece. What is the focal length of the objective lens?

For an astronomical telescope to produce bright images of faint stars, the objective lens must be large to allow in as much light as possible. Indeed, the diameter of the objective lens (and hence its "light-gathering power") is an important parameter for an astronomical telescope, which is why the largest ones are specified by giving the objective diameter (such as the 10-meter Keck telescope in Hawaii). The construction and grinding of large lenses is very difficult. And they would be very heavy. Therefore, the largest telescopes are **reflecting telescopes** which use a curved mirror as the objective, Fig. 33–38. A mirror has only one surface to be ground and can be supported along its entire surface† (a large lens, supported at its edges, would sag under its own weight). Often, the eyepiece lens or mirror (see Fig. 33–38) is removed so that the real image formed by the objective mirror can be recorded directly on film or on an electronic sensor (CCD or CMOS, Section 33–5).



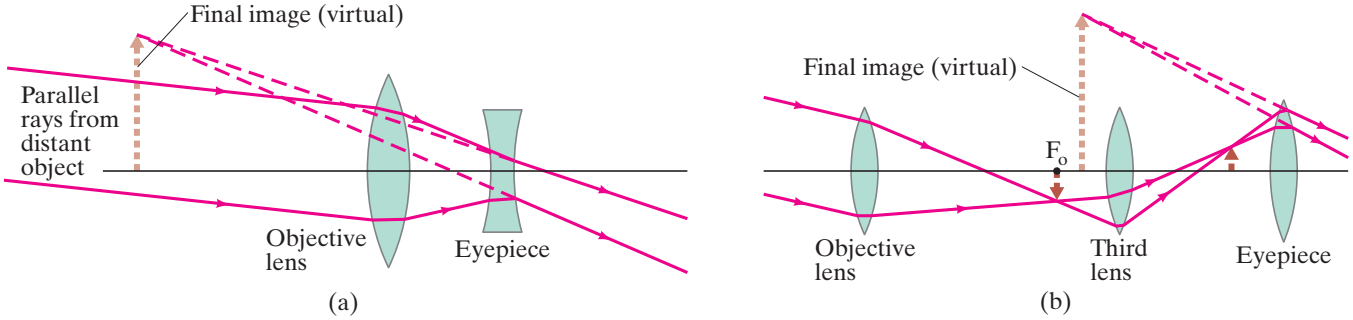


**FIGURE 33–38** A concave mirror can be used as the objective of an astronomical telescope. Arrangement (a) is called the Newtonian focus, and (b) the Cassegrainian focus. Other arrangements are also possible. (c) The 200-inch (mirror diameter) Hale telescope on Palomar Mountain in California. (d) The Large Binocular Telescope in Arizona uses two 8.4-m-diameter objective reflectors; it was constructed in Italy.

A **terrestrial telescope**, for viewing objects on Earth, must provide an upright image—seeing normal objects upside down would be difficult (much less important for viewing stars). Two designs are shown in Fig. 33–39. The **Galilean** type, which Galileo used for his great astronomical discoveries, has a diverging lens as eyepiece which intercepts the converging rays from the objective lens before they reach a focus, and acts to form a virtual upright image, Fig. 33–39a. This design is still used in opera glasses. The tube is reasonably short, but the field of view is small. The second type, shown in Fig. 33–39b, is often called a **spyglass** and makes use of a third convex lens that acts to make the image upright as shown. A spyglass must be quite long. The most practical design today is the **prism binocular** which was shown in Fig. 32–34. The objective and eyepiece are converging lenses. The prisms reflect the rays by total internal reflection and shorten the physical size of the device, and they also act to produce an upright image. One prism reinverts the image in the vertical plane, the other in the horizontal plane.

**FIGURE 33–39** Terrestrial telescopes that produce an upright image: (a) Galilean; (b) spyglass, or erector type.

†Another advantage of mirrors is that they exhibit no chromatic aberration because the light doesn't refract through them; and mirrors can be ground into a parabolic shape to correct for spherical aberration (Section 33–10). The reflecting telescope was first proposed by Newton.

# 33–9 Compound Microscope

The compound **microscope**, like the telescope, has both objective and eyepiece (or ocular) lenses, Fig. 33–40. The design is different from that for a telescope because a microscope is used to view objects that are very close, so the object distance is very small. The object is placed just beyond the objective's focal point as shown in Fig. 33–40a. The image $I_1$ formed by the objective lens is real, quite far from the objective lens, and much enlarged. The eyepiece is positioned so that this image $I_1$ (which serves as object for the eyepiece) is near the eyepiece focal point $F_e$. The image $I_1$ is magnified by the eyepiece into a very large virtual image, $I_2$, which is seen by the eye and is inverted. Modern microscopes use a third "tube" lens behind the objective, but we will analyze the simpler arrangement shown in Fig. 33–40a.

**PHYSICS APPLIED**
*Microscopes*

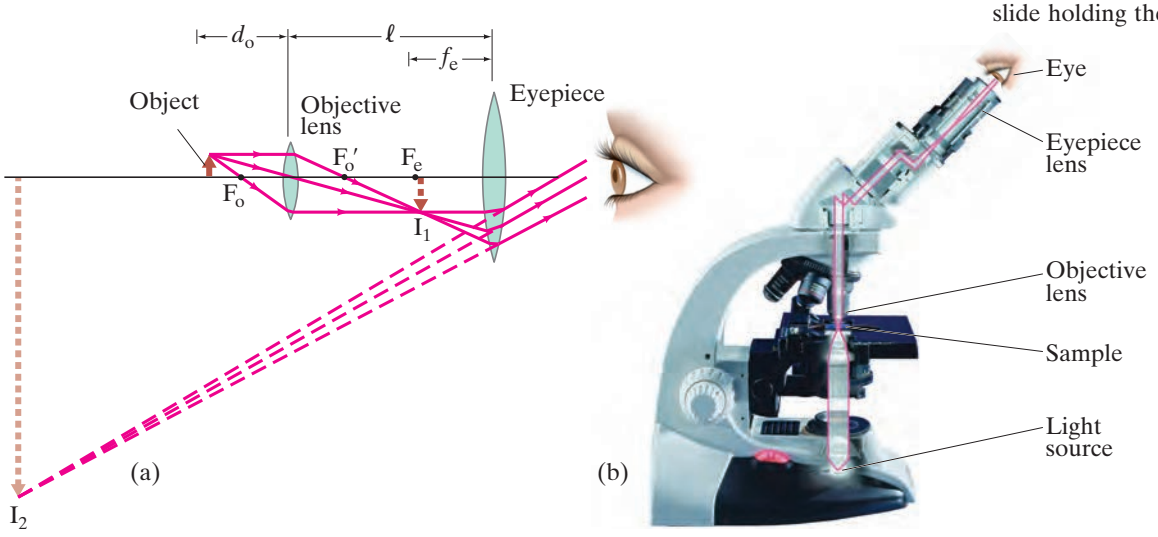

**FIGURE 33–40** Compound microscope: (a) ray diagram, (b) photograph (illumination comes from below, outlined in red, then up through the slide holding the sample or object).

The overall magnification of a microscope is the product of the magnifications produced by the two lenses. The image $I_1$ formed by the objective lens is a factor $m_o$ greater than the object itself, so we use the lateral magnification, Eq. 33–3. From Fig. 33–40a, the lateral magnification of the objective lens is

$$m_o = \frac{h_i}{h_o} = \frac{d_i}{d_o} = \frac{\ell - f_e}{d_o}, \qquad \textbf{(33–8)}$$

where $d_o$ and $d_i$ are the object and image distances for the objective lens, and $\ell$ is the distance between the lenses (equal to the length of the barrel); we ignored the minus sign in Eq. 33–3 which only tells us that the image is inverted. We wrote $d_i = \ell - f_e$, which is exact only if the eye is relaxed, so that the image $I_1$ is at the eyepiece focal point $F_e$. The eyepiece acts like a simple magnifier, so we use the angular magnification $M_e$ (Eq. 33–6a) assuming the eye is relaxed:

$$M_e = \frac{N}{f_e}, \qquad \textbf{(33–9)}$$

where the near point $N = 25\,\text{cm}$ for the normal eye. Since the eyepiece enlarges the image formed by the objective, the overall angular magnification $M$ is the product of the magnification of the objective lens, $m_o$, times the angular magnification, $M_e$, of the eyepiece lens (Eqs. 33–8 and 33–9):

$$M = M_e m_o = \left(\frac{N}{f_e}\right)\left(\frac{\ell - f_e}{d_o}\right) \qquad \left[\begin{matrix}\text{microscope}\\ \text{magnification}\end{matrix}\right] \qquad \textbf{(33–10a)}$$

$$\approx \frac{N\ell}{f_e f_o}. \qquad [f_o \text{ and } f_e \ll \ell] \qquad \textbf{(33–10b)}$$

The approximation, Eq. 33–10b, is accurate when $f_e$ and $f_o$ are small compared to $\ell$, so $\ell - f_e \approx \ell$, and the object is near $F_o$ so $d_o \approx f_o$ (Fig. 33–40a). This is a good approximation for large magnifications, which are obtained when $f_o$ and $f_e$ are very small (they are in the denominator of Eq. 33–10b). These microscope lenses of very short focal length are compound lenses involving several elements to avoid serious aberrations, as discussed in the next Section.

**EXAMPLE 33–15 Microscope.** A compound microscope consists of a 10× eyepiece and a 50× objective 17.0 cm apart. Determine (*a*) the overall magnification, (*b*) the focal length of each lens, and (*c*) the position of the object when the final image is in focus with the eye relaxed. Assume a normal eye, so $N = 25\,\text{cm}$.

**APPROACH** The overall magnification is the product of the eyepiece magnification and the objective magnification. The focal length of the eyepiece is found from Eq. 33–6a or 33–9 for the magnification of a simple magnifier. For the objective lens, it is easier to next find $d_o$ (part *c*) using Eq. 33–8 before we find $f_o$.

**SOLUTION** (*a*) The overall magnification is $(10\times)(50\times) = 500\times$.

(*b*) The eyepiece focal length is (Eq. 33–9) $f_e = N/M_e = 25\,\text{cm}/10 = 2.5\,\text{cm}$. Next we solve Eq. 33–8 for $d_o$, and find

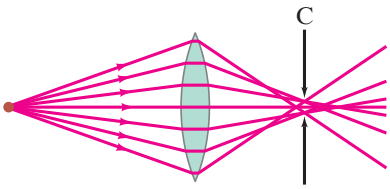
$$d_o = \frac{\ell - f_e}{m_o} = \frac{(17.0\,\text{cm} - 2.5\,\text{cm})}{50} = 0.29\,\text{cm}.$$

Then, from the thin lens equation for the objective with $d_i = \ell - f_e = 14.5\,\text{cm}$ (see Fig. 33–40a),

$$\frac{1}{f_o} = \frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{0.29\,\text{cm}} + \frac{1}{14.5\,\text{cm}} = 3.52\,\text{cm}^{-1};$$

so $f_o = 1/(3.52\,\text{cm}^{-1}) = 0.28\,\text{cm}$.

(*c*) We just calculated $d_o = 0.29\,\text{cm}$, which is very close to $f_o$.



## 33–10 Aberrations of Lenses and Mirrors

PHYSICS APPLIED
*Lens aberrations*

Earlier in this Chapter we developed a theory of image formation by a thin lens. We found, for example, that all rays from each point on an object are brought to a single point as the image point. This result, and others, were based on approximations for a thin lens, mainly that all rays make small angles with the axis and that we can use $\sin\theta \approx \theta$. Because of these approximations, we expect deviations from the simple theory, which are referred to as **lens aberrations**. There are several types of aberration; we will briefly discuss each of them separately, but all may be present at one time.

Consider an object at any point (even at infinity) on the axis of a lens with spherical surfaces. Rays from this point that pass through the outer regions of the lens are brought to a focus at a different point than those that pass through the center of the lens. This is called **spherical aberration**, and is shown exaggerated in Fig. 33–41. Consequently, any object point will have its image on a screen or film not as a point but as a tiny circular patch of light. If the sensor or film is placed at point C, as indicated, the circle will have its smallest diameter, which is referred to as the **circle of least confusion**. Spherical aberration is present whenever spherical surfaces are used. It can be reduced by using nonspherical (= aspherical) lens surfaces, but grinding such lenses is difficult and expensive. Spherical aberration can be reduced by the use of several lenses in combination (a **compound lens**), and by using primarily the central part of lenses.

**FIGURE 33–41** Spherical aberration (exaggerated). Circle of least confusion is at C.

For object points off the lens axis, additional aberrations occur. Rays passing through the different parts of the lens cause spreading of the image that is noncircular. There are two effects: **coma** (because the image of a point is comet-shaped rather than a tiny circle) and **off-axis astigmatism**.† Furthermore, the image points for objects off the axis but at the same distance from the lens do not fall on a flat plane but on a curved surface—that is, the focal plane is not flat. (We expect this because the points on a flat plane, such as the film in a camera, are not equidistant

†Although the effect is the same as for astigmatism in the eye (Section 33–6), the cause is different. Off-axis astigmatism is no problem in the eye because objects are clearly seen only at the fovea, on the lens axis.

from the lens.) This aberration is known as **curvature of field** and is a problem in cameras and other devices where the sensor or film is a flat plane. In the eye, however, the retina is curved, which compensates for this effect.

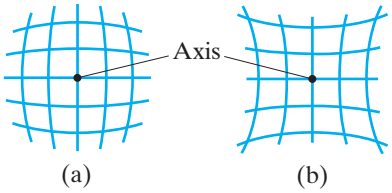
Another aberration, **distortion**, is a result of variation of magnification at different distances from the lens axis. Thus a straight-line object some distance from the axis may form a curved image. A square grid of lines may be distorted to produce *barrel distortion*, or *pincushion distortion*, Fig. 33–42. The former is common in extreme wide-angle lenses.

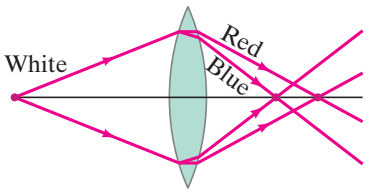
All the above aberrations occur for monochromatic light and hence are referred to as *monochromatic aberrations*. Normal light is not monochromatic, and there will also be **chromatic aberration**. This aberration arises because of dispersion—the variation of index of refraction of transparent materials with wavelength (Section 32–6). For example, blue light is bent more than red light by glass. So if white light is incident on a lens, the different colors are focused at different points, Fig. 33–43, and have slightly different magnifications resulting in colored fringes in the image. Chromatic aberration can be eliminated for any two colors (and reduced greatly for all others) by the use of two lenses made of different materials with different indices of refraction and dispersion. Normally one lens is converging and the other diverging, and they are often cemented together (Fig. 33–44). Such a lens combination is called an **achromatic doublet** (or "color-corrected" lens).

To reduce aberrations, high-quality lenses are **compound lenses** consisting of many simple lenses, referred to as **elements**. A typical high-quality camera lens may contain six to eight (or more) elements. For simplicity we will usually indicate lenses in diagrams as if they were simple lenses.

The human eye is also subject to aberrations, but they are minimal. Spherical aberration, for example, is minimized because (1) the cornea is less curved at the edges than at the center, and (2) the lens is less dense at the edges than at the center. Both effects cause rays at the outer edges to be bent less strongly, and thus help to reduce spherical aberration. Chromatic aberration is partially compensated for because the lens absorbs some of the shorter wavelengths and the retina is less sensitive to the blue and violet wavelengths. This is just the region of the spectrum where dispersion—and thus chromatic aberration—is greatest (Fig. 32–28).

Spherical mirrors (Section 32–3) also suffer aberrations including spherical aberration (see Fig. 32–13). Mirrors can be ground in a parabolic shape to correct for aberrations, but they are much harder to make and therefore very expensive. Spherical mirrors do not, however, exhibit chromatic aberration because the light does not pass through them (no refraction, no dispersion).





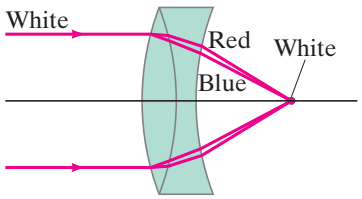


**FIGURE 33–42** Distortion: lenses may image a square grid of perpendicular lines to produce (a) barrel distortion or (b) pincushion distortion. These distortions can be seen in the photograph of Fig. 33–2d for a simple lens.

**FIGURE 33–43** Chromatic aberration. Different colors are focused at different points.

**PHYSICS APPLIED**
*Human eye*

**FIGURE 33–44** Achromatic doublet.

# Summary

A lens uses refraction to produce a real or virtual image. Parallel rays of light are focused to a point, the **focal point**, by a **converging** lens. The distance of the focal point from a thin lens is the **focal length** $f$ of the lens. It is the same on both sides of the lens.

After parallel rays pass through a **diverging** lens, they appear to diverge from a point in front of the lens, which is its focal point; and the corresponding focal length is considered negative.

The **power** $P$ of a lens, which is

$$P = \frac{1}{f} \qquad \textbf{(33–1)}$$

is given in diopters, which are units of inverse meters $(\mathrm{m}^{-1})$.

For a given object, the position and size of the image formed by a lens can be found approximately by ray tracing. Algebraically, the relation between image and object distances, $d_\mathrm{i}$ and $d_\mathrm{o}$, and the focal length $f$ of a thin lens, is given by the **thin lens equation**:

$$\frac{1}{d_\mathrm{o}} + \frac{1}{d_\mathrm{i}} = \frac{1}{f}. \qquad \textbf{(33–2)}$$

The ratio of image height to object height, which equals the **lateral magnification** $m$ for a lens, is

$$m = \frac{h_\mathrm{i}}{h_\mathrm{o}} = -\frac{d_\mathrm{i}}{d_\mathrm{o}}. \qquad \textbf{(33–3)}$$

When using the equations of geometric optics, you must remember the **sign conventions** for all quantities involved: carefully review them (page 963) when doing Problems.

When two (or more) thin lenses are used in combination to produce an image, the thin lens equation can be used for each lens in sequence. The image produced by the first lens acts as the object for the second lens.

The **lensmaker's equation** relates the radii of curvature of the lens surfaces and the lens' index of refraction to the focal length of the lens.

A **camera** lens forms an image on film, or on an electronic sensor (CCD or CMOS) in a digital camera. Light is allowed in briefly through a shutter. The image is focused by moving the lens relative to the film or sensor, and the ***f*-stop** (or lens opening) must be adjusted for the brightness of the scene and the chosen shutter speed. The *f*-stop is defined as the ratio of the focal length to the diameter of the lens opening.

The human **eye** also adjusts for the available light—by opening and closing the iris. It focuses not by moving the lens, but by using muscles to adjust the shape of the lens to vary its focal length. The image is formed on the retina, which contains an array of receptors known as rods and cones.

Diverging eyeglass or contact lenses are used to correct the defect of a nearsighted eye, which cannot focus well on distant objects. Converging lenses are used to correct for defects in which the eye cannot focus on close objects.

A **simple magnifier**, or **magnifying glass**, is a converging lens that forms a virtual image of an object placed at (or within) the focal point.

The **angular magnification**, when viewed by a relaxed eye, is

$$M = \frac{N}{f}, \qquad \textbf{(33–6a)}$$

where $f$ is the focal length of the lens and $N$ is the near point of the eye (25 cm for a "normal" eye).

An **astronomical telescope** consists of an **objective** lens or mirror, and an **eyepiece** that magnifies the real image formed by the objective. The **magnification** is equal to the ratio of the objective and eyepiece focal lengths, and the image is inverted:

$$M = -\frac{f_o}{f_e}. \qquad \textbf{(33–7)}$$

A **terrestrial telescope**, for which there are several designs, produces an upright image.

A compound **microscope** also uses objective and eyepiece lenses, and the final image is inverted. The total magnification is the product of the magnifications of the two lenses and is approximately

$$M \approx \frac{N\ell}{f_e f_o}, \qquad \textbf{(33–10b)}$$

where $\ell$ is the distance between the lenses, $N$ is the near point of the eye, and $f_o$ and $f_e$ are the focal lengths of objective and eyepiece, respectively.

Microscopes, telescopes, and other optical instruments are limited in the formation of sharp images by **lens aberrations**. These include **spherical aberration**, in which rays passing through the edge of a lens are not focused at the same point as rays that pass near the center; and **chromatic aberration**, in which different colors are focused at different points. Compound lenses, consisting of several elements, can largely correct for aberrations.

# Questions

1. Where must the film be placed if a camera lens is to make a sharp image of an object far away? Explain.
2. A photographer moves closer to his subject and then refocuses. Does the camera lens move farther away from, or closer to, the camera film or sensor? Explain.
3. Use ray diagrams to show that a real image formed by a thin lens is always inverted, whereas a virtual image is always upright if the object is real.
4. Light rays are said to be "reversible." Is this consistent with the thin lens equation? Explain.
5. A thin converging lens is moved closer to a nearby object. Does the real image formed change (*a*) in position, (*b*) in size? If yes, describe how.
6. Explain how you could have a virtual object.
7. A dog with its tail in the air stands facing a converging lens. If the nose and the tail are each focused on a screen in turn, which will have the greater magnification?
8. A cat with its tail in the air stands facing a converging lens. Under what circumstances (if any) would the image of the nose be virtual and the image of the tail be real? Where would the image of the rest of the cat be?
9. The thicker a double convex lens is in the center as compared to its edges, the shorter its focal length for a given lens diameter. Explain.
10. Consider two converging lenses separated by some distance. An object is placed so that the image from the first lens lies exactly at the focal point of the second lens. Will this combination produce an image? If so, where? If not, why not?
11. Example 33–6 shows how to use a converging lens to measure the focal length of a diverging lens. (*a*) It is said that for this to work, the converging lens must be stronger than the diverging lens. What is meant by "stronger," and why is this statement true? (*b*) Why can't you measure the focal length of a diverging lens directly?
12. A non-symmetrical lens (say, planoconvex) forms an image of a nearby object. Use the lensmaker's equation to explain if the image point changes when the lens is turned around.
13. If a glass converging lens is placed in water, its focal length in water will be (*a*) longer, (*b*) shorter, or (*c*) the same as in air. Explain.
14. (*a*) Does the focal length of a lens depend on the fluid in which it is immersed? (*b*) What about the focal length of a spherical mirror? Explain.
15. A lens is made of a material with an index of refraction $n = 1.25$. In air, it is a converging lens. Will it still be a converging lens if placed in water? Explain, using a ray diagram.
16. An underwater lens consists of a carefully shaped thin-walled plastic container filled with air. What shape should it have in order to be (*a*) converging (*b*) diverging? Use ray diagrams to support your answer.
17. Will a nearsighted person who wears corrective lenses in her glasses be able to see clearly underwater when wearing those glasses? Use a diagram to show why or why not.

18. Why can a nearsighted person, wearing distance glasses, read a book more easily by moving his glasses down a bit on his nose? [*Hint*: see paragraph on contact lenses, page 978.]

19. You can tell whether people are nearsighted or farsighted by looking at the width of their face through their glasses. If a person's face appears narrower through the glasses (Fig. 33–45), is the person farsighted or nearsighted? Try to explain, but also check experimentally with friends who wear glasses.

**FIGURE 33–45**
Question 19.

20. In attempting to discern distant details, people will sometimes squint. Why does this help?

21. Is the image formed on the retina of the human eye upright or inverted? Discuss the implications of this for our perception of objects.

22. Reading glasses use converging lenses. A simple magnifier is also a converging lens. Are reading glasses therefore magnifiers? Discuss the similarities and differences between converging lenses as used for these two different purposes.

23. Nearsighted people often look over (or under) their glasses when they want to see something small up close, like a cell phone screen. Why?

24. Why are bifocals needed mainly by older persons and not generally by younger people?

25. Why is the depth of field greater, and the image sharper, when a camera lens is "stopped down" to a larger *f*-number? (Ignore diffraction.)

26. (*a*) Describe the difference between a real image and a virtual image. (*b*) Can your eyes tell the difference? (*c*) How can you tell the difference on a ray diagram? (*d*) How could you tell the difference between a virtual image and a real image experimentally? (*e*) If you were to take a photograph of a virtual image, would you see the image in the photograph? (*f*) If you were to put a CCD digital sensor at the location of a virtual image, would the image be captured on the sensor? (*g*) Explain any differences in your answers to parts (*e*) and (*f*).

27. Digital cameras may offer an optical zoom or a digital zoom. An optical zoom uses a variable focal-length lens, so only the central part of the field of view fills the entire sensor; a digital zoom electronically includes only the central pixels of the sensor, so objects are larger in the final picture. Discuss which is better, and why.

28. Spherical aberration in a thin lens is minimized if rays are bent equally by the two surfaces. If a planoconvex lens is used to form a real image of an object at infinity, which surface should face the object? Use ray diagrams to show why.

29. For both converging and diverging lenses, discuss how the focal length for red light differs from that for violet light.

30. Describe at least four advantages of using mirrors rather than lenses for an astronomical telescope.

31. Which aberrations present in a simple lens are not present (or are greatly reduced) in the human eye?

## MisConceptual Questions

1. The focal length of a converging lens is
   (*a*) the diameter of the lens.
   (*b*) the thickness of the lens.
   (*c*) the distance from the lens at which incoming parallel rays bend to intersect at a point.
   (*d*) the distance from the lens at which all real images are formed.

2. Virtual images can be formed by
   (*a*) only mirrors.
   (*b*) only lenses.
   (*c*) only plane mirrors.
   (*d*) only curved mirrors or lenses.
   (*e*) plane and curved mirrors, and lenses.

3. Virtual images cannot be
   (*a*) seen.
   (*b*) photographed.
   (*c*) projected on a screen.
   (*d*) All of the above.
   (*e*) None of the above.

4. Thin lenses have two focal points. These are
   (*a*) always the image and object locations.
   (*b*) usually at different distances from the lens.
   (*c*) sometimes on the same side of the lens.
   (*d*) the same distance from the lens but on opposite sides.
   (*e*) one is the real image location and the other is the virtual image location.

5. The only means to create a real image with a single lens would be to place
   (*a*) the object inside the focal length of a converging lens.
   (*b*) the object inside the focal length of a diverging lens.
   (*c*) the object outside the focal length of a converging lens.
   (*d*) the object outside the focal length of a diverging lens.
   (*e*) Any of the above, given the correct distance from the focal point.

6. You cover half of a lens that is forming an image on a screen. Compare what happens when you cover the top half of the lens versus the bottom half.
   (*a*) When you cover the top half of the lens, the top half of the image disappears; when you cover the bottom half of the lens, the bottom half of the image disappears.
   (*b*) When you cover the top half of the lens, the bottom half of the image disappears; when you cover the bottom half of the lens, the top half of the image disappears.
   (*c*) The image becomes half as bright in both cases.
   (*d*) Nothing changes in either case.
   (*e*) The image disappears in both cases.

7. A lens can be characterized by its *power*, which
   (*a*) is the same as the magnification.
   (*b*) tells how much light the lens can focus.
   (*c*) depends on where the object is located.
   (*d*) is the reciprocal of the focal length.

8. Which of the following can form an image?
(*a*) A plane mirror.
(*b*) A curved mirror.
(*c*) A lens curved on both sides.
(*d*) A lens curved on only one side.
(*e*) All of the above.

9. The image of a nearby object formed by a camera lens is
(*a*) at the lens' focal point.
(*b*) always blurred.
(*c*) at the same location as the image of an object at infinity.
(*d*) farther from the lens than the lens' focal point.

10. While you are photographing a dog, it begins to move away. What must you do to keep it in focus?
(*a*) Increase the *f*-stop value.
(*b*) Decrease the *f*-stop value.
(*c*) Move the lens away from the sensor or film.
(*d*) Move the lens closer to the sensor or film.
(*e*) None of the above.

11. A converging lens, such as a typical magnifying glass,
(*a*) always produces a magnified image (image taller than the object).
(*b*) always produces an image smaller than the object.
(*c*) always produces an upright image.
(*d*) always produces an inverted image (upside down).
(*e*) None of these statements are true.

12. If the distance from your eye's lens to the retina is shorter than for a normal eye, you will struggle to see objects that are
(*a*) nearby.
(*b*) far away.
(*c*) colorful.
(*d*) moving fast.

13. When a nearsighted person looks at a distant object through her glasses, the image produced by the glasses should be
(*a*) about 25 cm from her eye.
(*b*) at her eye's far point.
(*c*) at her eye's near point.
(*d*) at the far point for a normal eye.

14. How do eyeglasses help a nearsighted person see more clearly?
(*a*) Diverging lenses bend light entering the eye, so the image focuses farther from the front of the eye.
(*b*) Diverging lenses bend light entering the eye, so the image focuses closer to the front of the eye.
(*c*) Converging lenses bend light entering the eye, so the image focuses farther from the front of the eye.
(*d*) Converging lenses bend light entering the eye, so the image focuses closer to the front of the eye.
(*e*) Lenses adjust the distance from the cornea to the back of the eye.

15. The image produced on the retina of the eye is _____ compared to the object being viewed.
(*a*) inverted
(*b*) upright
(*c*) sideways
(*d*) enlarged

16. Which of the following statements is true? (See Section 33–6.)
(*a*) Contact lenses and eyeglasses for the same person would have the same power.
(*b*) Farsighted people can see far clearly but not near.
(*c*) Nearsighted people cannot see near or far clearly.
(*d*) Astigmatism in vision is corrected by using different spherical lenses for each eye.

# Problems

## 33–1 and 33–2 Thin Lenses

1. (I) A sharp image is located 373 mm behind a 235-mm-focal-length converging lens. Find the object distance (*a*) using a ray diagram, (*b*) by calculation.

2. (I) Sunlight is observed to focus at a point 16.5 cm behind a lens. (*a*) What kind of lens is it? (*b*) What is its power in diopters?

3. (I) (*a*) What is the power of a 26.5-cm-focal-length lens? (*b*) What is the focal length of a −6.25-D lens? Are these lenses converging or diverging?

4. (II) A certain lens focuses an object 2.15 m away as an image 48.3 cm on the other side of the lens. What type of lens is it and what is its focal length? Is the image real or virtual?

5. (II) A 105-mm-focal-length lens is used to focus an image on the sensor of a camera. The maximum distance allowed between the lens and the sensor plane is 132 mm. (*a*) How far in front of the sensor should the lens (assumed thin) be positioned if the object to be photographed is 10.0 m away? (*b*) 3.0 m away? (*c*) 1.0 m away? (*d*) What is the closest object this lens could photograph sharply?

6. (II) A stamp collector uses a converging lens with focal length 28 cm to view a stamp 15 cm in front of the lens. (*a*) Where is the image located? (*b*) What is the magnification?

7. (II) It is desired to magnify reading material by a factor of 3.0× when a book is placed 9.0 cm behind a lens. (*a*) Draw a ray diagram and describe the type of image this would be. (*b*) What type of lens is needed? (*c*) What is the power of the lens in diopters?

8. (II) How far from a converging lens with a focal length of 25 cm should an object be placed to produce a real image which is the same size as the object?

9. (II) An object is located 1.35 m from an 8.0-D lens. By how much does the image move if the object is moved (*a*) 0.90 m closer to the lens, and (*b*) 0.90 m farther from the lens?

10. (II) (*a*) How far from a 75.0-mm-focal-length lens must an object be placed if its image is to be magnified 2.50× and be real? (*b*) What if the image is to be virtual and magnified 2.50×?

11. (II) Repeat Problem 10 for a −75.0-mm-focal-length lens. [*Hint*: Consider objects real or virtual (formed by some other piece of optics).]

12. (II) A 3.10-cm-high insect is 1.30 m from a 135-mm-focal-length lens. (*a*) Where is the image, how high is it, and what type is it? (*b*) What if $f = -135$ mm?

13. (II) A bright object and a viewing screen are separated by a distance of 86.0 cm. At what location(s) between the object and the screen should a lens of focal length 16.0 cm be placed in order to produce a sharp image on the screen? [*Hint*: First draw a diagram.]

14. (II) How far apart are an object and an image formed by a 78-cm-focal-length converging lens if the image is 2.95× larger than the object and is real?

15. (II) Show algebraically that the image formed by a converging lens (*a*) is real and inverted if the object is beyond the focal point $(d_o > f)$, and (*b*) is virtual and upright if the object is within the focal point $(d_o < f)$. (*c*) Next, describe the image if the object is itself an image (formed by another lens), and its position is on the opposite side of the lens from the incoming light, for $-d_o > f$, and for $0 < -d_o < f$.

16. (II) In a film projector, the film acts as the object whose image is projected on a screen (Fig. 33–46). If a 105-mm-focal-length lens is to project an image on a screen 22.5 m away, how far from the lens should the film be? If the film is 24 mm wide, how wide will the picture be on the screen?

**FIGURE 33–46** Film projector, Problem 16.

17. (III) (*a*) Show that the thin lens equation can be written in the *Newtonian form*:

$$xx' = f^2,$$

where $x$ is the distance of the object from the focal point on the front side of the lens, and $x'$ is the distance of the image to the focal point on the other side of the lens. (*b*) Calculate the location of an image if the object is placed 58.0 cm in front of a convex lens with a focal length of 36.0 cm using the standard form of the thin lens formula, and (*c*) again by using the Newtonian form, derived above.

18. (III) A bright object is placed on one side of a converging lens of focal length $f$, and a white screen for viewing the image is on the opposite side. The distance $d_T = d_i + d_o$ between the object and the screen is kept fixed, but the lens can be moved. (*a*) Show that if $d_T > 4f$, there will be two positions where the lens can be placed and a sharp image will be produced on the screen. (*b*) If $d_T < 4f$, show that there will be no lens position where a sharp image is formed. (*c*) Determine a formula for the distance between the two lens positions in part (*a*), and the ratio of the image sizes.

## 33–3 Lens Combinations

19. (II) Two 28.0-cm-focal-length converging lenses are placed 16.5 cm apart. An object is placed 35.0 cm in front of one lens. (*a*) Where will the final image formed by the second lens be located? (*b*) What is the total magnification?

20. (II) A diverging lens with $f = -36.5$ cm is placed 14.0 cm behind a converging lens with $f = 20.0$ cm. Where will an object at infinity be focused?

21. (II) A 38.0-cm-focal-length converging lens is 24.0 cm behind a diverging lens. Parallel light strikes the diverging lens. After passing through the converging lens, the light is again parallel. What is the focal length of the diverging lens? [*Hint*: First draw a ray diagram.]

22. (II) A diverging lens with a focal length of −14 cm is placed 12 cm to the right of a converging lens with a focal length of 18 cm. An object is placed 29 cm to the left of the converging lens. (*a*) Where will the final image be located? (*b*) Where will the image be if the diverging lens is 38 cm from the converging lens?

23. (II) Two lenses, one converging with focal length 20.0 cm and one diverging with focal length −10.0 cm, are placed 25.0 cm apart. An object is placed 60.0 cm in front of the converging lens. Determine (*a*) the position and (*b*) the magnification of the final image formed. (*c*) Sketch a ray diagram for this system.

24. (II) A diverging lens is placed next to a converging lens of focal length $f_C$, as in Fig. 33–14. If $f_T$ represents the focal length of the combination, show that the focal length of the diverging lens, $f_D$, is given by

$$\frac{1}{f_D} = \frac{1}{f_T} - \frac{1}{f_C}.$$

25. (II) A lighted candle is placed 36 cm in front of a converging lens of focal length $f_1 = 13$ cm, which in turn is 56 cm in front of another converging lens of focal length $f_2 = 16$ cm (see Fig. 33–47). (*a*) Draw a ray diagram and estimate the location and the relative size of the final image. (*b*) Calculate the position and relative size of the final image.

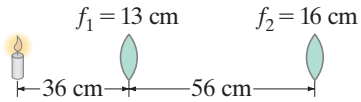

**FIGURE 33–47** Problem 25.

## 33–4 Lensmaker's Equation

26. (I) A double concave lens has surface radii of 33.4 cm and 28.8 cm. What is the focal length if $n = 1.63$?

27. (I) Both surfaces of a double convex lens have radii of 31.4 cm. If the focal length is 26.3 cm, what is the index of refraction of the lens material?

28. (II) An object is placed 96.0 cm from a glass lens $(n = 1.52)$ with one concave surface of radius 22.0 cm and one convex surface of radius 18.5 cm. (*a*) Where is the final image? (*b*) What is the magnification?

29. (II) A prescription for an eyeglass lens calls for +3.50 diopters. The lensmaker grinds the lens from a "blank" with $n = 1.56$ and convex front surface with radius of curvature of 30.0 cm. What should be the radius of curvature of the other surface?

30. (II) A symmetric double convex lens with a focal length of 20.5 cm is to be made from glass with an index of refraction of 1.52. What should be the radius of curvature for each surface?

*31. (III) Derive the lensmaker's equation (like Eq. 33–4) for a lens immersed in a liquid of index of refraction $n_1$. The lens has index of refraction $n_2$ and radii $R_1$ and $R_2$.

## 33–5 Cameras

**32.** (I) A 65-mm-focal-length lens has $f$-stops ranging from $f/1.4$ to $f/22$. What is the corresponding range of lens diaphragm diameters?

**33.** (I) A light meter reports that a camera setting of $\frac{1}{500}$ s at $f/5.6$ will give a correct exposure. But the photographer wishes to use $f/11$ to increase the depth of field. What should the shutter speed be?

**34.** (I) A television camera lens has a 17-cm focal length and a lens diameter of 6.0 cm. What is its $f$-number?

**35.** (II) A "pinhole" camera uses a tiny pinhole instead of a lens. Show, using ray diagrams, how reasonably sharp images can be formed using such a pinhole camera. In particular, consider two point objects 2.0 cm apart that are 1.0 m from a 1.0-mm-diameter pinhole. Show that on a piece of film 7.0 cm behind the pinhole the two objects produce two separate circles that do not overlap.

**36.** (II) Suppose that a correct exposure is $\frac{1}{250}$ s at $f/11$. Under the same conditions, what exposure time would be needed for a pinhole camera (Problem 35) if the pinhole diameter is 1.0 mm and the film is 7.0 cm from the hole?

**37.** (II) Human vision normally covers an angle of roughly 40° horizontally. A "normal" camera lens then is defined as follows: When focused on a distant horizontal object which subtends an angle of 40°, the lens produces an image that extends across the full horizontal extent of the camera's light-recording medium (film or electronic sensor). Determine the focal length $f$ of the "normal" lens for the following types of cameras: (*a*) a 35-mm camera that records images on film 36 mm wide; (*b*) a digital camera that records images on a digital electronic sensor 1.00 cm wide.

**38.** (II) A nature photographer wishes to shoot a 34-m-tall tree from a distance of 55 m. What focal-length lens should be used if the image is to fill the 24-mm height of the sensor?

**39.** (II) How large is the image of the Sun on a camera sensor when using (*a*) a 28-mm-focal-length lens, (*b*) a 50-mm-focal-length lens, and (*c*) a 135-mm-focal-length lens? (*d*) If the 50-mm lens is considered normal for this camera, what relative magnification does each of the other two lenses provide? The Sun has diameter $1.4 \times 10^6$ km, and it is $1.5 \times 10^8$ km away.

**40.** (II) If a 155-mm telephoto lens is designed to cover object distances from 1.30 m to $\infty$, over what distance must the lens move relative to the plane of the sensor or film?

**41.** (II) A 200-mm-focal-length lens can be adjusted so that it is 200.0 mm to 208.2 mm from the film. For what range of object distances can it be adjusted?

**42.** (III) Show that for objects very far away (assume infinity), the magnification of any camera lens is proportional to its focal length.

## 33–6 Eye and Corrective Lenses

**43.** (I) A human eyeball is about 2.0 cm long and the pupil has a maximum diameter of about 8.0 mm. What is the "speed" of this lens?

**44.** (II) One lens of a nearsighted person's eyeglasses has a focal length of −23.0 cm and the lens is 1.8 cm from the eye. If the person switches to contact lenses placed directly on the eye, what should be the focal length of the corresponding contact lens?

**45.** (II) Reading glasses of what power are needed for a person whose near point is 105 cm, so that he can read a computer screen at 55 cm? Assume a lens–eye distance of 1.8 cm.

**46.** (II) A person struggles to read by holding a book at arm's length, a distance of 55 cm away, so the print seems too small to read. What power of reading glasses should be prescribed for her, assuming they will be placed 2.0 cm from the eye and she wants to read at the "normal" near point of 25 cm?

**47.** (II) An eye is corrected by a −3.50-D lens, 2.0 cm from the eye. (*a*) Is this eye near- or farsighted? (*b*) What is this eye's far point without glasses?

**48.** (II) A person's right eye can see objects clearly only if they are between 25 cm and 88 cm away. (*a*) What power of contact lens is required so that objects far away are sharp? (*b*) What will be the near point with the lens in place?

**49.** (II) A person has a far point of 13 cm. What power glasses would correct this vision if the lenses are 2.0 cm from the eye? What power contact lenses, placed on the eye, would the person need?

**50.** (II) What is the focal length of the eye–lens system when viewing an object (*a*) at infinity, and (*b*) 45 cm from the eye? Assume that the cornea–retina distance is 2.0 cm.

**51.** (II) A nearsighted person has near and far points of 10.6 and 18.0 cm respectively. If she puts on contact lenses with power $P = -4.00$ D, what are her new near and far points?

**52.** (II) The closely packed cones in the fovea of the eye each have a diameter of about 2 $\mu$m. For the eye to discern two images on the fovea as distinct, assume that the images must be separated by at least one cone that is not excited. If these images are of two point-like objects at the eye's 25-cm near point, how far apart are these barely resolvable objects? Assume the diameter of the eye (cornea-to-fovea distance) is 2.0 cm.

**53.** (II) About how much longer is the nearsighted eye in Example 33–12 than the 2.0 cm of a normal eye?

## 33–7 Magnifying Glass

**54.** (I) A magnifier is rated at 2.5× for a normal eye focusing on an image at the near point. (*a*) What is its focal length? (*b*) What is its focal length if the 2.5× refers to a relaxed eye?

**55.** (I) What is the magnification of a lens used with a relaxed eye if its focal length is 16 cm?

**56.** (II) Sherlock Holmes is using an 8.80-cm-focal-length lens as his magnifying glass. To obtain maximum magnification, where must the object be placed (assume a normal eye), and what will be the magnification?

**57.** (II) A 3.40-mm-wide bolt is viewed with a 9.20-cm-focal-length lens placed near the eye. A normal eye views the image at its near point. Calculate (*a*) the angular magnification, (*b*) the width of the image, and (*c*) the object distance from the lens.

**58.** (II) A magnifying glass with a focal length of 9.8 cm is used to read print placed at a distance of 8.3 cm. Calculate (*a*) the position of the image; (*b*) the angular magnification.

**59.** (II) A magnifying glass is rated at 3.0× for a normal eye that is relaxed. What would be the magnification for a relaxed eye whose near point is (*a*) 57 cm, and (*b*) 17 cm? Explain the differences.

60. (II) A converging lens of focal length $f = 12\,\text{cm}$ is being used by a writer as a magnifying glass to read some fine print on his book contract. Initially, the writer holds the lens above the fine print so that its image is at infinity. To get a better look, he then moves the lens so that the image is at his 25-cm near point. How far, and in what direction (toward or away from the fine print) did the writer move the lens? Assume his eye is adjusted to remain always very near the magnifying glass.

## 33–8 Telescopes

61. (I) What is the magnification of an astronomical telescope whose objective lens has a focal length of 86 cm, and whose eyepiece has a focal length of 2.8 cm? What is the overall length of the telescope when adjusted for a relaxed eye?

62. (I) The overall magnification of an astronomical telescope is desired to be $35\times$. If an objective of 78 cm focal length is used, what must be the focal length of the eyepiece? What is the overall length of the telescope when adjusted for use by the relaxed eye?

63. (II) An $8.0\times$ binocular has 3.0-cm-focal-length eyepieces. What is the focal length of the objective lenses?

64. (II) A Galilean telescope adjusted for a relaxed eye is 33.8 cm long. If the objective lens has a focal length of 36.0 cm, what is the magnification?

65. (II) An astronomical telescope has its two lenses spaced 78.0 cm apart. If the objective lens has a focal length of 75.5 cm, what is the magnification of this telescope? Assume a relaxed eye.

66. (II) The Moon's image appears to be magnified $140\times$ by a reflecting astronomical telescope with an eyepiece having a focal length of 3.1 cm. What are the focal length and radius of curvature of the main (objective) mirror?

67. (II) What is the magnifying power of an astronomical telescope using a reflecting mirror whose radius of curvature is 6.1 m and an eyepiece whose focal length is 2.8 cm?

68. (II) A $120\times$ astronomical telescope is adjusted for a relaxed eye when the two lenses are 1.15 m apart. What is the focal length of each lens?

69. (II) An astronomical telescope longer than about 50 cm is not easy to hold by hand. Estimate the maximum angular magnification achievable for a telescope designed to be handheld. Assume its eyepiece lens, if used as a magnifying glass, provides a magnification of $5\times$ for a relaxed eye with near point $N = 25\,\text{cm}$.

70. (III) A reflecting telescope (Fig. 33–38b) has a radius of curvature of 3.25 m for its objective mirror and a radius of curvature of $-1.75\,\text{m}$ for its secondary mirror. If the distance between the two mirrors is 0.90 m, how far in front of the secondary mirror should you place the electronic sensor to record the image of a star?

71. (III) A $6.5\times$ pair of binoculars has an objective focal length of 26 cm. If the binoculars are focused on an object 4.0 m away (from the objective), what is the magnification? (The $6.5\times$ refers to objects at infinity; Eq. 33–7 holds only for objects at infinity and not for nearby ones.)

## 33–9 Microscopes

72. (I) A microscope uses an eyepiece with a focal length of 1.50 cm. Using a normal eye with a final image at infinity, the barrel length is 19.5 cm and the focal length of the objective lens is 0.65 cm. What is the magnification of the microscope?

73. (I) A $630\times$ microscope uses a 0.40-cm-focal-length objective lens. If the barrel length is 17.5 cm, what is the focal length of the eyepiece? Assume a normal eye and that the final image is at infinity.

74. (II) A microscope has a $13.0\times$ eyepiece and a $62.0\times$ objective lens 20.0 cm apart. Calculate (*a*) the total magnification, (*b*) the focal length of each lens, and (*c*) where the object must be for a normal relaxed eye to see it in focus.

75. (II) Repeat Problem 74 assuming that the final image is located 25 cm from the eyepiece (near point of a normal eye).

76. (II) A microscope has a 1.8-cm-focal-length eyepiece and a 0.80-cm objective. Assuming a relaxed normal eye, calculate (*a*) the position of the object if the distance between the lenses is 16.8 cm, and (*b*) the total magnification.

77. (II) The eyepiece of a compound microscope has a focal length of 2.80 cm and the objective lens has $f = 0.740\,\text{cm}$. If an object is placed 0.790 cm from the objective lens, calculate (*a*) the distance between the lenses when the microscope is adjusted for a relaxed eye, and (*b*) the total magnification.

78. (II) An inexpensive instructional lab microscope allows the user to select its objective lens to have a focal length of 32 mm, 15 mm, or 3.9 mm. It also has two possible eyepieces with magnifications $5\times$ and $15\times$. Each objective forms a real image 160 mm beyond its focal point. What are the largest and smallest overall magnifications obtainable with this instrument?

79. (III) Given two 12-cm-focal-length lenses, you attempt to make a crude microscope using them. While holding these lenses a distance 55 cm apart, you position your microscope so that its objective lens is distance $d_o$ from a small object. Assume your eye's near point $N = 25\,\text{cm}$. (*a*) For your microscope to function properly, what should $d_o$ be? (*b*) Assuming your eye is relaxed when using it, what magnification $M$ does your microscope achieve? (*c*) Since the length of your microscope is not much greater than the focal lengths of its lenses, the approximation $M \approx N\ell/f_e f_o$ is not valid. If you apply this approximation to your microscope, what % error do you make in your microscope's true magnification?

## 33–10 Lens Aberrations

80. (II) A planoconvex lens (Fig. 33–2a) has one flat surface and the other has $R = 15.3\,\text{cm}$. This lens is used to view a red and yellow object which is 62.0 cm away from the lens. The index of refraction of the glass is 1.5106 for red light and 1.5226 for yellow light. What are the locations of the red and yellow images formed by the lens?

81. (II) An achromatic lens is made of two very thin lenses, placed in contact, that have focal lengths $f_1 = -28\,\text{cm}$ and $f_2 = +25\,\text{cm}$. (*a*) Is the combination converging or diverging? (*b*) What is the net focal length?

# General Problems

**82.** A small object is 25.0 cm from a diverging lens as shown in Fig. 33–48. A converging lens with a focal length of 12.0 cm is 30.0 cm to the right of the diverging lens. The two-lens system forms a real inverted image 17.0 cm to the right of the converging lens. What is the focal length of the diverging lens?

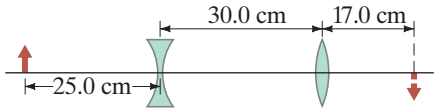

**FIGURE 33–48** Problem 82.

**83.** A converging lens with focal length of 13.0 cm is placed in contact with a diverging lens with a focal length of −18.0 cm. What is the focal length of the combination, and is the combination converging or diverging?

**84.** Figure 33–49 is a photograph of an eyeball with the image of a boy in a doorway. (*a*) Is the eye here acting as a lens or as a mirror? (*b*) Is the eye being viewed right side up or is the camera taking this photo upside down? (*c*) Explain, based on all possible images made by a convex mirror or lens.

**FIGURE 33–49** Problem 84.

**85.** Which of the two lenses shown in Fig. 33–50 is converging, and which is diverging? Explain using ray diagrams and show how each image is formed.

**FIGURE 33–50** Problem 85.

**86.** (*a*) An object 37.5 cm in front of a certain lens is imaged 8.60 cm in front of that lens (on the same side as the object). What type of lens is this, and what is its focal length? Is the image real or virtual? (*b*) If the image were located, instead, 44.5 cm in front of the lens, what type of lens would it be and what focal length would it have?

**87.** An object is placed 30.0 cm from a +5.0-D lens. A spherical mirror with focal length +25 cm is placed 65 cm behind the lens. Where is the final image? (Note that the mirror reflects light back through the lens.) Be sure to draw a diagram.

**88.** (*a*) Show that if two thin lenses of focal lengths $f_1$ and $f_2$ are placed in contact with each other, the focal length of the combination is given by $f_T = f_1 f_2/(f_1 + f_2)$. (*b*) Show that the power $P$ of the combination of two lenses is the sum of their separate powers, $P = P_1 + P_2$.

**89.** Two converging lenses are placed 30.0 cm apart. The focal length of the lens on the right is 20.0 cm, and the focal length of the lens on the left is 15.0 cm. An object is placed to the left of the 15.0-cm-focal-length lens. A final image from both lenses is inverted and located halfway between the two lenses. How far to the left of the 15.0-cm-focal-length lens is the original object?

**90.** Figure 33–51 was taken from the NIST Laboratory (National Institute of Standards and Technology) in Boulder, CO, 2.0 km from the hiker in the photo. The Sun's image was 15 mm across on the film. Estimate the focal length of the camera lens (actually a telescope). The Sun has diameter $1.4 \times 10^6$ km, and it is $1.5 \times 10^8$ km away.

**FIGURE 33–51** Problem 90.

**91.** A movie star catches a reporter shooting pictures of her at home. She claims the reporter was trespassing. To prove her point, she gives as evidence the film she seized. Her 1.75-m height is 8.55 mm high on the film, and the focal length of the camera lens was 220 mm. How far away from the subject was the reporter standing?

**92.** As early morning passed toward midday, and the sunlight got more intense, a photographer noted that, if she kept her shutter speed constant, she had to change the $f$-number from $f/5.6$ to $f/16$. By what factor had the sunlight intensity increased during that time?

**93.** A person with normal vision adjusts a microscope for a good image when her eye is relaxed. She then places a camera where her eye was. For what object distance should the camera be set? Explain.

**94.** A child has a near point of 15 cm. What is the maximum magnification the child can obtain using an 8.2-cm-focal-length magnifier? What magnification can a normal eye obtain with the same lens? Which person sees more detail?

**95.** A woman can see clearly with her right eye only when objects are between 45 cm and 175 cm away. Prescription bifocals should have what powers so that she can see distant objects clearly (upper part) and be able to read a book 25 cm away (lower part) with her right eye? Assume that the glasses will be 2.0 cm from the eye.

***96.** In a science-fiction novel, an intelligent ocean-dwelling creature's eye functions underwater with a near point of 25 cm. This creature would like to create an underwater magnifier out of a thin plastic container filled with air. What shape should the air-filled plastic container have (i.e., determine radii of curvature of its surfaces) in order for it to be used by the creature as a $3.5\times$ magnifier? Assume the eye is focused at its near point. [*Note*: see Problem 31.]

**97.** A physicist lost in the mountains tries to make a telescope using the lenses from his reading glasses. They have powers of $+2.0$ D and $+4.5$ D, respectively. (*a*) What maximum magnification telescope is possible? (*b*) Which lens should be used as the eyepiece?

**98.** A 50-year-old man uses $+2.5$-D lenses to read a newspaper 25 cm away. Ten years later, he must hold the paper 32 cm away to see clearly with the same lenses. What power lenses does he need now in order to hold the paper 25 cm away? (Distances are measured from the lens.)

**99.** An object is moving toward a converging lens of focal length $f$ with constant speed $v_o$, but its distance $d_o$ from the lens is always greater than $f$. (*a*) Determine the velocity $v_i$ of the image as a function of $d_o$. (*b*) Which direction (toward or away from the lens) does the image move? (*c*) For what $d_o$ does the image's speed equal the object's speed?

**100.** Two converging lenses, one with $f = 4.0$ cm and the other with $f = 41$ cm, are made into a telescope. (*a*) Determine the telescope's length and its magnification. Which lens should be the eyepiece? (*b*) Assume these lenses are now combined to make a microscope; if the magnification needs to be $125\times$, how long would the microscope be? Explain why the result in (*b*) is so impractical.

**101.** Both a converging lens and a concave mirror can produce virtual images that are larger than the object. Concave mirrors can be used as magnifying makeup or shaving mirrors, but converging lenses cannot be. (*a*) Draw ray diagrams to explain why not. (*b*) If a concave mirror has the same focal length as a converging lens, and an object is placed first at a distance of $\frac{1}{2}f$ from the lens and then at a distance of $\frac{1}{2}f$ from the mirror, how will the magnification of the object compare in the two cases?

**102.** What is the magnifying power of a $+4.0$-D lens used as a magnifier? Assume a relaxed normal eye.

**103.** Sam purchases $+3.70$-D eyeglasses which correct his faulty vision to put his near point at 25 cm. (Assume he wears the lenses 2.0 cm from his eyes.) (*a*) Calculate the focal length of Sam's glasses. (*b*) Calculate Sam's near point without glasses. (*c*) Pam, who has normal eyes with near point at 25 cm, puts on Sam's glasses. Calculate Pam's near point with Sam's glasses on.

**104.** The proper functioning of certain optical devices (e.g., optical fibers and spectrometers) requires that the input light be a collection of diverging rays within a cone of half-angle $\theta$ (Fig. 33–52). If the light initially exists as a collimated beam (i.e., parallel rays), show that a single lens of focal length $f$ and diameter $D$ can be used to create the required input light if $D/f = 2\tan\theta$. If $\theta = 3.5°$ for a certain device, what focal length lens should be used if the lens diameter is 5.0 cm?

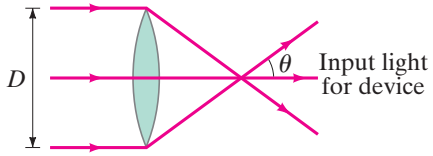

**FIGURE 33–52** Problem 104.

**105.** The power of one lens in a pair of eyeglasses is $-3.5$ D. The radius of curvature of the outside surface is 14.0 cm. What is the radius of curvature of the inside surface? The lens is made of plastic with $n = 1.62$.

**106.** Draw ray diagrams for the following two cases: (*a*) A 10-mm-high object 100 mm from a 40-mm-focal-length converging lens. (*b*) A 10-mm-high object 100 mm from a 40-mm-focal-length convex mirror.

**107.** Figure 33–53 shows a converging lens held above three equal-sized letters A. In (a) the lens is 5 cm from the paper, and in (b) the lens is 15 cm from the paper. Estimate the focal length of the lens. What is the image position for each case?

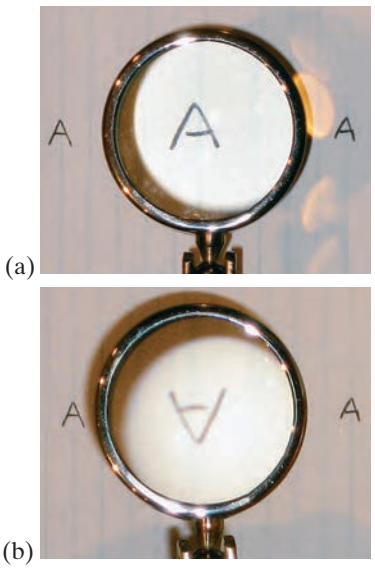

**FIGURE 33–53** Problem 107

**108.** An astronomical telescope, Fig. 33–36, produces an inverted image. One way to make a telescope that produces an upright image is to insert a third lens between the objective and the eyepiece, Fig. 33–39b. To have the same magnification, the non-inverting telescope will be longer. Suppose lenses of focal length 150 cm, 1.5 cm, and 10 cm are available. Where should these three lenses be placed to make a non-inverting telescope with magnification 100×?

**109.** An object is placed so it is touching one surface of a thin lens. Where is the image in this case (i.e., when $d_o$ approaches 0)?

**110.** Students in a physics lab are assigned to find the location where a bright object may be placed in order that a converging lens with $f = 12\,\text{cm}$ will produce an image three times the size of the object. Two students complete the assignment at different times using identical equipment, but when they compare notes later, they discover that their answers for the object distance are not the same. Explain why they do not necessarily need to repeat the lab, and justify your response with a calculation.

**111.** Redo Examples 33–9 and 33–10 assuming the sensor has only 6 MP. Explain the different results and their impact on finished photographs.

**112.** The focal length $f$ of a converging lens can be found by placing an object of known size at various locations in front of the lens and measuring the resulting real-image distances $d_i$ and their associated magnifications $m$ (minus sign indicates that image is inverted). The data taken in such an experiment are given here:

| $d_i$ (cm) | 20 | 25 | 30 | 35 | 40 |
|---|---|---|---|---|---|
| $m$ | −0.43 | −0.79 | −1.14 | −1.50 | −1.89 |

(*a*) Show algebraically that a graph of $m$ vs. $d_i$ should produce a straight line. What are the theoretically expected values for the slope and the $y$-intercept of this line? [*Hint*: $d_o$ is not constant.] (*b*) Using the data above, graph $m$ vs. $d_i$ and show that a straight line does indeed result. Use the slope of this line to determine the focal length of the lens. Does the $y$-intercept of your plot have the expected value?

**113.** A telephoto lens system obtains a large magnification in a compact package. A simple such system can be constructed out of two lenses, one converging and one diverging, of focal lengths $f_1$ and $f_2 = -\frac{1}{2}f_1$, respectively, separated by a distance $\ell = \frac{3}{4}f_1$ as shown in Fig. 33–54. (*a*) For a distant object located at distance $d_o$ from the first lens, show that the first lens forms an image with lateral magnification $m_1 \approx -f_1/d_o$ located very close to its focal point. Go on to show that the total magnification for the two-lens system is $m \approx -2f_1/d_o$. (*b*) For an object located at infinity, show that the two-lens system forms an image that is a distance $\frac{5}{4}f_1$ behind the first lens. (*c*) A single 250-mm-focal-length thin lens would have to be mounted about 250 mm from a camera's film in order to produce an image of a distant object at $d_o$ with magnification $-(250\,\text{mm})/d_o$. To produce an image of this object with the same magnification using the two-lens system, what value of $f_1$ should be used and how far in front of the film should the first lens be placed? How much smaller is the "focusing length" (i.e., first lens-to-final image distance) of this two-lens system in comparison with the 250-mm "focusing length" of the equivalent single lens?

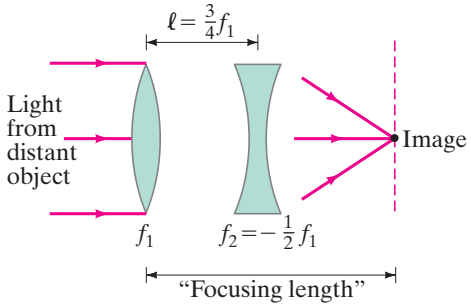

**FIGURE 33–54** Problem 113.

## ANSWERS TO EXERCISES

**A:** Closer to it.
**B:** (*b*) and (*d*) are true.
**C:** Use Table 32–1: $f = 1/[(0.50)(0 - 1/18.4\,\text{cm})] = -37\,\text{cm}$; diverging.
**D:** 33 dots/mm.
**E:** $P = -4.0\,\text{D}$.
**F:** 48 cm.

The beautiful colors from the surface of this soap bubble can be nicely explained by the wave theory of light. A soap bubble is a very thin spherical film filled with air. Light reflected from the outer and inner surfaces of this thin film of soapy water interferes constructively to produce the bright colors. Which color we see at any point depends on the thickness of the soapy water film at that point and also on the viewing angle. Near the top of the bubble, we see a small black area surrounded by a silver or white area. The bubble's thickness is smallest at that black spot, perhaps only about 30 nm thick, and is fully transparent (we see the black background).

We cover fundamental aspects of the wave nature of light, including two-slit interference, interference in thin films, polarization and its applications, and lumens.

CHAPTER 34

# The Wave Nature of Light: Interference and Polarization

**CHAPTER-OPENING QUESTION—Guess now!**

When a thin layer of oil lies on top of water or wet pavement, you can often see swirls of color. We also see swirls of color on the soap bubble shown above. What causes these colors?

**(a)** Additives in the oil or soap reflect various colors.
**(b)** Chemicals in the oil or soap absorb various colors.
**(c)** Dispersion due to differences in index of refraction in the oil or soap.
**(d)** The interactions of the light with a thin boundary layer where the oil (or soap) and the water have mixed irregularly.
**(e)** Light waves reflected from the top and bottom surfaces of the thin oil or soap film can add up constructively for particular wavelengths.

Light carries energy. You can feel it on your skin on a hot day. Also you may have noted that focusing the Sun's rays with a magnifying glass on a piece of paper can burn a hole in it. But how does light travel, and in what form is this energy carried? In our discussion of waves in Chapter 15, we noted that energy can be carried from place to place in basically two ways: by particles or by waves. In the first case, material objects or particles can carry energy, such as an avalanche of rocks or rushing water. In the second case, water waves and sound waves, for example, can carry energy over long distances even though the oscillating particles of the medium do not travel these distances.

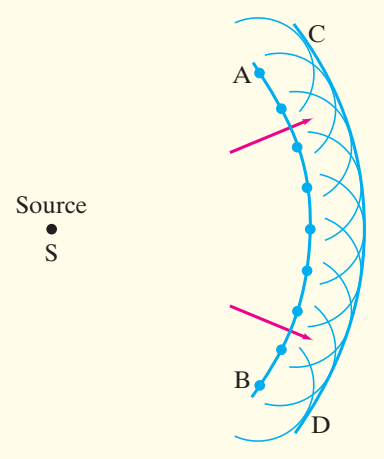
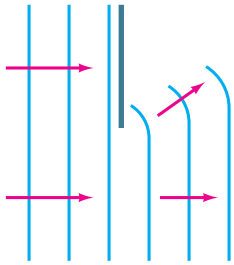
What can we say about the nature of light: does light travel as a stream of particles away from its source, or does light travel in the form of waves that spread outward from the source?

Historically, this question has turned out to be a difficult one. For one thing, light does not reveal itself in any obvious way as being made up of tiny particles; nor do we see tiny light waves passing by as we do water waves. The evidence seemed to favor first one side and then the other until about 1830, when most physicists had accepted the wave theory. By the end of the nineteenth century, light was considered to be an *electromagnetic wave* (Chapter 31). In the early twentieth century, light was shown to have a particle nature as well, as we shall discuss in Chapter 37. We now speak of the wave–particle duality of light. The wave theory of light remains valid and has proved very successful. In this Chapter we investigate the evidence for the wave theory and how it has been used to explain a wide range of phenomena.





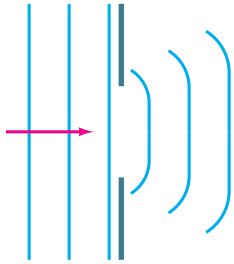


**FIGURE 34–1** Huygens' principle, used to determine wave front CD when wave front AB is given.

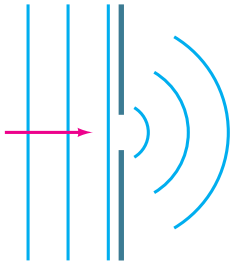

**FIGURE 34–2** Huygens' principle is consistent with diffraction (a) around the edge of an obstacle, (b) through a large hole, (c) through a small hole whose size is on the order of the wavelength of the wave.

## 34–1 Waves vs. Particles; Huygens' Principle and Diffraction

The Dutch scientist Christian Huygens (1629–1695), a contemporary of Newton, proposed a wave theory of light that had much merit. Still useful today is a technique Huygens developed for predicting the future position of a wave front when an earlier position is known. By a **wave front**, we mean all the points along a two- or three-dimensional wave that form a wave *crest*—what we often just call a "wave" as seen on the ocean. Wave fronts are perpendicular to rays as discussed in Chapter 15 (Fig. 15–20). **Huygens' principle** can be stated as follows: *Every point on a wave front can be considered as a source of tiny wavelets that spread out in the forward direction at the speed of the wave itself. The new wave front is the envelope of all the wavelets*—that is, *the tangent to all of them*.

As an example of the use of Huygens' principle, consider the wave front AB in Fig. 34–1, which is traveling away from a source S. We assume the medium is *isotropic*—that is, the speed $v$ of the waves is the same in all directions. To find the wave front a short time $t$ after it is at AB, tiny circles are drawn at points along AB with radius $r = vt$. The centers of these tiny circles are shown as blue dots on the original wave front AB, and the circles represent Huygens' (imaginary) wavelets. The tangent to all these wavelets, the curved line CD, is the new position of the wave front after a time $t$.

Huygens' principle is particularly useful for analyzing what happens when waves run into an obstacle and the wave fronts are partially interrupted. Huygens' principle predicts that waves bend in behind an obstacle, as shown in Fig. 34–2. This is just what water waves do, as we saw in Chapter 15 (Figs. 15–31 and 15–32). The bending of waves behind obstacles into the "shadow region" is known as **diffraction**. Since diffraction occurs for waves, but not for particles, it can serve as one means for distinguishing the nature of light.

Note, as shown in Fig. 34–2, that diffraction is most prominent when the size of the opening is on the order of the wavelength of the wave. If the opening is much larger than the wavelength, diffraction may go unnoticed.

Does light exhibit diffraction? In the mid-seventeenth century, the Jesuit priest Francesco Grimaldi (1618–1663) had observed that when sunlight entered a darkened room through a tiny hole in a screen, the spot on the opposite wall was larger than would be expected from geometric rays. He also observed that the border of the image was not clear but was surrounded by colored fringes. Grimaldi attributed this to the diffraction of light.

The wave model of light nicely accounts for diffraction, and we discuss diffraction in detail in the next Chapter. But the ray model (Chapter 32) cannot account for diffraction, and it is important to be aware of such limitations to the ray model. Geometric optics using rays is successful in a wide range of situations only because normal openings and obstacles are much larger than the wavelength of the light, and so relatively little diffraction or bending occurs.

# 34–2 Huygens' Principle and the Law of Refraction; Mirages

The laws of reflection and refraction were well known in Newton's time. The law of reflection could not distinguish between the two theories we just discussed: waves versus particles. For when waves reflect from an obstacle, the angle of incidence equals the angle of reflection (Fig. 15–21). The same is true of particles—think of a tennis ball without spin striking a flat surface.

The law of refraction is another matter. Consider a ray of light entering a medium where it is bent toward the normal, as when traveling from air into water. As shown in Fig. 34–3, this bending can be constructed using Huygens' principle if we assume the speed of light is less in the second medium $(v_2 < v_1)$. In time $t$, point B on wave front AB (perpendicular to the incoming ray) travels a distance $v_1 t$ to reach point D. Point A on the wave front, traveling in the second medium, goes a distance $v_2 t$ to reach point C, and $v_2 t < v_1 t$. Huygens' principle is applied to points A and B to obtain the curved wavelets shown at C and D. The wave front is tangent to these two wavelets, so the new wave front is the line CD. Hence the rays, which are perpendicular to the wave fronts, bend toward the normal if $v_2 < v_1$, as drawn.

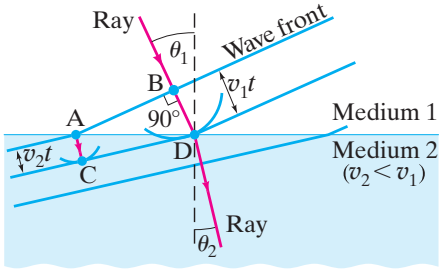

**FIGURE 34–3** Refraction explained, using Huygens' principle. Wave fronts are perpendicular to the rays.

Newton favored a particle theory of light which predicted the opposite result, that the speed of light would be greater in the second medium $(v_2 > v_1$ if $\theta_2 < \theta_1)$. Thus the wave theory predicts that the speed of light in water, for example, is less than in air; and Newton's particle theory predicts the reverse. An experiment to actually measure the speed of light in water was performed in 1850 by the French physicist Jean Foucault, and it confirmed the wave-theory prediction. By then, however, the wave theory was already fully accepted because of interference phenomena, as we shall see in the next Section.

Snell's law of refraction follows directly from Huygens' principle, given that the speed of light $v$ in any medium is related to the speed in a vacuum, $c$, and the index of refraction, $n$, by Eq. 32–4: that is, $v = c/n$. From the Huygens' construction of Fig. 34–3, angle ADC is equal[†] to $\theta_2$ and angle BAD is equal to $\theta_1$. Then for the two triangles that have the common side AD, we have

$$\sin\theta_1 = \frac{v_1 t}{\text{AD}}, \qquad \sin\theta_2 = \frac{v_2 t}{\text{AD}}.$$

We divide these two equations and obtain

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{v_1}{v_2}.$$

Then, by Eq. 32–4, $v_1 = c/n_1$ and $v_2 = c/n_2$, so we have

$$n_1 \sin\theta_1 = n_2 \sin\theta_2,$$

which is Snell's law of refraction, Eq. 32–5. (The law of reflection can be derived from Huygens' principle in a similar way: Problem 1 at the end of this Chapter.)

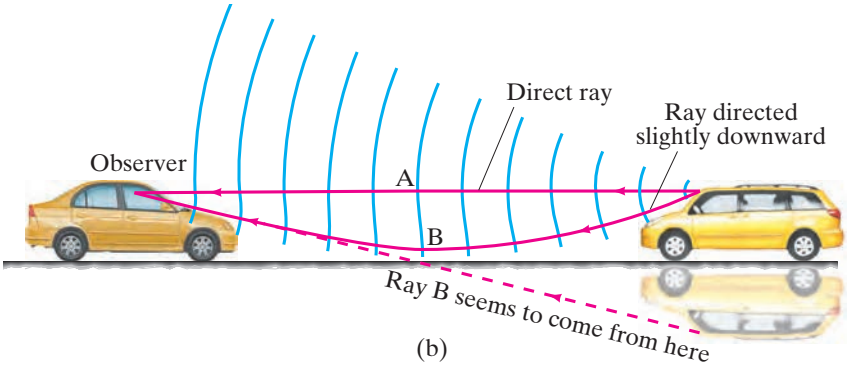
When a light wave travels from one medium to another, its frequency is not affected, but its wavelength does change. This can be seen from Fig. 34–3, where each of the blue lines representing a wave front corresponds to a crest (peak) of the wave. Then

$$\frac{\lambda_2}{\lambda_1} = \frac{v_2 t}{v_1 t} = \frac{v_2}{v_1} = \frac{n_1}{n_2},$$

where, in the last step, we used Eq. 32–4, $v = c/n$. If medium 1 is a vacuum (or air), we have $n_1 = 1$ and $v_1 = c$, and we call $\lambda_1$ simply $\lambda$, then the wavelength in another medium of index of refraction $n\ (= n_2)$ will be

$$\lambda_n = \frac{\lambda}{n}. \qquad \textbf{(34–1)}$$

This result is consistent with the frequency $f$ being unchanged no matter what medium the wave is traveling in, since $c = f\lambda$.



**CAUTION**
*Frequency is fixed, wavelength can change*

**EXERCISE A** A light beam in air, with wavelength = 500 nm, frequency = $6.0 \times 10^{14}$ Hz, and speed = $3.0 \times 10^8$ m/s, goes into glass which has an index of refraction = 1.5. What are the wavelength, frequency, and speed of the light in the glass?

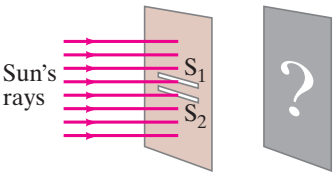
[†]Right sides of the 2 angles are perpendicular, the left sides are perpendicular: see Appendix page A–2, Fig. A–2.

(a)

(b)

**FIGURE 34–4** (a) A highway mirage (there is not really water on the road). (b) Drawing (greatly exaggerated) showing wave fronts and rays to explain highway mirages. Note how sections of the wave fronts near the ground are slightly farther apart, which means they are moving faster.

**PHYSICS APPLIED**
*Highway mirages*



Wave fronts can be used to explain how **mirages** are produced by refraction of light. For example, on a hot day motorists sometimes see a mirage of water on the highway ahead of them, with distant vehicles seemingly reflected in it (Fig. 34–4a). On a hot day, there can be a layer of very hot air next to the roadway (made hot by the Sun beating down on the road). Hot air is less dense than cooler air, so the index of refraction is slightly lower in the hot air. In Fig. 34–4b, we see a diagram of light coming from one point on a distant car (on the right) heading left toward the observer. Wave fronts and two rays (perpendicular to the wave fronts) are shown. Ray A heads directly at the observer and follows a straight-line path, and represents the normal view of the distant car. Ray B is a ray initially directed slightly downward but, instead of hitting the road, it refracts slightly as it moves through layers of air of different index of refraction. The wave fronts, shown in blue in Fig. 34–4b, move slightly faster in the layers of (less dense) air nearer the ground. Thus ray B is bent as shown, and seems to the observer to be coming from below (dashed line) as if reflected off the road. Hence the mirage.

## 34–3 Interference—Young's Double-Slit Experiment

In 1801, the Englishman Thomas Young (1773–1829) obtained convincing evidence for the wave nature of light and was even able to measure wavelengths for visible light. Figure 34–5a shows a schematic diagram of Young's famous double-slit experiment. To have light from a single source, Young used the sunlight passing through a very narrow slit in a window covering. This beam of parallel rays falls on a screen containing two closely spaced slits, $S_1$ and $S_2$. (The slits and their separation are very narrow, not many times greater than the wavelength of the light.) If light consists of tiny particles, we would expect to see two bright lines on a screen placed behind the slits as in (b). But instead, a series of bright lines are seen as in (c). Young was able to explain this result as a **wave-interference** phenomenon.

To understand why, consider **plane waves**† of light of a single wavelength—called **monochromatic**, meaning "one color"—falling on the two slits as shown in Fig. 34–6. Because of diffraction, the waves leaving the two small slits spread out as shown. This is equivalent to the interference pattern produced when two rocks are thrown into a lake (Fig. 15–23), or when sound from two loudspeakers interferes (Fig. 16–15). Recall Section 15–8 on wave interference.

**FIGURE 34–5** (a) Young's double-slit experiment. The slits and their separation need to be very thin. (b) If light consists of particles, we would expect to see two bright lines on the screen behind the slits. (c) In fact, many lines are observed.

(a) Viewing screen

(b) Viewing screen (particle theory prediction)

(c) Viewing screen (actual)

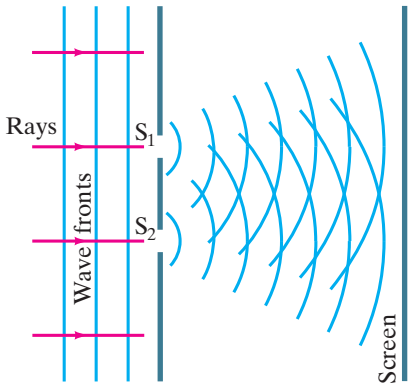


**FIGURE 34–6** Plane waves (parallel flat wave fronts) fall on two slits. If light is a wave, light passing through one of two slits should interfere with light passing through the other slit.

†See Figs. 15–20 and 31–8, pages 443 and 904.

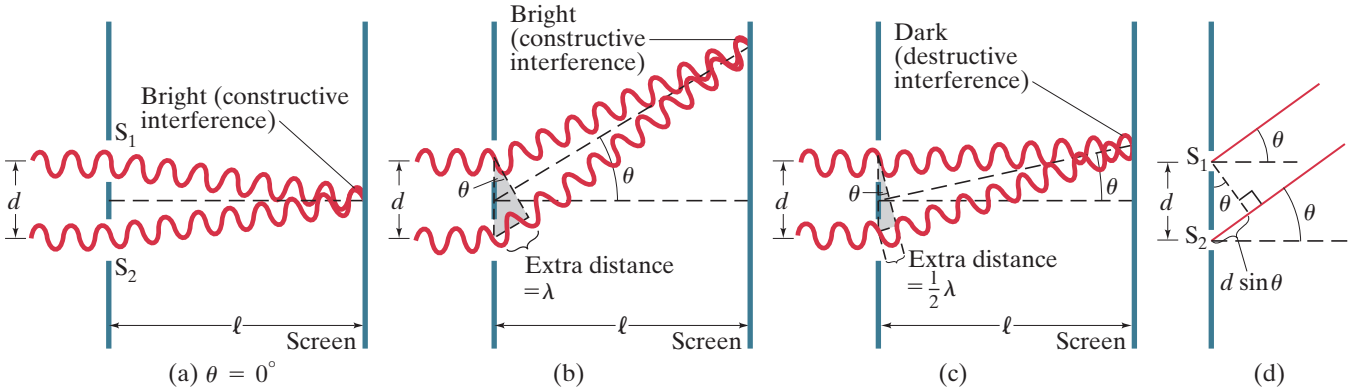

**FIGURE 34–7** How the wave theory explains the pattern of lines seen on a viewing screen due to a double-slit experiment. (a) At the center of the screen, the waves from each slit travel the same distance and are in phase. [Assume $\ell \gg d$.] (b) At this angle $\theta$, the lower wave travels an extra distance of one whole wavelength, and the waves are in phase; note from the shaded triangle that the path difference equals $d \sin\theta$. (c) For this angle $\theta$, the lower wave travels an extra distance equal to one-half wavelength, so the two waves arrive at the screen fully out of phase. (d) A more detailed diagram showing the geometry for parts (b) and (c).

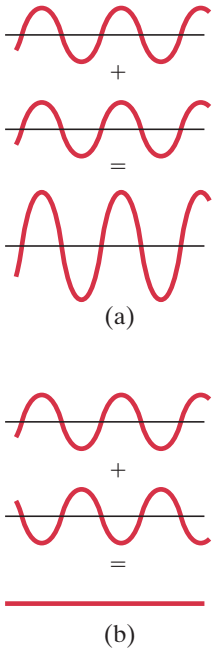
To see how an interference pattern is produced on the screen, we make use of Fig. 34–7. Waves of wavelength $\lambda$ are shown entering the slits $S_1$ and $S_2$, which are a distance $d$ apart. The waves continually spread out in all directions after passing through the slits (Fig. 34–6), but they are shown in Fig. 34–7a, b, and c only for three different angles $\theta$. In Fig. 34–7a, the waves reaching the center of the screen are shown ($\theta = 0°$). Waves from the two slits travel the same distance, so they are always **in phase**: crests of one wave arrive at the same time as crests of the other wave. Hence the amplitudes of the two waves add to form a larger amplitude as shown in Fig. 34–8a. This is **constructive interference**, and there is a bright line at the center of the screen. Constructive interference also occurs when the paths of the two rays differ by one wavelength (or any whole number of wavelengths), as shown in Fig. 34–7b; also here there will be a bright line on the screen. But if one ray travels an extra distance of one-half wavelength (or $\frac{3}{2}\lambda$, $\frac{5}{2}\lambda$, and so on), the two waves are always exactly **out of phase** (Section 15–8) when they reach the screen: the crests of one wave arrive at the same time as the troughs of the other wave, and so they add to produce zero amplitude (Fig. 34–8b). This is **destructive interference**, and the screen is dark, Fig. 34–7c. Thus, there will be a series of bright and dark lines (or **fringes**) on the viewing screen.

To determine exactly where the bright lines fall, first note that Fig. 34–7 is somewhat exaggerated; in real situations, the distance $d$ between the slits is very small compared to the distance $\ell$ to the screen. The rays from each slit for each case will therefore be essentially parallel, and $\theta$ is the angle they make with the horizontal as shown in Fig. 34–7d. From the shaded right triangles shown in Figs. 34–7b and c, we can see that the extra distance traveled by the lower ray is $d \sin\theta$ (seen more clearly in Fig. 34–7d). Constructive interference will occur, and a bright fringe will appear on the screen, when the *path difference*, $d \sin\theta$, equals a whole number of wavelengths:

$$d \sin\theta = m\lambda, \qquad m = 0, 1, 2, \cdots. \qquad \begin{bmatrix}\text{constructive}\\ \text{interference}\\ \text{(bright)}\end{bmatrix} \qquad \textbf{(34–2a)}$$



The value of $m$ is called the **order** of the interference fringe. The first order ($m = 1$), for example, is the first fringe on each side of the central fringe (which is at $\theta = 0$, $m = 0$). Destructive interference occurs when the path difference $d \sin\theta$ is $\frac{1}{2}\lambda$, $\frac{3}{2}\lambda$, and so on:

$$d \sin\theta = \left(m + \tfrac{1}{2}\right)\lambda, \qquad m = 0, 1, 2, \cdots. \qquad \begin{bmatrix}\text{destructive}\\ \text{interference}\\ \text{(dark)}\end{bmatrix} \qquad \textbf{(34–2b)}$$

The bright fringes are peaks or maxima of light intensity, the dark fringes are minima.[†]

[†]The plural of minimun and maximum are minima and maxima, from Latin, and not minimums or maximums.

**FIGURE 34–8** Two traveling waves are shown undergoing (a) constructive interference, (b) destructive interference. (See also Section 15–8.)

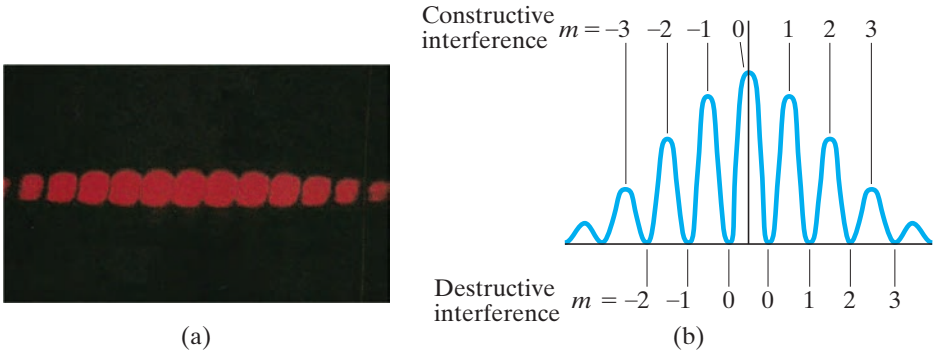


**FIGURE 34–9** (a) Interference fringes produced by a double-slit experiment and detected by photographic film placed on the viewing screen. (b) Graph of the intensity of light in the interference pattern. Also shown are values of $m$ for Eq. 34–2a (constructive interference) and Eq. 34–2b (destructive interference).

The intensity of the bright fringes in the double-slit pattern is greatest for the central fringe $(m = 0)$ and decreases for higher orders as shown in Fig. 34–9. How much the intensity decreases with increasing order depends on the width of the two slits.

**CONCEPTUAL EXAMPLE 34–1** **Interference pattern lines.** ($a$) Will there be an infinite number of points on the viewing screen where constructive and destructive interference occur, or only a finite number of points? ($b$) Are neighboring points of constructive interference uniformly spaced, or is the spacing between neighboring points of constructive interference not uniform?

**RESPONSE** ($a$) When you look at Eqs. 34–2a and b you might be tempted to say, given the statement $m = 0, \pm 1, 2, \cdots$. beside the equations, that there are an infinite number of points of constructive and destructive interference. However, recall that $\sin\theta$ cannot exceed 1. Thus, there is an upper limit to the values of $m$ that can be used in these equations. For Eq. 34–2a, the maximum value of $m$ is the integer closest in value but smaller than $d/\lambda$. So there are a *finite* number of points of constructive and destructive interference no matter how large the screen. ($b$) The spacing between neighboring points of constructive or destructive interference is not uniform: The spacing gets larger as $\theta$ gets larger, because as $\theta$ increases, a doubling of $\sin\theta$ more than doubles $\theta$ (see trig Table, page A–5 in Appendix A). For small values of $\theta$ the spacing is nearly uniform as we will see in Example 34–2.

**EXAMPLE 34–2** **Line spacing for double-slit interference.** A screen containing two slits 0.100 mm apart is 1.20 m from the viewing screen. Light of wavelength $\lambda = 500$ nm falls on the slits from a distant source. Approximately how far apart will adjacent bright interference fringes be on the screen?

**CAUTION**
*Use the approximation $\theta \approx \tan\theta$ or $\theta \approx \sin\theta$ only if $\theta$ is small and in radians*

**APPROACH** The angular position of bright (constructive interference) fringes is found using Eq. 34–2a. The distance between the first two fringes (say) can be found using right triangles as shown in Fig. 34–10.

**SOLUTION** Given $d = 0.100\,\text{mm} = 1.00 \times 10^{-4}\,\text{m}$, $\lambda = 500 \times 10^{-9}\,\text{m}$, and $\ell = 1.20\,\text{m}$, the first-order fringe $(m = 1)$ occurs at an angle $\theta$ given by Eq. 34–2a:

$$\sin\theta_1 = \frac{m\lambda}{d} = \frac{(1)(500 \times 10^{-9}\,\text{m})}{1.00 \times 10^{-4}\,\text{m}} = 5.00 \times 10^{-3}.$$

This is a very small angle, so we can take $\sin\theta \approx \theta$, with $\theta$ in radians. The first-order fringe will occur a distance $x_1$ above the center of the screen (see Fig. 34–10), given by $x_1/\ell = \tan\theta_1 \approx \theta_1$, so

$$x_1 \approx \ell\theta_1 = (1.20\,\text{m})(5.00 \times 10^{-3}) = 6.00\,\text{mm}.$$

The second-order fringe $(m = 2)$ will occur at

$$x_2 \approx \ell\theta_2 = \ell\frac{2\lambda}{d} = 12.0\,\text{mm}$$

above the center, and so on. Thus the lower-order fringes are 6.00 mm apart.

**NOTE** The spacing between fringes is essentially uniform until the approximation $\sin\theta \approx \theta$ is no longer valid.

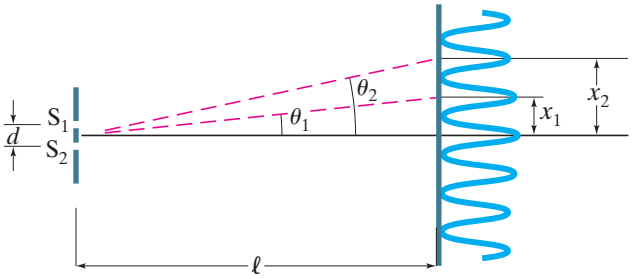

**FIGURE 34–10** Examples 34–2 and 34–3. For small angles $\theta$ (give $\theta$ in radians), the interference fringes occur at distance $x = \theta\ell$ above the center fringe $(m = 0)$; $\theta_1$ and $x_1$ are for the first-order fringe $(m = 1)$; $\theta_2$ and $x_2$ are for $m = 2$.

**CONCEPTUAL EXAMPLE 34–3** **Changing the wavelength.** (*a*) What happens to the interference pattern shown in Fig. 34–10, Example 34–2, if the incident light (500 nm) is replaced by light of wavelength 700 nm? (*b*) What happens instead if the wavelength stays at 500 nm but the slits are moved farther apart?

**RESPONSE** (*a*) When $\lambda$ increases in Eq. 34–2a but $d$ stays the same, the angle $\theta$ for bright fringes increases and the interference pattern spreads out. (*b*) Increasing the slit spacing $d$ reduces $\theta$ for each order, so the lines are closer together.

From Eqs. 34–2 we can see that, except for the zeroth-order fringe at the center, the position of the fringes depends on wavelength. When white light falls on the two slits, as Young found in his experiments, the central fringe is white, but the first (and higher) order fringes contain a spectrum of colors like a rainbow. Using Eq. 34–2a, we can see that $\theta$ is smallest for violet light and largest for red (Fig. 34–11). By measuring the position of these fringes, Young was the first to determine the wavelengths of visible light. In doing so, he showed that what distinguishes different colors physically is their wavelength (or frequency), an idea put forward earlier by Grimaldi in 1665.

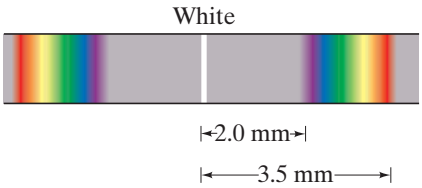

**FIGURE 34–11** First-order fringes for a double slit are a full spectrum, like a rainbow. Also Example 34–4.

**EXAMPLE 34–4** **Wavelengths from double-slit interference.** White light passes through two slits 0.50 mm apart, and an interference pattern is observed on a screen 2.5 m away. The first-order fringe resembles a rainbow with violet and red light at opposite ends. The violet light is about 2.0 mm and the red 3.5 mm from the center of the central white fringe (Fig. 34–11). Estimate the wavelengths for the violet and red light.

**APPROACH** We find the angles for violet and red light from the distances given and the diagram of Fig. 34–10. Then we use Eq. 34–2a to obtain the wavelengths. Because 3.5 mm is much less than 2.5 m, we can use the small-angle approximation.

**SOLUTION** We use Eq. 34–2a $(d \sin\theta = m\lambda)$ with $m = 1$, $d = 5.0 \times 10^{-4}$ m, and $\sin\theta \approx \tan\theta \approx \theta$. Also $\theta \approx x/\ell$ (Fig. 34–10), so for violet light, $x = 2.0$ mm, and

$$\lambda = \frac{d \sin\theta}{m} \approx \frac{d\theta}{m} \approx \frac{d}{m}\frac{x}{\ell} = \left(\frac{5.0 \times 10^{-4}\,\text{m}}{1}\right)\left(\frac{2.0 \times 10^{-3}\,\text{m}}{2.5\,\text{m}}\right) = 4.0 \times 10^{-7}\,\text{m},$$

or 400 nm. For red light, $x = 3.5$ mm, so

$$\lambda \approx \frac{d}{m}\frac{x}{\ell} = \left(\frac{5.0 \times 10^{-4}\,\text{m}}{1}\right)\left(\frac{3.5 \times 10^{-3}\,\text{m}}{2.5\,\text{m}}\right) = 7.0 \times 10^{-7}\,\text{m} = 700\,\text{nm}.$$

These values correspond to the visible spectrum as discussed in Section 32–8.

**EXERCISE B** For the setup in Example 34–4, how far from the central white fringe is the first-order fringe for green light $\lambda = 500$ nm?

## Coherence

The two slits in Figs. 34–6 and 34–7 act as if they were two sources of radiation. They are called **coherent sources** because the waves leaving them have the same wavelength and frequency, and bear the same phase relationship to each other at all times. This happens because the waves come from a single source to the left of the two slits. An interference pattern is observed only when the sources are coherent.

If two tiny lightbulbs replaced the two slits, an interference pattern would not be seen. The light emitted by one lightbulb would have a random phase with respect to the second bulb, and the screen would be more or less uniformly illuminated. Two such sources, whose output waves have phases that bear no fixed relationship to each other over time, are called **incoherent sources**.

## *34–4 Intensity in the Double-Slit Interference Pattern

We saw in Section 34–3 that the interference pattern produced by the coherent light from two slits, $S_1$ and $S_2$ (Figs. 34–7 and 34–9), produces a series of bright and dark fringes. If the two monochromatic waves of wavelength $\lambda$ are in phase at the slits, the maxima (brightest points) occur at angles $\theta$ given by (Eqs. 34–2)

$$d \sin\theta = m\lambda,$$

and the minima (darkest points) when

$$d \sin\theta = \left(m + \tfrac{1}{2}\right)\lambda,$$

where $m$ is an integer $(m = 0, \pm 1, \pm 2, \cdots)$.

We now determine the intensity of the light at all points in the pattern, assuming that if either slit were covered, the light passing through the other would diffract sufficiently to illuminate a large portion of the screen uniformly. The intensity $I$ of the light at any point is proportional to the square of its wave amplitude (Section 15–3). Treating light as an electromagnetic wave, $I$ is proportional to the square of the electric field $E$ (or to the magnetic field $B$, Section 31–8): $I \propto E^2$. The electric field $\vec{\mathbf{E}}$ at any point P (see Fig. 34–12) will be the sum of the electric field vectors of the waves coming from each of the two slits, $\vec{\mathbf{E}}_1$ and $\vec{\mathbf{E}}_2$. Since $\vec{\mathbf{E}}_1$ and $\vec{\mathbf{E}}_2$ are essentially parallel (on a screen far away compared to the slit separation), the magnitude of the electric field at angle $\theta$ (that is, at point P) will be

$$E_\theta = E_1 + E_2.$$

Both $E_1$ and $E_2$ vary sinusoidally with frequency $f = c/\lambda$, but they differ in phase, depending on their different travel distances from the slits. The electric field at P can then be written for the light from each of the two slits, using $\omega = 2\pi f$, as

$$\begin{aligned} E_1 &= E_{10} \sin\omega t \\ E_2 &= E_{20} \sin(\omega t + \delta) \end{aligned} \qquad \textbf{(34–3)}$$

where $E_{10}$ and $E_{20}$ are their respective amplitudes and $\delta$ is the phase difference. The value of $\delta$ depends on the angle $\theta$, so let us now determine $\delta$ as a function of $\theta$.

At the center of the screen (point 0), $\delta = 0$. If the difference in path length from P to $S_1$ and $S_2$ is $d \sin\theta = \lambda/2$, the two waves are exactly out of phase so $\delta = \pi$ (or 180°). If $d \sin\theta = \lambda$, the two waves differ in phase by $\delta = 2\pi$. In general, then, $\delta$ is related to $\theta$ by

$$\frac{\delta}{2\pi} = \frac{d \sin\theta}{\lambda}$$

or (note that if $d \sin\theta = \lambda$, then $\delta = 2\pi$ as we just observed)

$$\delta = \frac{2\pi}{\lambda} d \sin\theta. \qquad \textbf{(34–4)}$$

To determine $E_\theta = E_1 + E_2$, we add the two scalars $E_1$ and $E_2$ which are sine functions differing by the phase $\delta$. One way to determine the sum of $E_1$ and $E_2$ is to use a **phasor diagram**. (We used this technique before, in Chapter 30.) As shown in Fig. 34–13, we draw an arrow of length $E_{10}$ to represent the amplitude of $E_1$ (Eq. 34–3); and an arrow of length $E_{20}$ for the amplitude of $E_2$, which we draw to make a fixed angle $\delta$ with $E_{10}$. When the diagram rotates at angular frequency $\omega$ about the origin, the projections of $E_{10}$ and $E_{20}$ on the vertical axis represent $E_1$ and $E_2$ as a function of time (Eqs. 34–3). We let $E_{\theta 0}$ be the "vector" sum† of $E_{10}$ and $E_{20}$; $E_{\theta 0}$ is the amplitude of the sum $E_\theta = E_1 + E_2$, and the projection of $E_{\theta 0}$ on the vertical axis is $E_\theta$, Fig. 34–13.

†We are not adding the actual electric field vectors; instead we are using the "phasor" technique to add the amplitudes, taking into account the phase difference of the two waves.

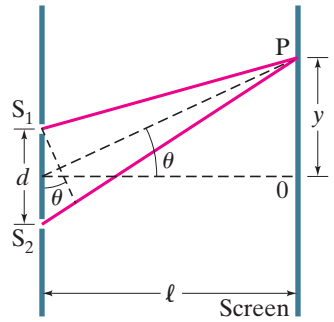

**FIGURE 34–12** Determining the intensity in a double-slit interference pattern. Not to scale: in fact $\ell \gg d$, and the two rays become essentially parallel.

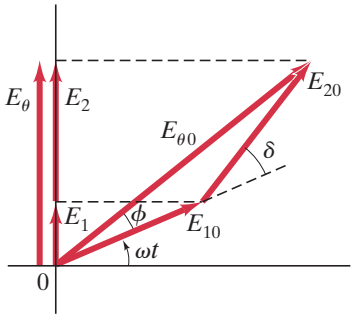

**FIGURE 34–13** Phasor diagram for double-slit interference pattern.

If the two slits provide equal illumination, so that $E_{10} = E_{20} = E_0$, then from *symmetry* in Fig. 34–13, the angle $\phi = \delta/2$, and we can write

$$E_\theta = E_{\theta 0} \sin\left(\omega t + \frac{\delta}{2}\right). \qquad \textbf{(34–5a)}$$

From Fig. 34–13 we can also see that

$$E_{\theta 0} = 2E_0 \cos\phi = 2E_0 \cos\frac{\delta}{2}. \qquad \textbf{(34–5b)}$$

Combining Eqs. 34–5a and b, we obtain

$$E_\theta = 2E_0 \cos\frac{\delta}{2} \sin\left(\omega t + \frac{\delta}{2}\right), \qquad \textbf{(34–5c)}$$

where $\delta$ is given by Eq. 34–4.

We are not really interested in $E_\theta$ as a function of time, since for visible light the frequency ($10^{14}$ to $10^{15}$ Hz) is much too high to be noticeable. We are interested in the *average* intensity, which is proportional to the amplitude squared, $E_{\theta 0}^2$. We drop the word "average," and let $I_\theta (I_\theta \propto E_\theta^2)$ be the intensity at any point P at an angle $\theta$ to the horizontal (Fig. 34–12). We let $I_0$ be the intensity at point O, the center of the screen, where $\theta = \delta = 0$, so $I_0 \propto (E_{10} + E_{20})^2 = (2E_0)^2$. Then the ratio $I_\theta/I_0$ is equal to the ratio of the squares of the electric-field amplitudes at points P and O (Fig. 34–12), so

$$\frac{I_\theta}{I_0} = \frac{E_{\theta 0}^2}{(2E_0)^2} = \cos^2\frac{\delta}{2}$$

where we used Eq. 34–5b. Thus the intensity $I_\theta$ at any point is related to the maximum intensity at the center of the screen by

$$I_\theta = I_0 \cos^2\frac{\delta}{2} = I_0 \cos^2\left(\frac{\pi d \sin\theta}{\lambda}\right) \qquad \textbf{(34–6)}$$

**PROBLEM SOLVING**
*Light intensity in double-slit interference pattern*

where $\delta$ was given by Eq. 34–4. This is the relation we sought.

From Eq. 34–6 we see that maxima occur where $\cos(\delta/2) = \pm 1$, which corresponds to $\delta = 0, \pm 2\pi, \pm 4\pi, \cdots$. From Eq. 34–4, $\delta$ has these values when

$$d \sin\theta = m\lambda, \qquad m = 0, \pm 1, \pm 2, \cdots.$$

Minima occur where $\cos(\delta/2) = 0$, so $\delta = \pm\pi, \pm 3\pi, \pm 5\pi, \cdots$, which corresponds to

$$d \sin\theta = \left(m + \tfrac{1}{2}\right)\lambda, \qquad m = 0, \pm 1, \pm 2, \cdots.$$

These are the same results we obtained in Section 34–3. But now we know not only the position of maxima and minima, but from Eq. 34–6 we can determine the intensity at all points on the viewing screen.

In the usual situation the distance $\ell$ to the screen from the slits is large compared to the slit separation $d$. Then, with $\ell \gg d$, if we consider only points P (Fig. 34–12) whose distance $y$ from the center (point O) is small compared to $\ell$ ($y \ll \ell$ in Fig. 34–12) then

$$\sin\theta \approx \frac{y}{\ell}.$$

From this it follows (see Eq. 34–4) that

$$\delta = \frac{2\pi}{\lambda}\frac{d}{\ell}y.$$

Equation 34–6 then becomes approximately

$$I_\theta = I_0\left[\cos\left(\frac{\pi d}{\lambda \ell}y\right)\right]^2. \qquad [y \ll \ell,\ d \ll \ell] \qquad \textbf{(34–7)}$$

**EXERCISE C** What are the values for the intensity $I_\theta$ when (*a*) $y = 0$, (*b*) $y = \lambda\ell/4d$, and (*c*) $y = \lambda\ell/2d$?

The intensity $I_\theta$ as a function of the phase difference $\delta$ is plotted in Fig. 34–14. In the approximation of Eq. 34–7, the horizontal axis could as well be $y$, the position on the screen.

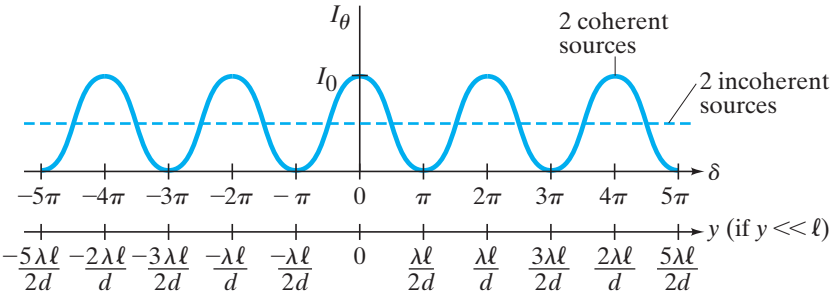

**FIGURE 34–14** Intensity $I$ as a function of phase difference $\delta$ and position on screen $y$ (assuming $y \ll \ell$).

The intensity pattern expressed in Eqs. 34–6 and 34–7, and plotted in Fig. 34–14, shows a series of maxima of equal height, and is based on the assumption that each slit (alone) would illuminate the screen uniformly. This is never quite true, as we shall see when we discuss diffraction in the next Chapter. We will see that the center maximum is strongest and each succeeding maximum to each side is a little less strong. See also Fig. 34–9.

**EXAMPLE 34–5** **Antenna intensity.** Two radio antennas are located close to each other as shown in Fig. 34–15, separated by a distance $d$. The antennas radiate in phase with each other, emitting waves of intensity $I_0$ at wavelength $\lambda$. (*a*) Calculate the net intensity as a function of $\theta$ for points very far from the antennas. (*b*) For $d = \lambda$, determine $I$ and find in which directions $I$ is a maximum and a minimum. (*c*) Repeat part (*b*) when $d = \lambda/2$.

**APPROACH** This setup is similar to Young's double-slit experiment.

**SOLUTION** (*a*) Points of constructive and destructive interference are still given by Eqs. 34–2a and b, and the net intensity as a function of $\theta$ is given by Eq. 34–6.

(*b*) We let $d = \lambda$ in Eq. 34–6, and find for the intensity,

$$I = I_0 \cos^2(\pi \sin\theta).$$

$I$ is a maximum, equal to $I_0$, when $\sin\theta = 0,\ 1,$ or $-1$, meaning $\theta = 0, 90°, 180°,$ and $270°$. $I$ is zero when $\sin\theta = \frac{1}{2}$ and $-\frac{1}{2}$, for which $\theta = 30°, 150°, 210°,$ and $330°$.

(*c*) For $d = \lambda/2$, $I = I_0 \cos^2(\pi \sin\theta/2)$ and is maximized for $\theta = 0$ and $180°$, and minimized for $90°$ and $270°$.

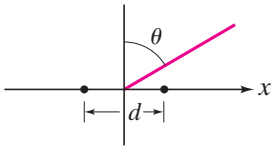

**FIGURE 34–15** Example 34–5. The two dots represent the antennas.

## 34–5 Interference in Thin Films

Interference of light gives rise to many everyday phenomena such as the bright colors reflected from soap bubbles and from thin oil or gasoline films on water, Fig. 34–16. In these and other cases, the colors are a result of constructive interference between light reflected from the two surfaces of the thin film.

**FIGURE 34–16** Thin-film interference patterns seen in (a) a soap bubble, (b) a thin film of soapy water, and (c) a thin layer of oil on wet pavement.

The effect is observed only if the thickness of the film is on the order of a few wavelengths of the light. If the film thickness is much greater, the effect gets washed out.

To see how this **thin-film interference** happens, consider a smooth surface of water on top of which is a thin uniform layer of another substance, say an oil whose index of refraction is less than that of water (we'll see why we assume this shortly); see Fig. 34–17. Assume for now that the incident light is of a single wavelength, and strikes the surface close to perpendicular. Part of the incident light is reflected at A on the top surface, and part of the light transmitted is reflected at B on the lower surface. The part reflected at the lower surface must travel the extra distance ABC. If this *path difference* ABC equals one or a whole number of wavelengths in the film $(\lambda_n)$, the two waves will reach the eye in phase and interfere constructively. Hence the region AC on the surface film will appear bright. But if ABC equals $\frac{1}{2}\lambda_n, \frac{3}{2}\lambda_n$, and so on, the two waves will be exactly out of phase and destructive interference occurs: the area AC on the film will show no reflection—it will be dark (transparent to the dark material below). The wavelength $\lambda_n$ is *the wavelength in the film*: $\lambda_n = \lambda/n$, where $n$ is the index of refraction in the film and $\lambda$ is the wavelength in vacuum. See Eq. 34–1.

When white light falls on such a film, the path difference ABC will equal $\lambda_n$ (or $m\lambda_n$, with $m$ = an integer) for only one wavelength at a given viewing angle. The color corresponding to $\lambda$ ($\lambda$ in air) will be seen as very bright. For light viewed at a slightly different angle, the path difference ABC will be longer or shorter and a different color will undergo constructive interference. Thus, for an extended (nonpoint) source emitting white light, a series of bright colors will be seen next to one another (Fig. 34–16). Variations in thickness of the film will also alter the path difference ABC and therefore affect the color of light that is most strongly reflected.

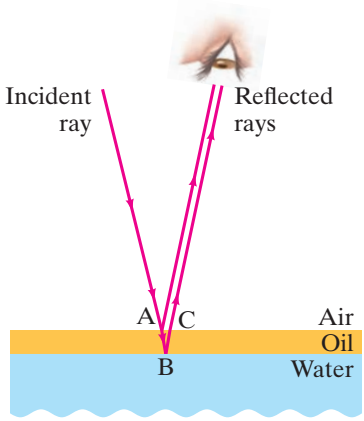

**FIGURE 34–17** Light reflected from the upper and lower surfaces of a thin film of oil lying on water. We assume the light rays are (nearly) perpendicular to the oil surface, but are drawn at an angle so we can distinguish them.

**EXERCISE D** Return to the Chapter-Opening Question, page 995, and answer it again now. Try to explain why you may have answered differently the first time.

When a curved glass surface is placed in contact with a flat glass surface, Fig. 34–18, a series of concentric rings is seen when illuminated from above by either white light (as shown) or by monochromatic light. These are called **Newton's rings**[†] and they are due to interference between waves reflected by the top and bottom surfaces of the very thin *air gap* between the two pieces of glass. Because this gap (which is equivalent to a thin film) increases in width from the central contact point out to the edges, the extra path length for the lower ray (equal to BCD) varies. Where it equals $0, \frac{1}{2}\lambda, \lambda, \frac{3}{2}\lambda, 2\lambda$, and so on, it corresponds to constructive or destructive interference; and this gives rise to the series of bright colored circles seen in Fig. 34–18b. The color you see at a given radius corresponds to constructive interference; at that radius, other colors partially or fully destructively interfere. (If monochromatic light is used, the rings are alternately bright and dark.)

The point of contact of the two glass surfaces (A in Fig. 34–18a) is not bright in Fig. 34–18b. Since the path difference is zero here, our previous analysis would suggest that the waves reflected from each surface are in phase—so this central area ought to be bright. But it is dark, which tells us the two waves must be completely out of phase.

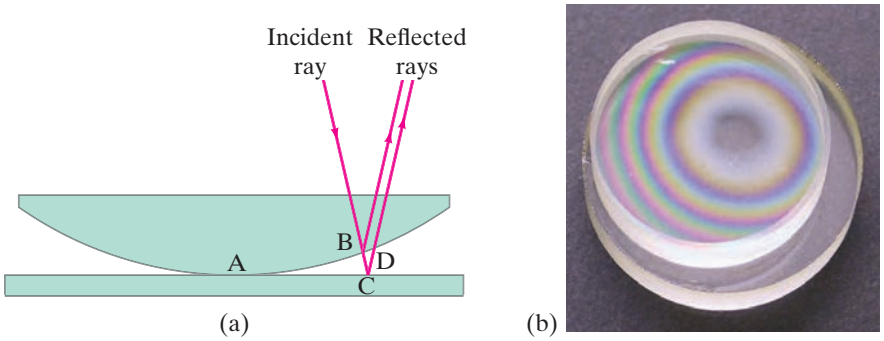

**FIGURE 34–18** Newton's rings. (a) Light rays reflected from upper and lower surfaces of the thin air gap can interfere. (b) Photograph of interference patterns using white light.

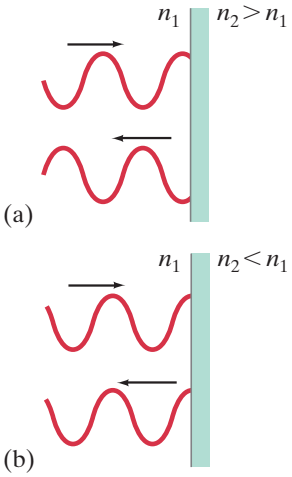
[†]Although Newton gave an elaborate description of them, they had been first observed and described by his contemporary, Robert Hooke.



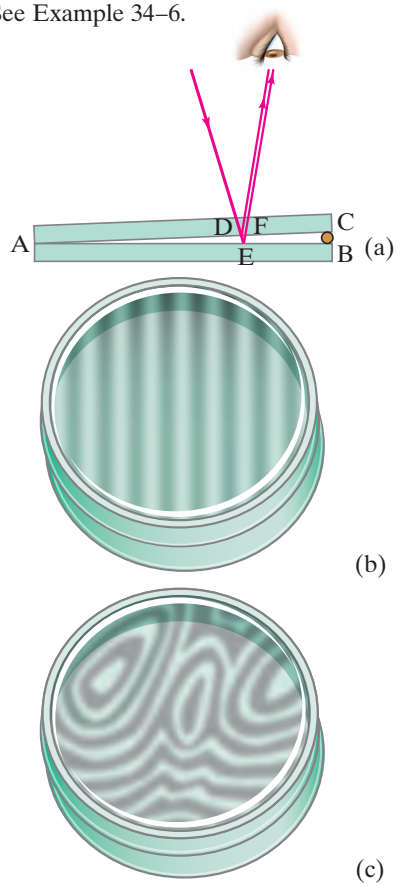


**FIGURE 34–19** (a) Reflected ray changes phase by 180° or $\frac{1}{2}$ cycle if $n_2 > n_1$, but (b) does not if $n_2 < n_1$.

**FIGURE 34–20** (a) Light rays reflected from the upper and lower surfaces of a thin wedge of air (between two glass plates) interfere to produce bright and dark bands. (b) Pattern observed when glass plates are optically flat; (c) pattern when plates are not so flat. See Example 34–6.

**PHYSICS APPLIED**
*Testing glass for flatness*

Let us see why the pattern is dark at the center of Fig. 34–18b (repeated here on facing page). This can happen only if one of the waves, upon reflection, flips over—a crest becomes a trough—see Fig. 34–19. We say that the reflected wave has undergone a **phase shift** of 180°, or of half a wave cycle ($\frac{1}{2}\lambda$). Indeed, this and other experiments reveal that, at normal incidence,

**a beam of light, reflected by a material with index of refraction greater than that of the material in which it is traveling, changes phase by 180° or $\frac{1}{2}$ cycle;**

see Fig. 34–19. This phase shift acts just like a path difference of $\frac{1}{2}\lambda$. If the index of refraction of the reflecting material is less than that of the material in which the light is traveling, *no phase change occurs.*† Thus the wave reflected at the curved surface above the air gap in Fig. 34–18a undergoes no change in phase. But the wave reflected at the lower surface, where the beam in air strikes the glass, undergoes a $\frac{1}{2}$-cycle phase shift, equivalent to a $\frac{1}{2}\lambda$ path difference. Thus the two waves reflected near the point of contact A of the two glass surfaces (where the air gap approaches zero thickness) will be a half cycle (or 180°) out of phase, and a dark spot occurs, Fig. 34–18b.

Bright colored rings will occur when the path difference is $\frac{1}{2}\lambda, \frac{3}{2}\lambda$, and so on, because the phase shift at one surface effectively adds a path difference of $\frac{1}{2}\lambda$ $(= \frac{1}{2}\text{ cycle})$. (If monochromatic light is used, the bright Newton's rings will be separated by dark bands which occur when the path difference BCD in Fig. 34–18a is equal to an integral number of wavelengths.)

Returning for a moment to Fig. 34–17, the light reflecting at both interfaces, air–oil and oil–water, *each* underwent a phase change of 180° equivalent to a path difference of $\frac{1}{2}\lambda$, since we assumed $n_{\text{water}} > n_{\text{oil}} > n_{\text{air}}$. Because the two phase shifts were equal, they didn't affect our analysis.

**EXAMPLE 34–6** **Thin film of air, wedge-shaped.** A very fine wire $7.35 \times 10^{-3}$ mm in diameter is placed between two flat glass plates as in Fig. 34–20a. The two plates touch at the other end (left). Light whose wavelength in air is 600 nm falls (and is viewed) perpendicular to the plates and a series of bright and dark bands is seen, Fig. 34–20b. How many light and dark bands will there be in this case? Will the area next to the wire be bright or dark?

**APPROACH** We need to consider two effects: (1) path differences for rays reflecting from the two close surfaces (thin wedge of air between the two glass plates), and (2) the $\frac{1}{2}$-cycle phase shift at the lower surface (point E in Fig. 34–20a), where rays in air can enter glass (or be reflected). Because there is a phase shift only at the lower surface, there will be a dark band (no reflection) when the path difference is 0, $\lambda$, $2\lambda$, $3\lambda$, and so on. Assuming the light rays are perpendicular to the plates, the extra path length (DEF) equals $2t$, where $t$ is the thickness of the air gap at any point.

**SOLUTION** Dark bands will occur where

$$2t = m\lambda, \qquad m = 0, 1, 2, \cdots.$$

Bright bands occur when $2t = (m + \frac{1}{2})\lambda$, where $m$ is an integer. At the position of the wire, $t = 7.35 \times 10^{-6}$ m. At this point there will be $2t/\lambda = (2)(7.35 \times 10^{-6}\text{ m})/(6.00 \times 10^{-7}\text{ m}) = 24.5$ wavelengths. This is a "half integer," so the area next to the wire will be bright. There will be a total of 25 dark lines along the plates, corresponding to path lengths DEF of $0\lambda$, $1\lambda$, $2\lambda$, $3\lambda, \cdots$, $24\lambda$, including the one at the point of contact A $(m = 0)$. Between them, there will be 24 bright lines plus the one at the end, or 25.

**NOTE** The bright and dark bands will be straight only if the glass plates are extremely flat. If they are not, the pattern is uneven, as in Fig. 34–20c. Thus we see a very precise way of testing a glass surface for flatness. Spherical lens surfaces can be tested for precision by placing the lens on a flat glass surface and observing Newton's rings (Fig. 34–18b) for perfect circularity.

†This result corresponds to the reflection of a wave traveling along a cord when it reaches the end. As we saw in Fig. 15–18, if the end is tied down, the wave changes phase and the pulse flips over, but if the end is free, no phase shift occurs.

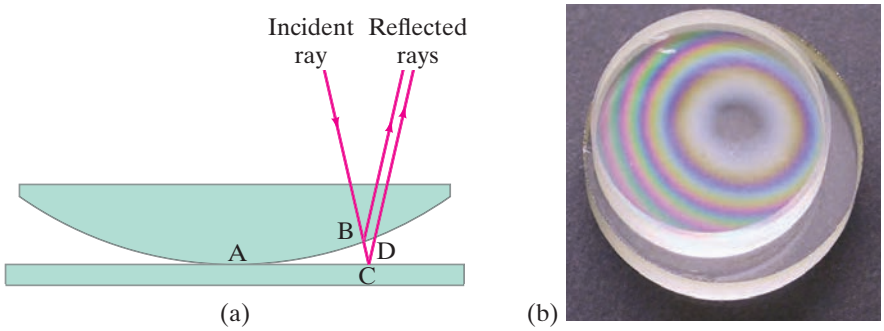

**FIGURE 34–18** (Repeated.) Newton's rings. (a) Light rays reflected from upper and lower surfaces of the thin air gap can interfere. (b) Photograph of interference patterns using white light.

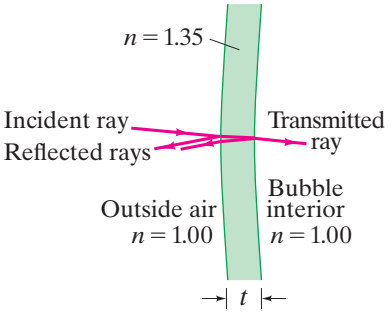
If the wedge between the two glass plates of Example 34–6 is filled with some transparent substance other than air—say, water—the pattern shifts because the wavelength of the light changes. In a material where the index of refraction is $n$, the wavelength is $\lambda_n = \lambda/n$, where $\lambda$ is the wavelength in vacuum (Eq. 34–1). For instance, if the thin wedge of Example 34–6 were filled with water, then $\lambda_n = 600\,\text{nm}/1.33 = 450\,\text{nm}$; instead of 25 dark lines, there would be 33.

When white light (rather than monochromatic light) is incident on the thin wedge of air in Figs. 34–18a or 34–20a, a colorful series of fringes is seen because constructive interference occurs for different wavelengths in the reflected light at different thicknesses along the wedge.

A soap bubble (Fig. 34–16a and Chapter-Opening Photo) is a thin spherical shell (or film) with air inside. The variations in thickness of a soap bubble film give rise to bright colors reflected from the soap bubble. (There is air on both sides of the bubble film.) Similar variations in film thickness produce the bright colors seen reflecting from a thin layer of oil or gasoline on a puddle or lake (Fig. 34–16c). Which wavelengths appear brightest also depends on the viewing angle.

**EXAMPLE 34–7** **Thickness of soap bubble skin.** A soap bubble appears green ($\lambda = 540\,\text{nm}$) at the point on its front surface nearest the viewer. What is the smallest thickness the soap bubble film could have? Assume $n = 1.35$.

**APPROACH** Assume the light is reflected perpendicularly from the point on a spherical surface nearest the viewer, Fig. 34–21. The light rays also reflect from the inner surface of the soap bubble film as shown. The path difference of these two reflected rays is $2t$, where $t$ is the thickness of the soap film. Light reflected from the first (outer) surface undergoes a 180° phase change (index of refraction of soapy water is greater than that of air), whereas reflection at the second (inner) surface does not. To determine the thickness $t$ for an interference maximum, we must use the wavelength of light in the soap ($n = 1.35$).



**SOLUTION** The 180° phase change at only one surface is equivalent to a $\frac{1}{2}\lambda$ path difference. Therefore, green light is bright when the minimum path difference equals $\frac{1}{2}\lambda_n$. Thus, $2t = \lambda_n/2$, so

$$t = \frac{\lambda_n}{4} = \frac{\lambda}{4n} = \frac{(540\,\text{nm})}{(4)(1.35)} = 100\,\text{nm}.$$

This is the smallest thickness.

**NOTE** At this small thickness, blue (450 nm) and red (600 nm) also would reflect fairly constructively, so the bubble would appear almost white. The green color is more likely to be seen at the *next* thickness that gives constructive interference, $2t = 3\lambda/2n$, because other colors would be more fully cancelled by destructive interference. Then $t$ would be $t = 3\lambda/4n = 300\,\text{nm}$. Note that green is seen in air, so $\lambda = 540\,\text{nm}$ (not $\lambda/n$).

**FIGURE 34–21** Soap bubble. Example 34–7. The incident and reflected rays are assumed to be perpendicular to the bubble's surface. They are shown at a slight angle so we can distinguish them.

**CAUTION**

*A formula is not enough: you must also check for phase changes at surfaces*

## Colors in a Thin Soap Film

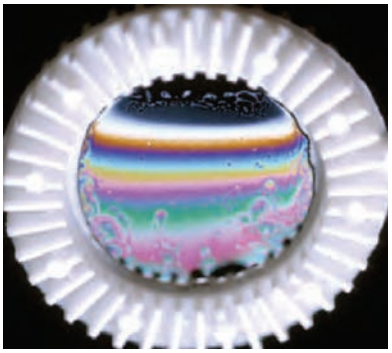


**FIGURE 34–16b** (Repeated.)

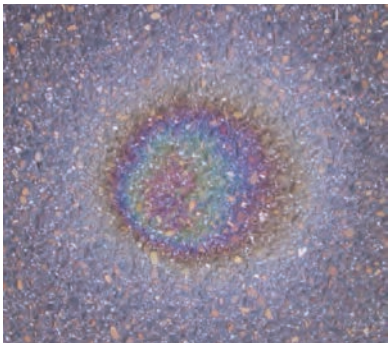
The thin film of soapy water (in a plastic loop) shown in Fig. 34–16b (repeated here) has stood vertically for a long time. Gravity has pulled the soapy water downward, so the film increases in thickness going toward the bottom. The top section of the soapy film in Fig. 34–16b is so thin (perhaps 30 nm thick $\ll \lambda$) that light reflected from the front and back surfaces have almost zero path difference. Thus the 180° phase change at the front surface assures that the two reflected waves are 180° out of phase for all wavelengths of visible light. The white light incident on this thin film does not reflect at the top part of the film, so the top is transparent and we see the background which is black.



Below the black area at the top of Fig. 34–16b, there is a thin blue line, and then a white band. The film has thickened to perhaps 75 to 100 nm, so the shortest wavelength (blue) light begins to partially interfere constructively. But just below, where the thickness is slightly greater (100 nm), the path difference is reasonably close to $\lambda/2$ for much of the spectrum and we see white or silver.[†]

Immediately below the white band in this Figure we see a brown band, where $t \approx 200$ nm, and many wavelengths (not all) are close to $\lambda$—and those colors destructively interfere, leaving only a few colors to partially interfere constructively, giving us murky brown.

Farther down in Fig. 34–16b, with increasing thickness $t$, a path length $2t = 510$ nm corresponds nicely to $\frac{3}{2}\lambda$ for blue, but not for other colors, so we see blue ($\frac{3}{2}\lambda$ path difference plus $\frac{1}{2}\lambda$ phase change = constructive interference). Other colors experience constructive interference (at $\frac{3}{2}\lambda$ and then at $\frac{5}{2}\lambda$) at still greater thicknesses, so going down we see a series of separated colors something like a rainbow.

In the soap bubble of our Chapter-Opening Photo (page 995), similar things happen: at the top (where the film is thinnest) we see black and then silver-white, just as in the soap film shown in Fig. 34–16b.

**FIGURE 34–16c** (Repeated.)

Next consider the oil film on wet pavement shown in Fig. 34–16c (repeated here). An oil film is thickest at the center and thins out toward the edges. Notice the whitish outer ring where most colors constructively interfere, which would suggest a thickness on the order of 100 nm as discussed above for the white band in the soap film. Beyond the outer white band of the oil film, Fig. 34–16c, there is still some oil, but the film is so thin that reflected light from upper and lower surfaces destructively interfere and you can see right through this very thin oil film.

## Lens Coatings

**PHYSICS APPLIED**
*Lens coatings*

An important application of thin-film interference is in the coating of glass to make it "nonreflecting," particularly for lenses. A glass surface reflects about 4% of the light incident upon it. Good-quality cameras, microscopes, and other optical devices may contain six to ten thin lenses. Reflection from all these surfaces can reduce the light transmitted considerably, and multiple reflections produce a background haze that reduces the quality of the image. By reducing reflection, transmission is increased.

A very thin coating on the lens surfaces can reduce reflections considerably. The thickness of the film is chosen so that light (at least for one wavelength) reflecting from the front and rear surfaces of the film destructively interferes, so all the light is transmitted. The amount of reflection at a boundary depends on the difference in index of refraction between the two materials. Ideally, the coating material should have an index of refraction which is the geometric mean $(= \sqrt{n_1 n_2})$ of those for air and glass, so that the amount of reflection at each surface is about equal. Then destructive interference can occur nearly completely for one particular wavelength depending on the thickness of the coating. Nearby wavelengths will at least partially destructively interfere, but a single coating cannot eliminate reflections for all wavelengths. Nonetheless, a single coating can reduce total reflection from 4% to 1% of the incident light. Often the coating is designed to eliminate the center of the reflected spectrum (around 550 nm).

[†]Why? Recall that red starts at 600 nm in air; so most colors in the spectrum lie between 450 nm and 600 nm in air; but in water the wavelengths are $n = 1.33$ times smaller, 340 nm to 450 nm, so a 100-nm thickness is a 200-nm path difference, not far from $\lambda/2$ for most colors.

The extremes of the spectrum—red and violet—will not be reduced as much by the lens coating. Since a mixture of red and violet produces purple, the light seen reflected from such coated lenses is purple (Fig. 34–22). Lenses containing two or three separate coatings can more effectively reduce a wider range of reflecting wavelengths, and increase transmission.

**FIGURE 34–22** A coated lens. Note color of light reflected from the front lens surface.

PROBLEM SOLVING

## Interference

1. **Interference effects** depend on the simultaneous arrival of two or more waves at the same point in space.
2. **Constructive interference** occurs when waves of a single wavelength continually arrive in phase with each other: crests of one wave arrive at the same time as crests of the other wave. The amplitudes of the waves then add to form a larger amplitude. Constructive interference also occurs when the path difference is exactly one full wavelength or any integer multiple of a full wavelength: $1\lambda, 2\lambda, 3\lambda, \cdots$.
3. **Destructive interference** occurs when crests of one wave continually arrive at the same time as troughs of the other wave. The amplitudes add, but they are of opposite sign, so the total amplitude is reduced to zero if the two amplitudes are equal. Destructive interference occurs whenever the phase difference is half a wave cycle, or the path difference is a half-integral number of wavelengths. Thus, the total amplitude will be zero if two identical waves arrive one-half wavelength out of phase, or $(m + \frac{1}{2})\lambda$ out of phase, where $m$ is an integer.
4. For thin-film interference, an extra half-wavelength **phase shift** occurs when light **reflects** from an optically more dense medium (going from a material of lesser toward greater index of refraction).

**EXAMPLE 34–8** **Nonreflective coating.** What is the thickness $t$ of an optical coating of $MgF_2$ whose index of refraction is $n = 1.38$ and which is designed to eliminate reflected light at wavelengths (in air) around 550 nm when incident normally on glass for which $n = 1.50$?

**APPROACH** We explicitly follow the procedure outlined in the Problem Solving Strategy above.

**SOLUTION**

1. **Interference effects**. Consider two rays reflected from the front and rear surfaces of the coating on the lens as shown in Fig. 34–23. The rays are drawn not quite perpendicular to the lens so we can see each of them. These two reflected rays will interfere with each other.
2. **Constructive interference**. We want to eliminate reflected light, so we do not consider constructive interference.
3. **Destructive interference**. To eliminate reflection, we want reflected rays 1 and 2 to be $\frac{1}{2}$ cycle out of phase with each other so that they destructively interfere. The phase difference is due to the path difference $2t$ traveled by ray 2, as well as any phase change in either ray due to reflection.
4. **Reflection phase shift**. Rays 1 and 2 *both* undergo a change of phase by $\frac{1}{2}$ cycle when they reflect from the coating's front and rear surfaces, respectively (at both surfaces the index of refraction increases). Thus there is no net change in phase due to the reflections. The net phase difference will be due to the extra path $2t$ taken by ray 2 in the coating, where $n = 1.38$. We want $2t$ to equal $\frac{1}{2}\lambda_n$ so that destructive interference occurs, where $\lambda_n = \lambda/n$ is the wavelength in the coating. With $2t = \lambda_n/2 = \lambda/2n$, then

$$t = \frac{\lambda_n}{4} = \frac{\lambda}{4n} = \frac{(550\,\text{nm})}{(4)(1.38)} = 99.6\,\text{nm}.$$

**NOTE** We could have set $2t = (m + \frac{1}{2})\lambda_n$, where $m$ is an integer. The smallest thickness $(m = 0)$ is usually chosen because destructive interference will occur over the widest angle.

**NOTE** Complete destructive interference occurs only for the given wavelength of visible light. Longer and shorter wavelengths will have only partial cancellation.

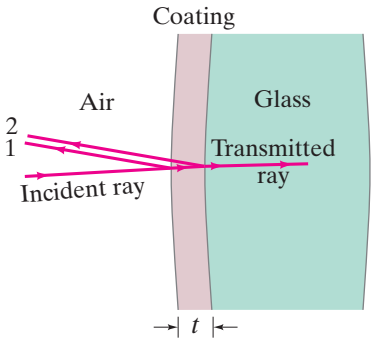


**FIGURE 34–23** Example 34–8. Incident ray of light is partially reflected at the front surface of a lens coating (ray 1) and again partially reflected at the rear surface of the coating (ray 2), with most of the energy passing as the transmitted ray into the glass.

# 34–6 Michelson Interferometer

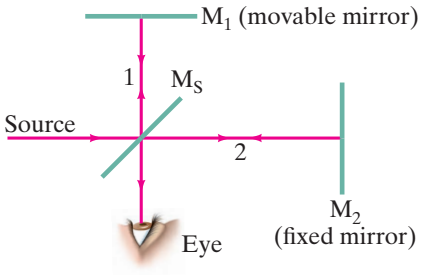

**FIGURE 34–24** Michelson interferometer.

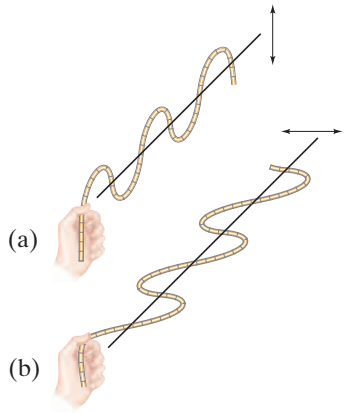

A useful instrument involving wave interference is the **Michelson interferometer** (Fig. 34–24),† invented by the American Albert A. Michelson (Section 31–7). Monochromatic light from a single point on an extended source is shown striking a half-silvered mirror $M_S$. This **beam splitter** mirror $M_S$ has a thin layer of silver that reflects only half the light that hits it, so that half of the beam passes through to a fixed mirror $M_2$, where it is reflected back. The other half is reflected by $M_S$ to a mirror $M_1$ that is movable (by a fine-thread screw), where it is also reflected back. Upon its return, part of beam 1 passes through $M_S$ and reaches a sensor or the eye; and part of beam 2, on its return, is reflected by $M_S$ into the eye. If the two path lengths are identical, the two coherent beams entering the eye constructively interfere and brightness will be seen. If the movable mirror is moved a distance $\lambda/4$, one beam will travel an extra distance equal to $\lambda/2$ (because it travels back and forth over the distance $\lambda/4$). In this case, the two beams will destructively interfere and darkness will be seen. As $M_1$ is moved farther, brightness will recur (when the path difference is $\lambda$), then darkness, and so on.

Very precise length measurements can be made with an interferometer. The motion of mirror $M_1$ by only $\frac{1}{4}\lambda$ produces a clear difference between brightness and darkness. For $\lambda = 400\,\text{nm}$, this means a precision of 100 nm or $10^{-4}$ mm! If mirror $M_1$ is tilted very slightly, the bright or dark spots are seen instead as a series of bright and dark lines or "fringes" that move as $M_1$ moves. By counting the number of fringes (or fractions thereof) that pass a reference line, extremely precise length measurements can be made.

# 34–7 Polarization

An important and useful property of light is that it can be *polarized*. To see what this means, let us examine waves traveling on a rope. A rope can oscillate in a vertical plane, Fig. 34–25a, or in a horizontal plane, Fig. 34–25b. In either case, the wave can be said to be **linearly polarized** or **plane-polarized**—*the oscillations are in a plane*.

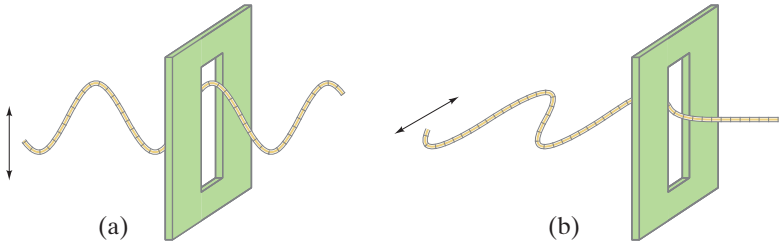

**FIGURE 34–25** Transverse waves on a rope polarized (a) in a vertical plane and (b) in a horizontal plane.

If we now place an obstacle containing a vertical slit in the path of the wave, Fig. 34–26, a vertically polarized wave passes through the vertical slit, but a horizontally polarized wave will not. If a horizontal slit were used, the vertically polarized wave would be stopped. If both types of slit were used, both types of wave would be stopped by one slit or the other. Note that polarization can exist *only* for *transverse waves*, and not for longitudinal waves such as sound. The latter oscillate only along the direction of motion, and neither orientation of slit would stop them.

Maxwell's theory of light as electromagnetic (EM) waves predicted that light can be polarized since an EM wave is a transverse wave. The direction of polarization in a plane-polarized EM wave is taken as the direction of the electric field vector $\vec{\mathbf{E}}$.

**FIGURE 34–26** (a) A vertically polarized wave passes through a vertical slit, but (b) a horizontally polarized wave will not.

†There are other types of interferometer, but Michelson's is the best known.

Light is not necessarily polarized. It can also be **unpolarized**, which means that the source has oscillations in many planes at once, as shown in Fig. 34–27a. Ordinary lightbulbs emit unpolarized light, as does the Sun.

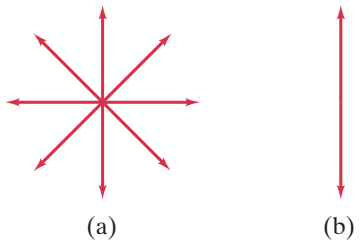

**FIGURE 34–27** (a) Oscillation of the electric field vectors in unpolarized light. The light is traveling into or out of the page. (b) Electric field in linear polarized light.

## Polaroids (Polarization by Absorption)

Plane-polarized light can be obtained from unpolarized light using certain crystals such as tourmaline. Or, more commonly, we use a **Polaroid sheet**. (Polaroid materials were invented in 1929 by Edwin Land.) A Polaroid sheet consists of long complex molecules arranged parallel to one another. Such a Polaroid acts like a series of parallel slits to allow one orientation of polarization to pass through nearly undiminished. This direction is called the *transmission axis* of the Polaroid. Polarization perpendicular to this direction is absorbed almost completely by the Polaroid.

Absorption by a Polaroid can be explained at the molecular level. An electric field $\vec{\mathbf{E}}$ that oscillates parallel to the long molecules can set electrons into motion along the molecules, thus doing work on them and transferring energy. Hence, if $\vec{\mathbf{E}}$ is parallel to the molecules, it gets absorbed. An electric field $\vec{\mathbf{E}}$ perpendicular to the long molecules does not have this possibility of doing work and transferring its energy, and so passes through freely. When we speak of the *transmission axis* of a Polaroid, we mean the direction for which $\vec{\mathbf{E}}$ is passed, so a Polaroid axis is *perpendicular* to the long molecules. [If we want to think of there being slits between the parallel molecules in the sense of Fig. 34–26, then Fig. 34–26 would apply for the $\vec{\mathbf{B}}$ field in the EM wave which is perpendicular to the $\vec{\mathbf{E}}$ field.]

If a beam of plane-polarized light strikes a Polaroid whose transmission axis is at an angle $\theta$ to the incident polarization direction, the beam will emerge plane-polarized parallel to the Polaroid transmission axis, and the amplitude of $E$ will be reduced to $E\cos\theta$, Fig. 34–28. Thus, a Polaroid passes only that component of polarization (the electric field vector, $\vec{\mathbf{E}}$) that is parallel to its transmission axis. Because the intensity of a light beam is proportional to the square of the amplitude (Sections 15–3 and 31–8), the intensity of a plane-polarized beam transmitted by a polarizer is proportional to $(E_0\cos\theta)^2$, a relation called Malus' law,

$$I = I_0\cos^2\theta, \qquad \left[\begin{array}{c}\text{intensity of plane-polarized}\\ \text{light passed by polarizer}\end{array}\right] \qquad \textbf{(34–8)}$$

**CAUTION**
*Intensity of previously polarized light*

where $I_0$ is the incoming intensity and $\theta$ is the angle between the polarizer transmission axis and the plane of polarization of the incoming wave.

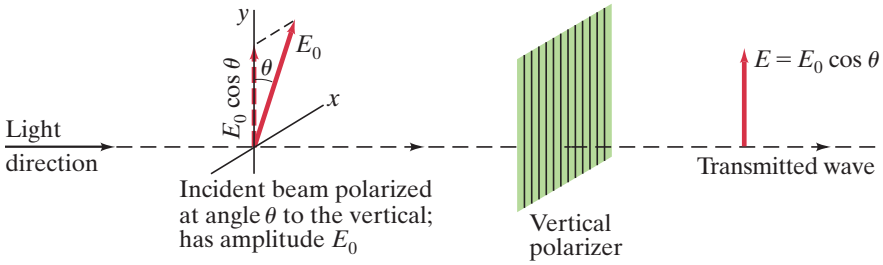

**FIGURE 34–28** Vertical Polaroid transmits only the vertical component of a wave (electric field) incident upon it.

A Polaroid can be used as a **polarizer** to *produce* plane-polarized light from unpolarized light, since only the component of light parallel to the axis is transmitted. A Polaroid can also be used as an **analyzer** to determine (1) if light is polarized and (2) the plane of polarization. A Polaroid acting as an analyzer will pass the same amount of light independent of the orientation of its axis if the light is unpolarized; try rotating one lens of a pair of Polaroid sunglasses while looking through it at a lightbulb. If the light is polarized, however, when you rotate the Polaroid the transmitted light will be a maximum when the plane of polarization is parallel to the Polaroid's transmission axis, and a minimum when perpendicular to it. If you do this while looking at the sky, preferably at right angles to the Sun's direction, you will see that skylight is polarized. (Direct sunlight is unpolarized, but don't look directly at the Sun, even through a polarizer, for damage to the eye may occur.) If the light transmitted by an analyzer Polaroid falls to zero at one orientation, then the light is 100% plane-polarized. If it merely reaches a minimum, the light is *partially polarized*.

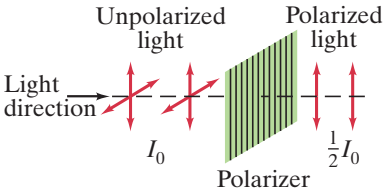

**FIGURE 34–29** Unpolarized light has equal intensity vertical and horizontal components. After passing through a polarizer, one of these components is eliminated. The intensity of the light is reduced to half.

Unpolarized light consists of light with random directions of polarization. Each of these polarization directions can be resolved into components along two mutually perpendicular directions. On average, an unpolarized beam can be thought of as two plane-polarized beams of equal magnitude perpendicular to one another. When unpolarized light passes through a polarizer, one component is eliminated. So the unpolarized light passing through a polarizer not only becomes polarized, but also its intensity is reduced by half because half the light is eliminated (Fig. 34–29):

$$I = \tfrac{1}{2}I_0. \qquad \left[\begin{array}{c}\text{intensity of initially}\\ \text{unpolarized light after}\\ \text{passing through polarizer}\end{array}\right]$$

(Note that Eq. 34–8 refers to already-polarized light.)

When two Polaroids are *crossed*—that is, their polarizing axes are perpendicular to one another—unpolarized light can be entirely stopped. As shown in Fig. 34–30, unpolarized light is made plane-polarized by the first Polaroid (the polarizer). The second Polaroid, the analyzer, then eliminates this component since its transmission axis is perpendicular to the first.

**FIGURE 34–30** Crossed Polaroids completely eliminate light.

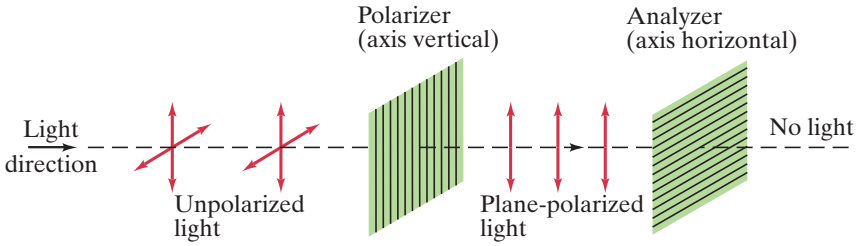

**FIGURE 34–31** Crossed Polaroids. When the two polarized sunglass lenses overlap, with axes perpendicular, almost no light passes through.

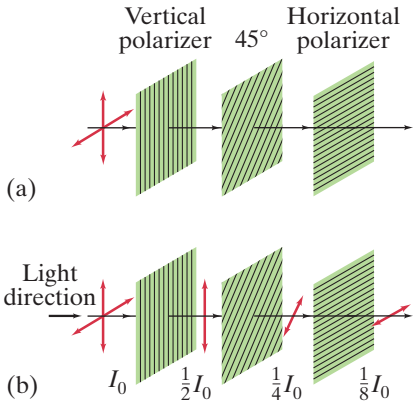
You can try this with Polaroid sunglasses (Fig. 34–31). Note that Polaroid sunglasses eliminate 50% of unpolarized light because of their polarizing property; they absorb even more because they are colored. Plane-polarized light in any direction is also stopped by crossed Polaroids.

**EXAMPLE 34–9** **Two Polaroids at 60°.** Unpolarized light passes through two Polaroids; the axis of the first is vertical and that of the second is at 60° to the vertical. Describe the orientation and intensity of the transmitted light.



**APPROACH** Half of the unpolarized light is absorbed by the first Polaroid, and the remaining light emerges plane-polarized vertically. When that light passes through the second Polaroid, the intensity is further reduced according to Eq. 34–8, and the plane of polarization is then along the axis of the second Polaroid.

**SOLUTION** The first Polaroid eliminates half the light, so the intensity is reduced by half: $I_1 = \frac{1}{2}I_0$. The light reaching the second polarizer is vertically polarized and so is reduced in intensity (Eq. 34–8) to

$$I_2 = I_1(\cos 60°)^2 = \tfrac{1}{4}I_1.$$

Thus, $I_2 = \frac{1}{8}I_0$. The transmitted light has an intensity one-eighth that of the original and is plane-polarized at a 60° angle to the vertical. If the Polaroids are colored, even more light is lost.

**FIGURE 34–32** Example 34–10.

**CONCEPTUAL EXAMPLE 34–10** **Three Polaroids.** We saw in Fig. 34–30 that when unpolarized light falls on two crossed Polaroids (axes at 90°), no light passes through. What happens if a third Polaroid, with axis at 45° to each of the other two, is placed between them (Fig. 34–32a)?

**RESPONSE** We start just as in Example 34–9 and recall again that light emerging from each Polaroid is polarized parallel to that Polaroid's axis. Thus the angle in Eq. 34–8 is that between the transmission axes of each pair of Polaroids taken in turn. The first Polaroid changes the unpolarized light to plane-polarized and reduces the intensity from $I_0$ to $I_1 = \frac{1}{2}I_0$. The second polarizer further reduces the intensity by $(\cos 45°)^2$, Eq. 34–8:

$$I_2 = I_1(\cos 45°)^2 = \tfrac{1}{2}I_1 = \tfrac{1}{4}I_0.$$

The light leaving the second polarizer is plane-polarized at 45° (Fig. 34–32b) relative to the third polarizer, so the third one reduces the intensity to

$$I_3 = I_2(\cos 45°)^2 = \tfrac{1}{2}I_2,$$

or $I_3 = \frac{1}{8}I_0$. Thus $\frac{1}{8}$ of the original intensity gets transmitted.

**NOTE** If we don't insert the 45° Polaroid, zero intensity results (Fig. 34–30).

**EXERCISE E** How much light would pass through if the 45° polarizer in Example 34–10 was placed not between the other two polarizers but (*a*) before the vertical (first) polarizer, or (*b*) after the horizontal polarizer?

## Polarization by Reflection

Another means of producing polarized light from unpolarized light is by reflection. When light strikes a nonmetallic surface at any angle other than perpendicular, the reflected beam is found to be polarized preferentially in the plane parallel to the surface, Fig. 34–33. In other words, the component with polarization in the plane perpendicular to the surface is preferentially transmitted or absorbed. You can check this by rotating Polaroid sunglasses while looking through them at a flat surface of a lake or road. Since most outdoor surfaces are horizontal, Polaroid sunglasses are made with their axes vertical to eliminate the more strongly reflected horizontal component, and thus reduce glare.

People who go fishing wear Polaroids to eliminate reflected glare from the surface of a lake or stream and thus see beneath the water more clearly (Fig. 34–34).

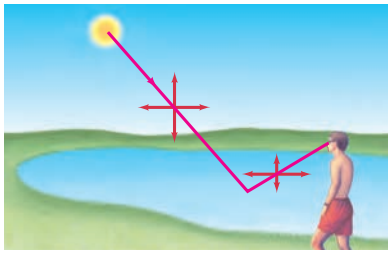


**FIGURE 34–33** Light reflected from a nonmetallic surface, such as the smooth surface of water in a lake, is partially polarized parallel to the surface.

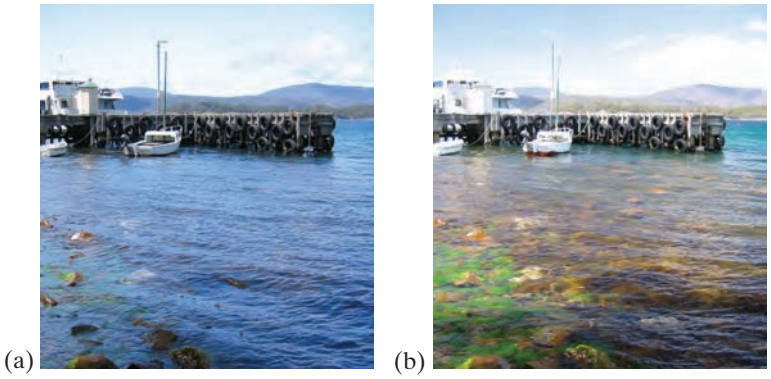

**FIGURE 34–34** Photographs of a lake, (a) allowing all light into the camera lens, and (b) using a polarizer. The polarizer is adjusted to absorb most of the (polarized) light reflected from the water's surface, allowing the dimmer light from the bottom of the lake, and any fish lying there, to be seen more readily.

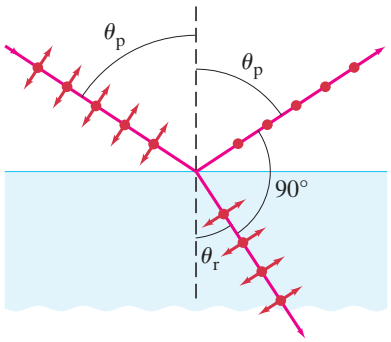
The amount of polarization in the reflected beam depends on the angle, varying from no polarization at normal incidence to 100% polarization at an angle known as the **polarizing angle** $\theta_p$.[†] This angle is related to the index of refraction of the two materials on either side of the boundary by the equation



$$\tan\theta_p = \frac{n_2}{n_1}, \qquad \textbf{(34–9a)}$$

where $n_1$ is the index of refraction of the material in which the incident beam is traveling, and $n_2$ is that of the medium beyond the reflecting boundary. If the beam is traveling in air, $n_1 = 1$, and Eq. 34–9a becomes

$$\tan\theta_p = n. \qquad \textbf{(34–9b)}$$

The polarizing angle $\theta_p$ is also called **Brewster's angle**, and Eqs. 34–9 *Brewster's law*, after the Scottish physicist David Brewster (1781–1868), who worked it out experimentally in 1812. Equations 34–9 can be derived from the electromagnetic wave theory of light. It is interesting that at Brewster's angle, the reflected ray and the transmitted (refracted) ray make a 90° angle to each other; that is, $\theta_p + \theta_r = 90°$, where $\theta_r$ is the refraction angle (Fig. 34–35). This can be seen by substituting Eq. 34–9a, $n_2 = n_1\tan\theta_p = n_1\sin\theta_p/\cos\theta_p$, into Snell's law, $n_1\sin\theta_p = n_2\sin\theta_r$, which gives $\cos\theta_p = \sin\theta_r$ which can only hold if $\theta_p = 90° - \theta_r$ (see Trigonometric identities inside back cover or Appendix A).

**FIGURE 34–35** At $\theta_p$ the reflected light is plane-polarized parallel to the surface, and $\theta_p + \theta_r = 90°$, where $\theta_r$ is the refraction angle. (The large dots represent electric field vibrations perpendicular to the page.)

[†]Only a fraction of the incident light is reflected at the surface of a transparent medium. Although this reflected light is 100% polarized (if $\theta = \theta_p$), the remainder of the light, which is transmitted into the new medium, is only partially polarized.

**EXAMPLE 34–11** **Polarizing angle.** (*a*) At what incident angle is sunlight reflected from a lake perfectly plane-polarized? (*b*) What is the refraction angle?

**APPROACH** The polarizing angle at the surface is Brewster's angle, Eq. 34–9b. We find the angle of refraction from Snell's law.

**SOLUTION** (*a*) We use Eq. 34–9b with $n = 1.33$, so $\tan\theta_p = 1.33$ giving $\theta_p = 53.1°$.
(*b*) From Snell's law, $\sin\theta_r = \sin\theta_p/n = \sin 53.1°/1.33 = 0.601$ giving $\theta_r = 36.9°$.

**NOTE** $\theta_p + \theta_r = 53.1° + 36.9° = 90.0°$, as expected.

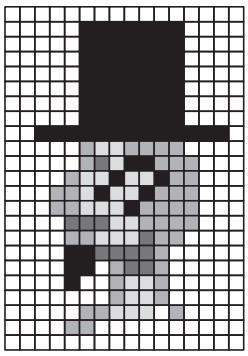


**FIGURE 34–36** Example of an image made up of many small picture elements or *pixels*.

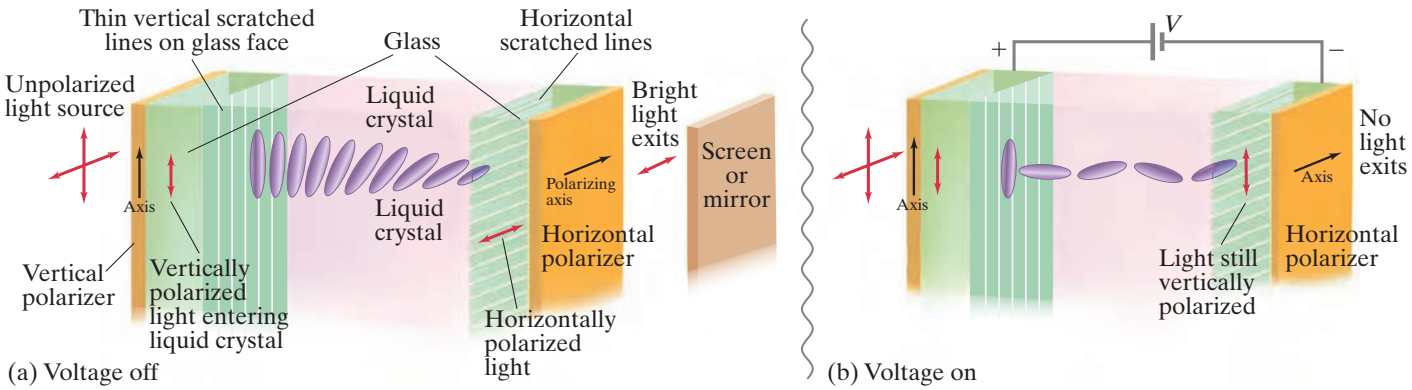
## *34–8 Liquid Crystal Displays (LCD)

A wonderful use of polarization is in a **liquid crystal display** (LCD). LCDs are used as the display in cell phones, other hand-held electronic devices, and flat-panel computer and television screens.

A liquid crystal display is made up of many tiny rectangles called **pixels**, or "picture elements." The picture you see depends on which pixels are dark or light and of what color, as suggested in Fig. 34–36 for a simple black and white picture. (Hopefully you can recognize Abe Lincoln.)

Liquid crystals are organic materials that at room temperature exist in a phase that is neither fully solid nor fully liquid. They are sort of gooey, and their molecules display a randomness of position characteristic of liquids, as discussed in Section 17–1 and Fig. 17–2b. They also show some of the orderliness of a solid crystal (Fig. 17–2a), but only in one dimension.

**FIGURE 34–37** Liquid crystal molecules tend to align in one dimension (parallel to each other) but have random positions (left-right, up-down).



The liquid crystals we find useful are made up of relatively rigid rod-like molecules that interact weakly with each other and tend to align parallel to each other, as shown in Fig. 34–37.

In a simple LCD, each pixel (picture element) contains liquid crystal material sandwiched between two glass plates (green in Fig. 34–38) whose inner surfaces have nanometer-wide parallel scratched lines. The rod-like liquid crystal molecules (violet) in contact with the scratched lines tend to line up along those lines. The front and back plates usually have their scratched lines at 90° to each other, and the weak electric forces between the rod-like molecules tend to keep them nearly aligned with their nearest neighbors (and lying in a plane parallel to the glass plates), resulting in a twisted pattern, molecules being vertical on the left, rotating gradually until horizontal on the right, Fig. 34–38a.

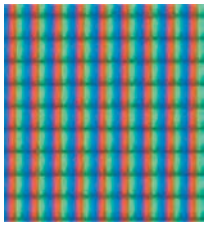
The outer surfaces of the two glass plates each have a thin film polarizer (orange), which are also oriented at 90° to each other. Unpolarized light incident from the left immediately becomes plane-polarized, and the liquid crystal molecules (purple) keep this polarization aligned with their rod-like shape. That is, the plane of polarization of the light rotates with the molecules as the light passes through the liquid crystal (pink). The light emerges with its plane of polarization rotated by 90°, and readily passes through the second polarizer, Fig. 34–38a. A tiny LCD pixel in this situation will appear bright.

Now suppose a voltage is applied to transparent electrodes on each glass plate of the pixel. The rod-like molecules are polar (or can acquire an internal separation of charge due to the applied electric field). The applied voltage tends to align

**FIGURE 34–38** (a) "Twisted" form of liquid crystal. Light polarization plane is rotated 90°, and so is transmitted by the horizontal polarizer. Only one series of molecules is shown. (b) Molecules disoriented by electric field. The plane of polarization does not get changed, so light does not pass through the horizontal polarizer. (Transparent electrodes not shown.)

the molecules end-to-end, and they no longer follow the careful twisted pattern shown in Fig. 34–38a. Instead the applied electric field tends to align the molecules end-to-end, left to right perpendicular to the glass plates, Fig. 34–38b, and so they don't affect the light polarization significantly. The entering plane-polarized light no longer has its plane of polarization rotated as it passes through the liquid crystal, and no light exits through the second (horizontal) polarizer (Fig. 34–38b). With the voltage on, the pixel appears dark.†

Simple display screens, such as for watches and calculators, use ambient light as the unpolarized source on the left in Fig. 34–38 (you can't see the display in the dark), with a mirror behind the LCD to reflect the light back. There are only a few pixels, corresponding to the straight segments needed to form the numbers from 0 to 9 (and letters in some displays), as seen in Fig. 34–39. Any pixels to which a voltage is applied appear dark and form part of a number. With no voltage, pixels pass light through the polarizers to the mirror and back out, which forms a bright background. Displays with white numbers on a dark background have the voltages reversed.

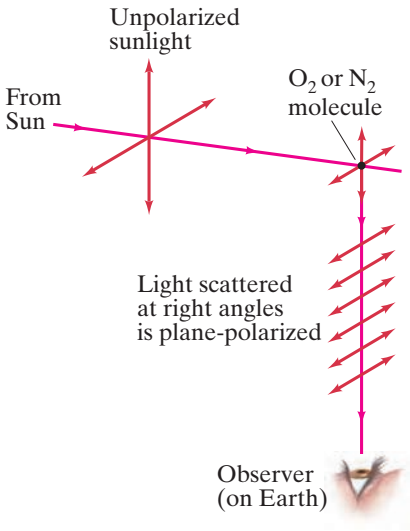


Television, cell phone, and computer LCDs are more sophisticated. A color pixel consists of three cells, or subpixels, each covered with a red, green, or blue filter (Fig. 34–40). Varying brightnesses of these three primary colors can yield almost any natural color. A good-quality screen consists of millions of pixels. Behind this array of pixels is a light source, sometimes thin fluorescent tubes the diameter of a straw, or light-emitting diodes (LEDs). The light passes through the liquid crystal subpixels, or not, depending on the voltage applied to each, as we discussed in detail in Section 23–10. See especially Figs. 23–31 and 23–32.

To obtain a range of gray scale or range of color brightness, each subpixel cannot simply go on or off as in Fig. 34–38. Several techniques can be used depending on the construction of the LCD. (1) If the voltage applied in Fig. 34–38b is small enough, the disorientation of the molecules may be small, allowing some rotation of the polarization vector and thus some light can pass through, the actual amount depending on the voltage. (2) Alternatively, each subpixel can be pulsed—the length of time it is *on* affects the perceived brightness. (3) The effect of stronger or weaker brightness can instead be provided by the number of nearby subpixels of the same color that are turned on or off; this third system lets the eye "average" over many pixels, but reduces the sharpness or resolution of the picture.

**FIGURE 34–39** Watch-face LCD display with altimeter. The black segments or pixels have a voltage applied to them. Note that the 8 uses all seven segments (pixels); other numbers use fewer.

**FIGURE 34–40** Arrangement of subpixels on a TV or computer display (enlarged).



## *34–9 Scattering of Light by the Atmosphere

Sunsets are red, the sky is blue, and skylight is polarized (at least partially). These phenomena can be explained on the basis of the *scattering* of light by the molecules of the atmosphere. In Fig. 34–41 we see unpolarized light from the Sun impinging on a molecule of the Earth's atmosphere. The electric field of the EM wave sets the electric charges within the molecule into oscillation, and the $N_2$ or $O_2$ molecule absorbs some of the incident radiation. But the molecule quickly reemits this light since the charges are oscillating. As discussed in Section 31–4 oscillating electric charges produce EM waves. The intensity is strongest along the direction perpendicular to the oscillation, and drops to zero along the line of oscillation (Section 31–4). In Fig. 34–41 the motion of the charges is resolved into two components. An observer at right angles to the direction of the sunlight, as shown, will see plane-polarized light because no light is emitted along the line of the other component of the oscillation. (When viewing along the line of an oscillation, you don't see that oscillation, and hence see no waves made by it.) At other viewing angles, both components will be present; one will be stronger, however, so the light appears partially polarized. Thus, this process of scattering explains the polarization of skylight.

Scattering of light by the Earth's atmosphere depends on wavelength $\lambda$. For particles much smaller than the wavelength of light (such as molecules of air), the particles will be less of an obstruction to long wavelengths than to short ones.

**FIGURE 34–41** Unpolarized sunlight scattered by molecules of the air. An observer at right angles sees plane-polarized light, since the component of oscillation along the line of sight emits no light along that line.

†Some displays use an opposite system: the polarizers are parallel to each other (the scratches remain at 90° to maintain the twist). Then voltage *off* results in *black* (no light), and voltage *on* results in bright light.

**PHYSICS APPLIED**

*Why the sky is blue*
*Why sunsets are red*
*Why clouds are white*

The scattering decreases, in fact, as $1/\lambda^4$. Blue and violet light are thus scattered much more than red and orange, which is why the sky looks blue. At sunset, the Sun's rays pass through a maximum length of atmosphere. Much of the blue has been taken out by scattering. The light that reaches us at this low angle where the Sun is near the horizon, and reflects off clouds and haze, is thus lacking in blue. That is why sunsets appear reddish.

The dependence of scattering on $1/\lambda^4$ is valid only if the scattering objects are much smaller than the wavelength of the light. This is valid for oxygen and nitrogen molecules whose diameters are about 0.2 nm. Clouds, however, contain water droplets or crystals that are much larger than $\lambda$. They scatter all frequencies of light nearly uniformly. Hence clouds appear white (or gray, if shadowed).

## 34–10 Brightness: Lumens and Luminous Intensity

The *intensity* of light, as for any electromagnetic wave, is measured by the Poynting vector in $W/m^2$, and the total power output of a source can be measured in watts (the *radiant flux*). But for measuring the visual sensation we call *brightness*, we must consider *only* the visible spectrum as well as the eye's sensitivity to different wavelengths—the eye is most sensitive in the central, 550-nm (green), portion of the spectrum.

These factors are taken into account by the quantity **luminous flux**, $F_\ell$, whose unit is the **lumen** (lm). One lumen is equivalent to $\frac{1}{683}$ watts of 555-nm light.

Since the luminous flux from a source may not be uniform over all directions, we define the **luminous intensity** $I_\ell$ as the luminous flux per unit solid angle[†] (steradian). Its unit is the **candela** (cd) where $1\text{ cd} = 1\text{ lm/sr}$.

The **illuminance**, $E_\ell$, is the luminous flux incident on a surface per unit area of the surface: $E_\ell = F_\ell/A$. Its unit is the lumen per square meter $(\text{lm/m}^2)$ and is a measure of the illumination falling on a surface.[‡]

**EXAMPLE 34–12** **Lightbulb illuminance.** The brightness of a particular type of 100-W lightbulb is rated at 1700 lm. Determine (*a*) the luminous intensity and (*b*) the illuminance at a distance of 2.0 m.

**APPROACH** Assume the light output is uniform in all directions.

**SOLUTION** (*a*) A full sphere corresponds to $4\pi$ sr.[†] Hence, $I_\ell = 1700\text{ lm}/4\pi\text{ sr} = 135\text{ cd}$. It does not depend on distance.

(*b*) At $d = 2.0\text{ m}$ from the source, the luminous flux per unit area is

$$E_\ell = \frac{F_\ell}{A} = \frac{F_\ell}{4\pi d^2} = \frac{1700\text{ lm}}{(4\pi)(2.0\text{ m})^2} = 34\text{ lm/m}^2.$$

The illuminance decreases as the square of the distance.

## *34–11 Efficiency of Lightbulbs

We can compare the efficiencies of different types of lightbulbs using the lumen. A 100-W traditional incandescent bulb (no halogen capsule) emits EM waves of a wide variety of wavelengths (Section 37–1), including about 1500 lumens of visible light, depending on the filament (a finer filament gets hotter and gives a more natural spectrum and more light output, but has a shorter life); output also depends on any coating on the inside of the glass bulb. "Soft-white" bulbs are coated and are considered by many as ideal for reading. As an average, let us estimate that a normal 100 W (input) incandescent bulb produces 1500 lm, which means an efficiency of $1500\text{ lm}/100\text{ W} = 15\text{ lm/W}$. Lifetimes are around 1000 hours.

[†]A solid angle is a sort of two-dimensional angle and is measured in steradians (sr). Think of a solid angle starting at a point and intercepting an area $\Delta A$ on a sphere of radius $r$ surrounding that point. The solid angle has magnitude $\Delta A/r^2$ steradians. A solid angle including all of space intercepts the full surface area of the sphere, $4\pi r^2$, and so has magnitude $4\pi r^2/r^2 = 4\pi$ steradians. (Compare to a normal angle, for which a full circle subtends $2\pi$ radians.)

[‡]The British unit is the foot-candle, or lumen per square foot.

A halogen bulb (incandescent having the filament in a capsule filled with halogen gas) does better, about 20 lm/W, plus a life that can reach about 2000 h. Compact fluorescent bulbs (CFL) for use in ordinary sockets are spiral-shaped (or have sharp bends) and can produce about 70 lm/W and may last up to 10,000 h if well made (often not the case). CFLs are less wasteful of energy and can last longer; but the light they produce can be displeasing to many people, they cost more, and contain toxic material. LED bulbs are even more efficient, as much as 160 or 180 lm/W for a good white color (a 300 lm/W bulb has been claimed) and a life of perhaps 20,000 h (again a reputable brand). How CFLs and LEDs (light emitting diodes) work is discussed in Chapter 39 and 40 respectively.

The spectrum of light emitted by a filament depends on its temperature (see Section 37–1), whereas CFL and LED may specify an "effective" temperature (technically, "correlated color temperature").†

We can look at all this in another way which connects with our definition in Section 34–10 that 683 lumens is equivalent to 1 watt of 555-nm light. For white light, the sensitivity of the eye peaks at about 555 nm and is less sensitive for longer or shorter wavelengths, dropping to zero around 400 nm and 700 nm. So let us estimate over the full visible spectrum ("white") that 1 watt of light entering the eye would correspond to about half of what it is at 555 nm (683 lm) or roughly 300 or 400 lumens. Then a 100-W incandescent bulb puts out about $(1500\,\text{lm})/(300\,\text{lm/W}) \approx 5\,\text{W}$ of visible light (100 W input to the bulb, 5 W output of visible light).

†LED bulbs may specify a temperature, but that is *not* its own temperature. A 3000 K LED means the mix of different color LEDs gives a warm yellowish light like a 3000 K incandescent bulb filament, and that would be a comfortable bulb to read by. If labeled 5000 K, which is close to the Sun's temperature of 6000 K, it is more white like outdoor light, and may be too harsh to read by. Temperature and color are connected for a filament (discussed in Section 37–1) but not for LEDs (Chapter 40).

# Summary

The wave theory of light is strongly supported by the observations that light exhibits **interference** and **diffraction**. Wave theory also explains the refraction of light and the fact that light travels more slowly in transparent solids and liquids than it does in air.

An aid to predicting wave behavior is **Huygens' principle**, which states that every point on a wave front can be considered as a source of tiny wavelets that spread out in the forward direction at the speed of the wave itself. The new wave front is the envelope (the common tangent) of all the wavelets.

The wavelength of light in a medium with index of refraction $n$ is

$$\lambda_n = \frac{\lambda}{n}, \qquad \textbf{(34–1)}$$

where $\lambda$ is the wavelength in vacuum; the frequency is not changed.

Young's double-slit experiment clearly demonstrated the interference of light. The observed bright lines of the interference pattern are explained as constructive interference between the beams coming through the two slits, where the beams differ in path length by zero or an integral number of wavelengths. The dark areas in between are due to destructive interference when the path lengths differ by $\frac{1}{2}\lambda$, $\frac{3}{2}\lambda$, and so on. The angles $\theta$ at which **constructive interference** occurs are given by

$$\sin\theta = m\frac{\lambda}{d}, \qquad \textbf{(34–2a)}$$

where $\lambda$ is the wavelength of the light, $d$ is the separation of the slits, and $m$ is an integer $(0, 1, 2, \cdots)$. **Destructive interference** occurs at angles $\theta$ given by

$$\sin\theta = \left(m + \tfrac{1}{2}\right)\frac{\lambda}{d}, \qquad \textbf{(34–2b)}$$

where $m$ is an integer $(0, 1, 2, \cdots)$.

[*The light intensity $I_\theta$ at any point in a double-slit interference pattern can be calculated using a phasor diagram, which predicts that

$$I_\theta = I_0\cos^2\frac{\delta}{2} \qquad \textbf{(34–6)}$$

where $I_0$ is the intensity at $\theta = 0$ and the phase angle $\delta$ is

$$\delta = \frac{2\pi d}{\lambda}\sin\theta. \qquad \textbf{(34–4)}]$$

Two sources of light are perfectly **coherent** if the waves leaving them are of the same single frequency and maintain the same phase relationship at all times. If the light waves from the two sources have a random phase with respect to each other over time (as for two lightbulbs), the two sources are **incoherent**.

Light reflected from the front and rear surfaces of a thin film of transparent material can interfere constructively or destructively, depending on the path difference. A phase change of 180° or $\frac{1}{2}\lambda$ occurs when the light reflects at a surface where the index of refraction increases. Such **thin-film interference** has many practical applications, such as lens coatings and using Newton's rings to check the uniformity of glass surfaces.

In **unpolarized light**, the electric field vectors oscillate in all transverse directions. If the electric vector oscillates only in one plane, the light is said to be **plane-polarized**. Light can also be partially polarized.

When an unpolarized light beam passes through a **Polaroid** sheet, the emerging beam is plane-polarized. When a light beam is polarized and passes through a Polaroid, the intensity varies as the Polaroid is rotated. Thus a Polaroid can act as a **polarizer** or as an **analyzer**.

The intensity $I$ of a plane-polarized light beam incident on a Polaroid is reduced by the factor

$$I = I_0\cos^2\theta \qquad \textbf{(34–8)}$$

where $\theta$ is the angle between the axis of the Polaroid and the initial plane of polarization.

Light can also be partially or fully **polarized by reflection**. If light traveling in air is reflected from a medium of index of refraction $n$, the reflected beam will be *completely* plane-polarized if the incident angle $\theta_p$ is given by

$$\tan\theta_p = n. \qquad \textbf{(34–9b)}$$

The fact that light can be polarized shows that it must be a transverse wave.

The brightness of a lightbulb may be specified in *lumens*, which takes into account the sensitivity of the eye.

# Questions

1. Does Huygens' principle apply to sound waves? To water waves? Explain how Huygens' principle makes sense for water waves, where each point vibrates up and down.
2. What is the evidence that light is energy?
3. Why is light sometimes described as rays and sometimes as waves?
4. We can hear sounds around corners but we cannot see around corners; yet both sound and light are waves. Explain the difference.
5. Can the wavelength of light be determined from reflection or refraction measurements?
6. Two rays of light from the same source destructively interfere if their path lengths differ by how much?
7. Monochromatic red light is incident on a double slit and the interference pattern is viewed on a screen some distance away. Explain how the fringe pattern would change if the red light source is replaced by a blue light source.
8. If Young's double-slit experiment were submerged in water, how would the fringe pattern be changed?
9. Compare Figs. 34–5, 34–6, and 34–7, which are different representations of the double-slit experiment. For each Figure state the direction the light is traveling. Where are the wave crests in terms of this direction? How are they represented in each Figure? Give one advantage of each Figure in helping you understand the double-slit experiment and interference.
10. Compare a double-slit experiment for sound waves to that for light waves. Discuss the similarities and differences.
11. Suppose white light falls on the two slits of Fig. 34–7, but one slit is covered by a red filter (700 nm) and the other by a blue filter (450 nm). Describe the pattern on the screen.
12. Why doesn't the light from the two headlights of a distant car produce an interference pattern?
13. Why are interference fringes noticeable only for a *thin* film like a soap bubble and not for a thick piece of glass, say?
14. Why are Newton's rings (Fig. 34–18) closer together farther from the center?
15. Some coated lenses appear greenish yellow when seen by reflected light. What reflected wavelengths do you suppose the coating is designed to eliminate completely?
16. A drop of oil on a pond appears bright at its edges where its thickness is much less than the wavelengths of visible light. What can you say about the index of refraction of the oil compared to that of water?
17. What does polarization tell us about the nature of light?
18. Explain the advantage of polarized sunglasses over plain tinted sunglasses.
19. How can you tell if a pair of sunglasses is polarizing or not?
*20. What would be the color of the sky if the Earth had no atmosphere?
*21. If the Earth's atmosphere were 50 times denser than it is, would sunlight still be white, or would it be some other color?

# MisConceptual Questions

1. When light passes through a narrow slit, it spreads out rather than traveling in a straight line. The reason for the spreading is
   (*a*) reflections from the edges of the slit.
   (*b*) refraction by fluctuations in the air density within the slit.
   (*c*) because light is a wave, and this is a basic wave property.
2. Light passing through a double-slit arrangement is viewed on a distant screen. The interference pattern observed on the screen would have the widest spaced fringes for the case of
   (*a*) red light and a small slit spacing.
   (*b*) blue light and a small slit spacing.
   (*c*) red light and a large slit spacing.
   (*d*) blue light and a large slit spacing.
3. In a double-slit experiment (Figs. 34–9 and 10), when the wavelength of the light is increased, the interference pattern
   (*a*) spreads out.
   (*b*) stays the same.
   (*c*) shrinks together.
   (*d*) disappears.
4. If the slits of the previous Question are moved farther apart (without changing the wavelength), the interference pattern
   (*a*) spreads out.
   (*b*) stays the same.
   (*c*) shrinks together.
   (*d*) disappears.
5. Destructive interference occurs when you look at monochromatic light reflecting from a very thin sheet of glass $(n = 1.5)$ surrounded by air. If the air on one side of the glass is replaced with water, then
   (*a*) constructive interference will occur.
   (*b*) destructive interference will still occur.
   (*c*) either constructive or destructive interference could occur, depending on the wavelength of the light.
6. Reflected light from a thin film of oil on glass shows destructive interference for a certain wavelength of visible light. If the thickness of the oil $(n_{oil} < n_{glass})$ is increased by 50%, that wavelength of light will experience
   (*a*) constructive interference.
   (*b*) destructive interference.
   (*c*) about 50% destructive (and therefore 50% constructive) interference.
   (*d*) Not enough information; we need to know the wavelength of light and the indices of refraction.
7. What is the difference in the interference pattern you would see with light reflecting from a thin soap film $(n = 1.42)$ in air versus the same film on water $(n = 1.33)$?
   (*a*) There would be no difference.
   (*b*) There would be a shift due to the phase change upon reflection at the soap-water interface.
   (*c*) There would be a shift due to the absence of a phase change upon reflection at the soap-water interface.
   (*d*) There would be a shift due to the phase change upon reflection at the air-soap interface.

8. Light strikes perpendicular to a thin film in air. Considering the wavelength of light inside the film, then if the film has a thickness that is
(*a*) $\frac{1}{4}$ of a wavelength, constructive interference will always occur.
(*b*) $\frac{1}{4}$ of a wavelength, destructive interference will always occur.
(*c*) $\frac{1}{2}$ of a wavelength, constructive interference will always occur.
(*d*) $\frac{1}{2}$ of a wavelength, destructive interference will always occur.
(*e*) None of the above is always true.

9. Suppose you have a detector between two identical, coherent red lasers ($\lambda$) on either side pointing at each other. The detector midway between detects total destructive interference. To detect total constructive interference, you need to move the detector
(*a*) a distance $\lambda$ toward one of the lasers.
(*b*) a distance $\frac{1}{2}\lambda$ toward one of the lasers.
(*c*) a distance $\frac{1}{4}\lambda$ toward one of the lasers.
(*d*) None of the above.

10. The two waves shown in Fig. 34–42 are
(*a*) out of phase by 180°.
(*b*) out of phase by 90°.
(*c*) out of phase by 45°.
(*d*) out of phase by 360°.
(*e*) in phase.

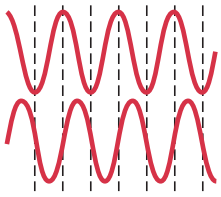


**FIGURE 34–42**
MisConceptual Question 10.

11. Reflection from a thin film (index of refraction $n$) in air shows destructive interference. This means the thickness of the film could be
(*a*) $\frac{\lambda}{4n}$.
(*b*) $\frac{\lambda}{2n}$.
(*c*) $\frac{\lambda}{n}$.
(*d*) Not enough information.

12. If unpolarized light is incident from the left on three polarizers as shown in Fig. 34–43, in which case will some light get through?
(*a*) Case 1 only.
(*b*) Case 2 only.
(*c*) Case 3 only.
(*d*) Case 1 and 3.
(*e*) All three cases.

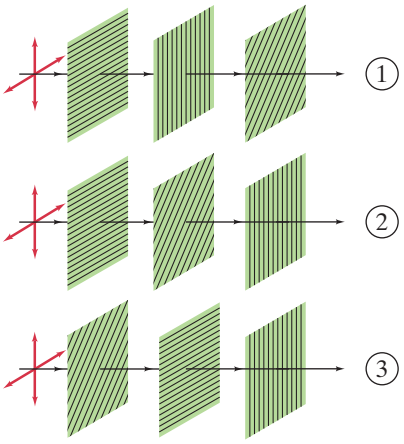

**FIGURE 34–43**
MisConceptual Question 12.

# Problems

## 34–2 Huygens' Principle

1. (II) Derive the law of reflection—namely, that the angle of incidence equals the angle of reflection from a flat surface—using Huygens' principle for waves.

## 34–3 Double-Slit Interference

2. (I) Monochromatic light falling on two slits 0.018 mm apart produces the fifth-order bright fringe at a 12° angle. What is the wavelength of the light used?

3. (I) The third-order bright fringe of 610-nm light is observed at an angle of 25° when the light falls on two narrow slits. How far apart are the slits?

4. (II) Monochromatic light falls on two very narrow slits 0.048 mm apart. Successive fringes on a screen 6.50 m away are 8.5 cm apart near the center of the pattern. Determine the wavelength and frequency of the light.

5. (II) Assume that light of a single color, rather than white light, passes through the two-slit setup described in Example 34–4. If the distance from the central fringe to a first-order fringe is measured to be 2.9 mm on the screen, determine the light's wavelength (in nm) and color (see Fig. 34–11).

6. (II) A red laser from the physics lab is marked as producing 632.8-nm light. When light from this laser falls on two closely spaced slits, an interference pattern formed on a wall several meters away has bright fringes spaced 6.00 mm apart near the center of the pattern. When the laser is replaced by a small laser pointer, the fringes are 5.04 mm apart. What is the wavelength of light produced by the pointer?

7. (II) If 720-nm and 660-nm light passes through two slits 0.61 mm apart, how far apart are the second-order fringes for these two wavelengths on a screen 1.0 m away?

8. (II) Water waves having parallel crests 4.5 cm apart pass through two openings 7.5 cm apart in a board. At a point 3.0 m beyond the board, at what angle relative to the "straight-through" direction would there be little or no wave action?

9. (II) Light of wavelength 680 nm falls on two slits and produces an interference pattern in which the third-order bright red fringe is 38 mm from the central fringe on a screen 2.2 m away. What is the separation of the two slits?

10. (II) A parallel beam of light from a He–Ne laser, with a wavelength 633 nm, falls on two very narrow slits 0.068 mm apart. How far apart are the fringes in the center of the pattern on a screen 4.2 m away?

11. (II) A physics professor wants to perform a lecture demonstration of Young's double-slit experiment for her class using the 633-nm light from a He–Ne laser. Because the lecture hall is very large, the interference pattern will be projected on a wall that is 4.6 m from the slits. For easy viewing by all students in the class, the professor wants the distance between the $m = 0$ and $m = 1$ maxima to be 25 cm. What slit separation is required in order to produce the desired interference pattern?

12. (II) Light of wavelength $\lambda$ passes through a pair of slits separated by 0.17 mm, forming a double-slit interference pattern on a screen located a distance 35 cm away. Suppose that the image in Fig. 34–9a is an actual-size reproduction of this interference pattern. Use a ruler to measure a pertinent distance on this image; then utilize this measured value to determine $\lambda$ (nm).

13. (II) Suppose a thin piece of glass is placed in front of the lower slit in Fig. 34–7 so that the two waves enter the slits 180° out of phase (Fig. 34–44). Describe in detail the interference pattern on the screen.

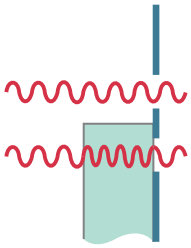

**FIGURE 34–44**
Problem 13.

14. (II) A very thin sheet of plastic $(n = 1.60)$ covers one slit of a double-slit apparatus illuminated by 640-nm light. The center point on the screen, instead of being a maximum, is dark. What is the (minimum) thickness of the plastic?

15. (II) Two narrow slits separated by 1.4 mm are illuminated by 544-nm light. Find the distance between adjacent bright fringes on a screen 5.0 m from the slits.

16. (II) In a double-slit experiment, the third-order maximum for light of wavelength 500 nm is located 12 mm from the central bright spot on a screen 1.3 m from the slits. Light of wavelength 650 nm is then projected through the same slits. How far from the central bright spot will the second-order maximum of this light be located?

17. (II) Light of wavelength 474 nm in air shines on two slits $6.00 \times 10^{-2}$ mm apart. The slits are immersed in water, as is a viewing screen 60.0 cm away. How far apart are the fringes on the screen?

18. (II) In a double-slit experiment it is found that blue light of wavelength 480 nm gives a second-order maximum at a certain location on the screen. What wavelength of visible light would have a minimum at the same location?

## *34–4 Intensity in Two-Slit Interference

*19. (I) If one slit in Fig. 34–12 is covered, by what factor does the intensity at the center of the screen change?

*20. (II) In a two-slit interference experiment, the path length to a certain point P on the screen differs for one slit in comparison with the other by 1.25λ. (*a*) What is the phase difference between the two waves arriving at point P? (*b*) Determine the intensity at P, expressed as a fraction of the maximum intensity $I_0$ on the screen.

*21. (II) Show that the angular full width at half maximum of the central peak in a double-slit interference pattern is given by $\Delta\theta = \lambda/2d$ if $\lambda \ll d$.

*22. (II) Derive an expression similar to Eq. 34–2 which gives the angles for which the double-slit intensity is one-half its maximum value, $I_\theta = \frac{1}{2} I_0$.

*23. (III) Suppose that one slit of a double-slit apparatus is wider than the other so that the intensity of light passing through it is twice as great. Determine the intensity $I$ as a function of position $(\theta)$ on the screen for coherent light.

*24. (III) (*a*) Consider three equally spaced and equal-intensity coherent sources of light (such as adding a third slit to the two slits of Fig. 34–12). Use the phasor method to obtain the intensity as a function of the phase difference $\delta$ (Eq. 34–4). (*b*) Determine the positions of maxima and minima.

## 34–5 Thin-Film Interference

25. (I) If a soap bubble is 120 nm thick, what wavelength is most strongly reflected at the center of the outer surface when illuminated normally by white light? Assume that $n = 1.35$.

26. (I) How far apart are the dark fringes in Example 34–6 if the glass plates are each 26.3 cm long?

27. (II) (*a*) What is the smallest thickness of a soap film $(n = 1.33)$ that would appear black if illuminated with 480-nm light? Assume there is air on both sides of the soap film. (*b*) What are two other possible thicknesses for the film to appear black? (*c*) If the thickness $t$ was much less than $\lambda$, why would the film also appear black?

28. (II) A thin oil slick $(n_o = 1.50)$ floats on water $(n_w = 1.33)$. When a beam of white light strikes this film at normal incidence from air, the only enhanced reflected colors are red (653 nm) and violet (392 nm). From this information, deduce the (minimum) thickness $t$ of the oil slick.

29. (II) A thin film of oil $(n_o = 1.50)$ with varying thickness floats on water $(n_w = 1.33)$. When it is illuminated from above by white light, the reflected colors are as shown in Fig. 34–45. In air, the wavelength of yellow light is 580 nm. (*a*) Why are there no reflected colors at point A? (*b*) What is the oil's thickness $t$ at point B?

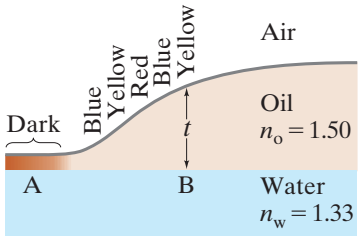

**FIGURE 34–45**
Problem 29.

30. (II) A lens appears greenish yellow ($\lambda = 570$ nm is strongest) when white light reflects from it. What minimum thickness of coating $(n = 1.25)$ do you think is used on such a glass lens $(n = 1.56)$, and why?

31. (II) A total of 35 bright and 35 dark Newton's rings (not counting the dark spot at the center) are observed when 560-nm light falls normally on a planoconvex lens resting on a flat glass surface (Fig. 34–18). How much thicker is the center than the edges?

32. (II) A fine metal foil separates one end of two pieces of optically flat glass, as in Fig. 34–20. When light of wavelength 670 nm is incident normally, 24 dark bands are observed (with one at each end). How thick is the foil?

33. (II) (*a*) How thick (minimum) should the air layer be between two flat glass surfaces if the reflected light is to appear bright when 480-nm light is incident normally? (*b*) What if the glass is to appear dark?

34. (II) A uniform thin film of alcohol $(n = 1.36)$ lies on a flat glass plate $(n = 1.56)$. When monochromatic light, whose wavelength can be changed, is incident normally, the reflected light is a minimum for $\lambda = 492$ nm and a maximum for $\lambda = 615$ nm. What is the minimum thickness of the film?

35. (II) If the wedge between the glass plates of Example 34–6 is filled with some transparent substance other than air—say, water—the pattern shifts because the wavelength of the light changes. In a material where the index of refraction is $n$, the wavelength is $\lambda_n = \lambda/n$, where $\lambda$ is the wavelength in vacuum (Eq. 34–1). How many dark bands would there be if the wedge of Example 34–6 is filled with water?

36. (II) Let's explore why only "thin" layers exhibit thin-film interference. Assume a layer of water, sitting atop a flat glass surface, is illuminated from the air above by white light (all wavelengths from 400 nm to 700 nm). Further, assume that the water layer's thickness $t$ is much greater than a micron ($= 1000$ nm); in particular, let $t = 200\ \mu$m. Take the index of refraction for water to be $n = 1.33$ for all visible wavelengths and the index for glass to be $n_g = 1.50$. (*a*) Show that a visible color will be reflected from the water layer if its wavelength is $\lambda = 2nt/m$, where $m$ is an integer. (*b*) Show that the two extremes in wavelengths (400 nm and 700 nm) of the incident light are both reflected from the water layer and determine the $m$-value associated with each. (*c*) How many other visible wavelengths, besides $\lambda = 400$ nm and 700 nm, are reflected from the "thick" layer of water? (*d*) How does this explain why such a thick layer does not reflect colorfully, but is white or grey?

37. (II) Show that the radius $r$ of the $m^{\text{th}}$ dark Newton's ring, as viewed from directly above (Fig. 34–18), is given by $r = \sqrt{m\lambda R}$ where $R$ is the radius of curvature of the curved glass surface and $\lambda$ is the wavelength of light used. Assume that the thickness of the air gap is much less than $R$ at all points and that $r \ll R$. [*Hint*: Use the binomial expansion.]

38. (II) Use the result of Problem 37 to show that the distance between adjacent dark Newton's rings is

$$\Delta r \approx \sqrt{\frac{\lambda R}{4m}}$$

for the $m^{\text{th}}$ ring, assuming $m \gg 1$.

39. (II) When a Newton's ring apparatus (Fig. 34–18) is immersed in a liquid, the diameter of the tenth dark ring decreases from 2.92 cm to 2.54 cm. What is the refractive index of the liquid? [*Hint*: See Problem 37.]

40. (II) A planoconvex Lucite lens 3.4 cm in diameter is placed on a flat piece of glass as in Fig. 34–18. When 580-nm light is incident normally, 41 bright rings are observed, the last one right at the edge. What is the radius of curvature of the lens surface, and the focal length of the lens? [*Hint*: See Problem 37.]

41. (II) How many uncoated thin lenses in an optical instrument would reduce the amount of light passing through the instrument to 50% or less? (Assume the same transmission percent at each of the two surfaces—see page 1008.)

42. (III) A single optical coating reduces reflection to zero for $\lambda = 550$ nm. By what factor is the intensity reduced by the coating for $\lambda = 430$ nm and $\lambda = 670$ nm as compared to no coating? Assume normal incidence.

## 34–6 Michelson Interferometer

43. (II) How far must the mirror $M_1$ in a Michelson interferometer be moved if 730 fringes of 589-nm light are to pass by a reference line?

44. (II) What is the wavelength of the light entering an interferometer if 368 bright fringes are counted when the movable mirror moves 0.125 mm?

45. (II) A micrometer is connected to the movable mirror of an interferometer. When the micrometer is tightened down on a thin metal foil, the net number of bright fringes that move, compared to the empty micrometer, is 272. What is the thickness of the foil? The wavelength of light used is 611 nm.

46. (III) One of the beams of an interferometer (Fig. 34–46) passes through a small evacuated glass container 1.155 cm deep. When a gas is allowed to slowly fill the container, a total of 163 dark fringes are counted to move past a reference line. The light used has a wavelength of 632.8 nm. Calculate the index of refraction of the gas at its final density, assuming that the interferometer is in vacuum.

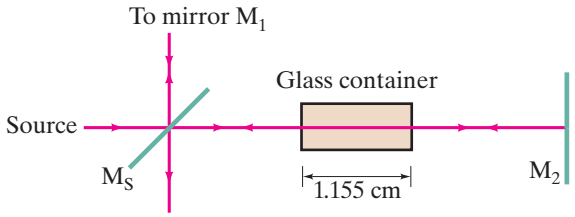

**FIGURE 34–46** Problem 46.

47. (III) The yellow sodium D lines have wavelengths of 589.0 and 589.6 nm. When they are used to illuminate a Michelson interferometer, it is noted that the interference fringes disappear and reappear periodically as the mirror $M_1$ is moved. Why does this happen? How far must the mirror move between one disappearance and the next?

## 34–7 Polarization

48. (I) Two polarizers are oriented at 75° to one another. Unpolarized light falls on them. What fraction of the light intensity is transmitted?

49. (I) What is Brewster's angle for an air-glass ($n = 1.56$) surface? Specify two answers.

50. (I) What is Brewster's angle for a diamond submerged in water? Specify two answers. Will the diamond sparkle as nicely as in air? (See Section 32–9.)

51. (II) Two polarizers are oriented at 44.0° to one another. Light polarized at a 22.0° angle to each polarizer passes through both. What is the transmitted intensity (%)?

52. (II) At what angle should the axes of two Polaroids be placed so as to reduce the intensity of the incident unpolarized light to (*a*) $\frac{1}{3}$, (*b*) $\frac{1}{10}$?

53. (II) The critical angle for total internal reflection at a boundary between two materials is 48°. What is Brewster's angle at this boundary? Give two answers, one for each material.

54. (II) What would Brewster's angle be for reflections off the surface of water for light coming from beneath the surface? Compare to the angle for total internal reflection, and to Brewster's angle from above the surface.

**55.** (II) Two Polaroids are aligned so that the initially unpolarized light passing through them is a maximum. At what angle should one of them be placed so the transmitted intensity is subsequently reduced by half?

**56.** (II) A piece of material, suspected of being a stolen diamond ($n = 2.42$), is submerged in oil of refractive index 1.43 and illuminated by unpolarized light. It is found that the reflected light is completely polarized at an angle of 56°. Is it diamond? Explain.

**57.** (II) Three perfectly polarizing sheets are spaced 2 cm apart and in parallel planes. The transmission axis of the second sheet is 30° relative to the first one. The transmission axis of the third sheet is 90° relative to the *first* one. Unpolarized light impinges on the first polarizing sheet. What percent of this light is transmitted out through the third polarizer?

**58.** (II) Unpolarized light of intensity $I_0$ passes through six successive Polaroid sheets each of whose axis makes a 38° angle with the previous one. What is the intensity of the transmitted beam?

**59.** (II) Two polarizers A and B are aligned so that their transmission axes are vertical and horizontal, respectively. A third polarizer is placed between these two with its axis aligned at angle $\theta$ with respect to the vertical. Assuming vertically polarized light of intensity $I_0$ is incident upon polarizer A, find an expression for the light intensity $I$ transmitted through this three-polarizer sequence. Calculate the derivative $dI/d\theta$; then use it to find the angle $\theta$ that maximizes $I$.

**60.** (III) The percent polarization $P$ of a partially polarized beam of light is defined as

$$P = \frac{I_{\max} - I_{\min}}{I_{\max} + I_{\min}} \times 100$$

where $I_{\max}$ and $I_{\min}$ are the maximum and minimum intensities that are obtained when the light passes through a polarizer that is slowly rotated. Such light can be considered as the sum of two unequal plane-polarized beams of intensities $I_{\max}$ and $I_{\min}$ perpendicular to each other. Show that the light transmitted by a polarizer, whose axis makes an angle $\phi$ to the direction in which $I_{\max}$ is obtained, has intensity

$$\frac{1 + p\cos 2\phi}{1 + p} I_{\max}$$

where $p = P/100$ is the "fractional polarization."

### 34–10 Brightness: Lumens and Luminous Intensity

**61.** (II) The illuminance of direct sunlight on Earth is about $10^5\,\text{lm/m}^2$. Estimate the luminous flux and luminous intensity of the Sun.

**62.** (II) The *luminous efficiency* of a lightbulb is the ratio of luminous flux to electric power input. (*a*) What is the luminous efficiency of a 100-W, 1600-lm bulb? (*b*) How many 40-W, 60-lm/W fluorescent lamps would be needed to provide an illuminance of $250\,\text{lm/m}^2$ on a factory floor of area $22\,\text{m} \times 30\,\text{m}$? Assume the lights are 10 m above the floor and that half their flux reaches the floor.

## General Problems

**63.** A series of polarizers are each rotated 10° from the previous polarizer. Unpolarized light is incident on this series of polarizers. How many polarizers does the light have to go through before it is $\frac{1}{6}$ of its original intensity?

**64.** Television and radio waves reflecting from mountains or airplanes can interfere with the direct signal from the station. (*a*) What kind of interference will occur when 75-MHz television signals arrive at a receiver directly from a distant station, and are reflected from a nearby airplane 122 m directly above the receiver? Assume $\frac{1}{2}\lambda$ change in phase of the signal upon reflection. (*b*) What kind of interference will occur if the plane is 22 m closer to the receiver?

**65.** *Stealth aircraft* are designed to not reflect radar, whose wavelength is typically 2 cm, by using an antireflecting coating. Ignoring any change in wavelength in the coating, estimate its thickness.

**66.** Calculate the minimum thickness needed for an antireflective coating ($n = 1.42$) applied to a glass lens in order to eliminate (*a*) blue (450 nm), or (*b*) red (720 nm) reflections for light at normal incidence.

**67.** Light of wavelength $5.0 \times 10^{-7}\,\text{m}$ passes through two parallel slits and falls on a screen 5.0 m away. Adjacent bright bands of the interference pattern are 2.0 cm apart. (*a*) Find the distance between the slits. (*b*) The same two slits are next illuminated by light of a different wavelength, and the fifth minimum for this light occurs at the same point on the screen as the fourth minimum for the previous light. What is the wavelength of the second source of light?

**68.** A radio station operating at 92.5 MHz broadcasts from two identical antennas at the same elevation but separated by a 9.0-m horizontal distance $d$, Fig. 34–47. A maximum signal is found along the midline, perpendicular to $d$ at its midpoint and extending horizontally in both directions. If the midline is taken as 0°, at what other angle(s) $\theta$ is a maximum signal detected? A minimum signal? Assume all measurements are made much farther than 9.0 m from the antenna towers.

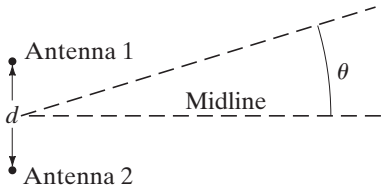

**FIGURE 34–47**
Problem 68.

**69.** Light of wavelength 690 nm passes through two narrow slits 0.66 mm apart. The screen is 1.75 m away. A second source of unknown wavelength produces its second-order fringe 1.23 mm closer to the central maximum than the 690-nm light. What is the wavelength of the unknown light?

**70.** Monochromatic light of variable wavelength is incident normally on a thin sheet of plastic film in air. The reflected light is a maximum only for $\lambda = 491.4$ nm and $\lambda = 688.0$ nm in the visible spectrum. What is the thickness of the film ($n = 1.62$)? [*Hint*: Assume successive values of $m$.]

**71.** A "60-watt equivalent" LED lightbulb is rated at 7.5 W and 800 lumens. How much power goes into light? (The rest goes into heat.)

72. At what angle above the horizon is the Sun when light reflecting off a smooth lake is polarized most strongly?

73. Light from a green laser of wavelength 530 nm passes through two slits that are 35 microns apart. The resulting pattern formed on a screen in front of the slits is shown in Fig. 34–48. If point A is the same distance from both slits, how much closer is point B to one slit than to the other?

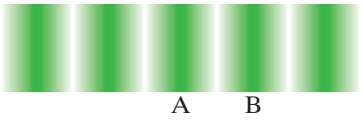

**FIGURE 34–48** Problem 73.

74. Suppose the mirrors in a Michelson interferometer are perfectly aligned and the path lengths to mirrors $M_1$ and $M_2$ are identical. With these initial conditions, an observer sees a bright maximum at the center of the viewing area. Now one of the mirrors is moved a distance $x$. Determine a formula for the intensity at the center of the viewing area as a function of $x$, the distance the movable mirror is moved from the initial position.

75. A highly reflective mirror can be made for a particular wavelength at normal incidence by using two thin layers of transparent materials of indices of refraction $n_1$ and $n_2$ $(1 < n_1 < n_2)$ on the surface of the glass $(n > n_2)$. What should be the minimum thicknesses $d_1$ and $d_2$ in Fig. 34–49 in terms of the incident wavelength $\lambda$, to maximize reflection?

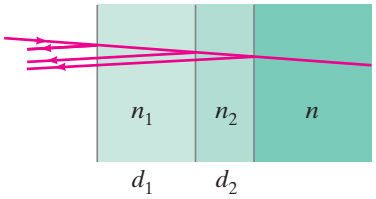

**FIGURE 34–49** Problem 75.

76. What is the index of refraction of a clear material if a minimum thickness of 125 nm, when laid on glass, is needed to reduce reflection to nearly zero when light of 655 nm is incident normally upon it? Do you have a choice for an answer?

77. Light of wavelength $\lambda$ strikes a screen containing two slits a distance $d$ apart at an angle $\theta_i$ to the normal. Determine the angle $\theta_m$ at which the $m^{\text{th}}$-order maximum occurs.

78. Consider two antennas radiating 6.8-MHz radio waves in phase with each other. They are located at points $S_1$ and $S_2$, separated by a distance $d = 175$ m, Fig. 34–50. Determine the points on the positive $y$ axis where the signals from the two sources will be out of phase (crests of one meet troughs of the other).

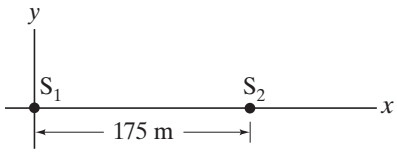

**FIGURE 34–50** Problem 78.

79. What is the minimum (non-zero) thickness for the air layer between two flat glass surfaces if the glass is to appear dark when 650-nm light is incident normally? What if the glass is to appear bright?

80. Suppose you viewed the light *transmitted* through a thin coating layered on a flat piece of glass. Draw a diagram, similar to Fig. 34–17 or 34–23, and describe the conditions required for maxima and minima. Consider all possible values of index of refraction. Discuss the relative intensity of the minima compared to the maxima and to zero.

81. Consider the antennas of Example 34–5, Fig. 34–15. Let $d = \lambda/2$, and suppose that the two antennas are now 180° out of phase with each other. Find the directions for constructive and destructive interference, and compare with the case when the sources are in phase. (These results illustrate the basis for directional antennas.)

82. *Lloyd's mirror* provides one way of obtaining a double-slit interference pattern from a single source so the light is coherent. As shown in Fig. 34–51, the light that reflects from the plane mirror appears to come from the virtual image of the slit. Describe in detail the interference pattern on the screen.

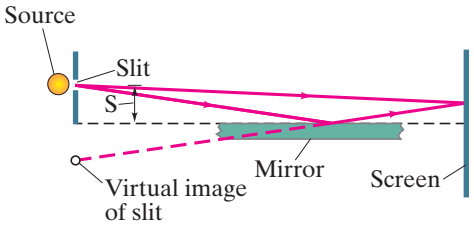

**FIGURE 34–51** Problem 82.

83. A thin film of soap $(n = 1.34)$ coats a piece of flat glass $(n = 1.52)$. What is the minimum film thickness if it reflects 643-nm red light most strongly when illuminated normally by white light?

84. Two narrow slits 0.070 mm apart are illuminated by a very bright 488-nm light source forming an interference pattern on a screen 4.0 m away. Calculate (*a*) the distance between the $m = 0$ and $m = 1$ lines in the pattern and (*b*) the distance between the $m = 100$ and $m = 101$ lines.

85. Unpolarized light falls on two polarizer sheets whose axes are at right angles. (*a*) What fraction of the incident light intensity is transmitted? (*b*) What fraction is transmitted if a third polarizer is placed between the first two so that its axis makes a 58° angle with the axis of the first polarizer? (*c*) What if the third polarizer is in front of the other two?

86. Four polarizers are placed in succession with their axes vertical, at 30.0° to the vertical, at 60.0° to the vertical, and at 90.0° to the vertical. (*a*) Calculate what fraction of the incident unpolarized light is transmitted by the four polarizers. (*b*) Can the transmitted light be *decreased* by removing one of the polarizers? If so, which one? (*c*) Can the transmitted light intensity be extinguished by removing polarizers? If so, which one(s)?

87. A two-slit interference set-up with slit separation $d = 0.10$ mm produces interference fringes at a particular set of angles $\theta_m$ (where $m = 0, 1, 2, \ldots$) for red light of frequency $f = 4.6 \times 10^{14}$ Hz. If one wishes to construct an analogous two-slit interference set-up that produces interference fringes at the same set of angles $\theta_m$ for room-temperature sound of middle-C frequency $f_S = 262$ Hz, what should the slit separation $d_S$ be for this analogous set-up?

88. Two polarizers are oriented at 55° to each other and plane-polarized light is incident on them. If only 25% of the light gets through both of them, what was the initial polarization direction of the incident light?

**89.** At what angle should the axes of two Polaroids be placed so as to reduce the intensity of the incident unpolarized light by an additional factor (after the first Polaroid cuts it in half) of (*a*) 4, (*b*) 10, (*c*) 100?

**90.** Two identical sources $S_1$ and $S_2$, separated by distance $d$, coherently emit light of wavelength $\lambda$ uniformly in all directions. Defining the $x$ axis with its origin at $S_1$ as shown in Fig. 34–52, find the locations (expressed as multiples of $\lambda$) where the signals from the two sources are out of phase along this axis for $x > 0$, if $d = 3\lambda$.

**FIGURE 34–52**
Problem 90.

**91.** In a compact disc (CD), digital information is stored as a sequence of raised surfaces called "pits" and recessed surfaces called "lands." Both pits and lands are highly reflective and are embedded in a thick plastic material with index of refraction $n = 1.55$ (Fig. 34–53). As a 780-nm wavelength (in air) laser scans across the pit–land sequence, the transition between a neighboring pit and land is sensed by monitoring the intensity of reflected laser light from the CD. At the moment when half the width of the laser beam is reflected from the pit and the other half from the land, we want the two reflected halves of the beam to be 180° out of phase with each other. What should be the (minimum) height difference $t$ between a pit and land? [When this light enters a detector, cancellation of the two out-of-phase halves of the beam produces a minimum detector output.]

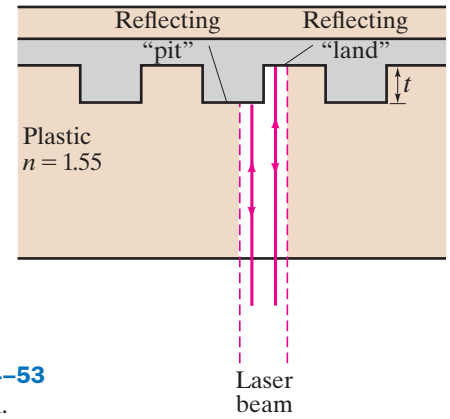

**FIGURE 34–53**
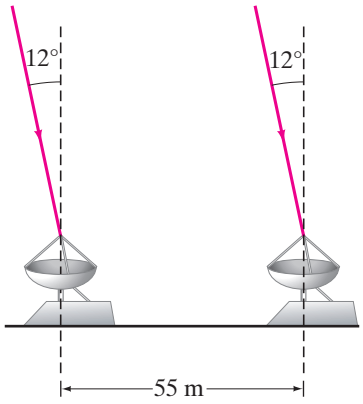
Problem 91.

**92.** Describe how to rotate the plane of polarization of a plane-polarized beam of light by 90° and produce only a 10% loss in intensity, using polarizers. Let $N$ be the number of polarizers and $\theta$ be the (same) angle between successive polarizers.

**93.** What percent of visible light is reflected from plain glass? Assume your answer refers to transmission through each surface, front and back. How does the presence of multiple lenses in a good camera degrade the image? What is suggested in Section 34–5 to reduce this reflection? Explain in words, and sketch how this solution works. For a 6-element glass lens in air, about how much improvement does this solution provide?

**94.** A radio telescope, whose two antennas are separated by 55 m, is designed to receive 3.0-MHz radio waves produced by astronomical objects. The received radio waves create 3.0-MHz electronic signals in the telescope's left and right antennas. These signals then travel by equal-length cables to a centrally located amplifier, where they are added together. The telescope can be "pointed" to a certain region of the sky by adding the instantaneous signal from the right antenna to a "time-delayed" signal received by the left antenna a time $\Delta t$ ago. (This time delay of the left signal can be easily accomplished with the proper electronic circuit.) If a radio astronomer wishes to "view" radio signals arriving from an object oriented at a 12° angle to the vertical as in Fig. 34–54, what time delay $\Delta t$ is necessary?



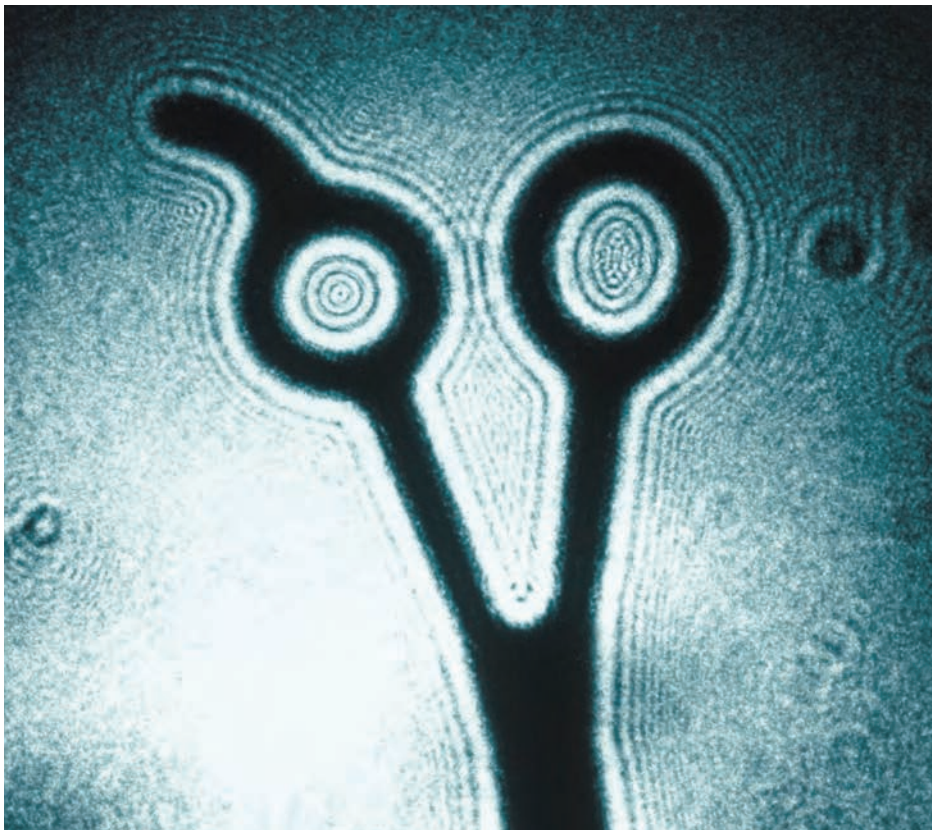


**FIGURE 34–54**
Problem 94.

## ANSWERS TO EXERCISES

**A:** 333 nm; $6.0 \times 10^{14}$ Hz; $2.0 \times 10^8$ m/s.
**B:** 2.5 mm.
**C:** (*a*) $I_0$; (*b*) $0.50I_0$; (*c*) 0.
**D:** (*e*).
**E:** Zero for both (*a*) and (*b*), because the two successive polarizers at 90° cancel all light. The 45° Polaroid must be inserted *between* the other two if any transmission is to occur.

Parallel coherent light from a laser, which acts as nearly a point source, illuminates these shears. Instead of a clean shadow, there is a dramatic diffraction pattern, which is a strong confirmation of the wave theory of light. Diffraction patterns are washed out when typical extended sources of light are used, and hence are not seen, although a careful examination of shadows will reveal fuzziness. We will examine diffraction by a single slit, and how it affects the double-slit pattern. We also discuss diffraction gratings and diffraction of X-rays by crystals. We will see how diffraction affects the resolution of optical instruments, and that the ultimate resolution can never be greater than the wavelength of the radiation used.

CHAPTER 35

# Diffraction

**CHAPTER-OPENING QUESTION—Guess now!**

A microscope using visible light has a useful magnification of about

**(a)** 50×;
**(b)** 100×;
**(c)** 500×;
**(d)** 2000×;
**(e)** 5000×;

and the smallest objects it can resolve have a size of about

**(a)** 10 nm;
**(b)** 100 nm;
**(c)** 500 nm;
**(d)** 2500 nm;
**(e)** 5500 nm.

Young's double-slit experiment put the wave theory of light on a firm footing. But full acceptance came only with studies on diffraction more than a decade later, in the 1810s and 1820s.

We have already discussed diffraction briefly with regard to water waves (Section 15–11) as well as for light (Section 34–1). We have seen that it refers to the spreading or bending of waves around edges. Now we look at diffraction in more detail, including its important practical effects of limiting the amount of detail, or *resolution*, that can be obtained with any optical instrument such as telescopes, cameras, and the eye.

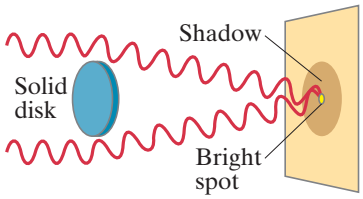

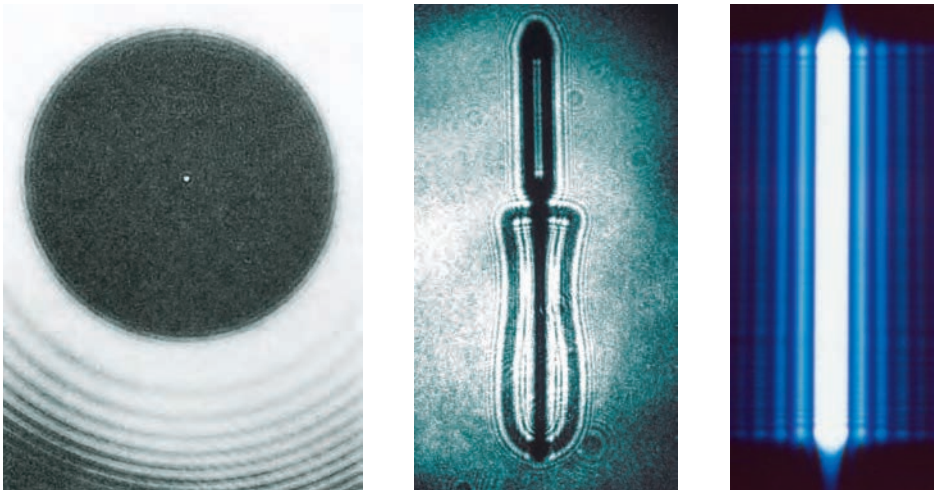

**FIGURE 35–1** If light is a wave, a bright spot will appear at the center of the shadow of a solid disk illuminated by a point source of monochromatic light.

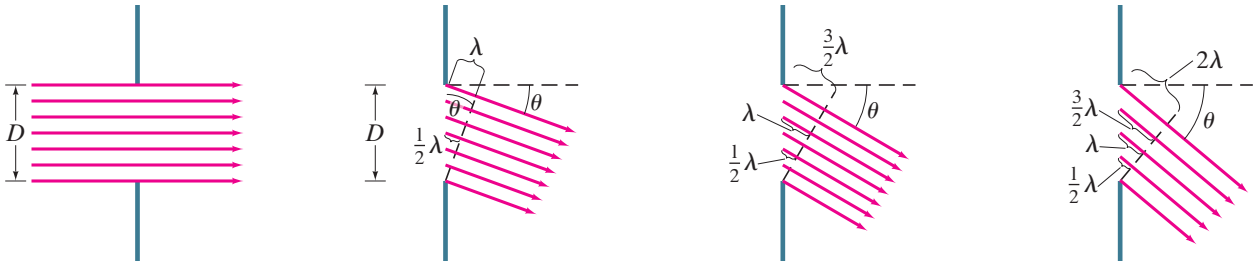
In 1819, Augustin Fresnel (1788–1827) presented to the French Academy a wave theory of light that predicted and explained interference and diffraction effects. Almost immediately Siméon Poisson (1781–1840) pointed out a counter-intuitive inference: according to Fresnel's wave theory, if light from a point source were to fall on a solid disk, part of the incident light would be diffracted around the edges and would constructively interfere at the center of the shadow (Fig. 35–1), producing a bright spot. That prediction seemed very unlikely. But when the experiment was actually carried out by François Arago, the bright spot was seen at the very center of the shadow (Fig. 35–2a). This was strong evidence for the wave theory.

Figure 35–2a is a photograph of the shadow cast by a coin using a coherent point source of light, a laser in this case. The bright spot is clearly present at the center. Note also the bright and dark fringes beyond the shadow. These resemble the interference fringes of a double slit. Indeed, they are due to interference of waves diffracted around the outer edge of the disk, and the group of fringes is referred to as a **diffraction pattern**. A diffraction pattern exists around any sharp-edged object illuminated by a point source, as shown in Fig. 35–2b and c. We are not always aware of diffraction because most sources of light in everyday life are not points (or coherent), so light from different parts of the source washes out the pattern.

(a) (b) (c)

**FIGURE 35–2** Diffraction pattern of (a) a circular disk (a coin), (b) a potato peeler, (c) a single slit, each illuminated by a nearly point source of coherent monochromatic light, such as a laser.

## 35–1 Diffraction by a Single Slit or Disk



To see how a diffraction pattern arises, we will analyze the important case of monochromatic light passing through a narrow slit, as in Fig. 35–2c. We assume that parallel rays (plane waves) of light pass through a slit whose narrow width is $D$, and continue to a viewing screen very far away. If the viewing screen is not far away, lenses can be used to make the rays parallel.[†] As we know from studying water waves and from Huygens' principle, waves passing through the slit spread out in all directions, Fig. 35–3. We will now examine how the waves passing through different parts of the slit interfere with each other.

**FIGURE 35–3** Water waves impinging on a small opening of a water break, pass through and spread out to either side. See also Section 15–11.

Parallel rays of monochromatic light pass through the narrow slit as shown in Fig. 35–4a. The slit width $D$ is assumed to be on the order of the wavelength $\lambda$ of the light, but the slit's length (into and out of page) can be large compared to $\lambda$. The light falls on a screen as in the double-slit experiment, page 998; the screen is assumed to be very far away, so the rays heading toward any point are very nearly parallel before they meet at the screen.

[†]Such a diffraction pattern, involving parallel rays, is called *Fraunhofer diffraction*. If the screen is close and no lenses are used, it is called *Fresnel diffraction*. The analysis in the latter case is rather involved, so we consider only the limiting case of Fraunhofer diffraction.

(a) $\theta = 0$
Bright

(b) $\sin\theta = \frac{\lambda}{D}$
Dark

(c) $\sin\theta = \frac{3\lambda}{2D}$
Bright

(d) $\sin\theta = \frac{2\lambda}{D}$
Dark

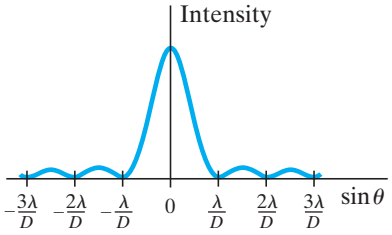
**FIGURE 35–4** Analysis of diffraction pattern formed by light passing through a narrow slit of width $D$.

First we consider rays that pass straight through as in Fig. 35–4a. They are all in phase, so there will be a central bright rectangle or line on the screen (see Fig. 35–2c). In Fig. 35–4b, we consider rays reaching the screen that move at an angle $\theta$ such that the ray from the top of the slit travels exactly one wavelength farther than the ray from the bottom of the slit. The ray passing through the very center of the slit will travel one-half wavelength $(\frac{1}{2}\lambda)$ farther than the ray at the bottom. These two rays will be exactly out of phase with one another and so will destructively interfere when they overlap at the screen. Similarly, a ray slightly above the bottom one will cancel a ray that is the same distance above the central one. Indeed, each ray passing through the lower half of the slit will cancel with a corresponding ray passing through the upper half, a distance $D/2$ above. Thus, all the rays destructively interfere in pairs, and so the light intensity will be zero on the viewing screen at this angle. The angle $\theta$ at which this takes place can be seen from Fig. 35–4b to occur when $\lambda = D\sin\theta$, so

$$\sin\theta = \frac{\lambda}{D}. \qquad \text{[first minimum]} \quad \textbf{(35–1)}$$

The light intensity is a maximum at $\theta = 0°$ and decreases to a minimum (intensity = zero) at the angle $\theta$ given by Eq. 35–1.

Now consider a larger angle $\theta$ such that the top ray travels $\frac{3}{2}\lambda$ farther than the bottom ray, as in Fig. 35–4c. In this case, the rays from the bottom third of the slit will cancel in pairs with those in the middle third because they will be $\lambda/2$ out of phase. However, light from the top third of the slit will still reach the screen, so there will be a bright spot or fringe centered near $\sin\theta \approx 3\lambda/2D$, but it will not be nearly as bright as the central spot at $\theta = 0°$. For an even larger angle $\theta$ such that the top ray travels $2\lambda$ farther than the bottom ray, Fig. 35–4d, rays from the bottom quarter of the slit will cancel with those in the quarter just above it because the path lengths differ by $\lambda/2$. And the rays through the quarter of the slit just above center will cancel with those through the top quarter. At this angle there will again be a minimum of zero intensity in the diffraction pattern. A plot of the intensity as a function of angle is shown in Fig. 35–5. This corresponds well with the photo of Fig. 35–2c. Notice that minima (zero intensity) occur on both sides of center at



$$D\sin\theta = m\lambda, \qquad m = \pm 1, \pm 2, \pm 3, \cdots, \qquad \text{[minima]} \quad \textbf{(35–2a)}$$

but *not* at $m = 0$ where there is the *strongest maximum* ($\theta = 0$). Between the minima, smaller intensity maxima occur at approximately (not exactly) $m \approx \frac{3}{2}, \frac{5}{2}, \cdots$:

$$D\sin\theta = m\lambda, \qquad m \approx \pm\frac{3}{2}, \pm\frac{5}{2}, \cdots. \qquad \text{[weak maxima]} \quad \textbf{(35–2b)}$$

Note that the *minima* for a diffraction pattern, Eq. 35–2a, satisfy a criterion that looks very similar to that for the *maxima* (bright spots or fringes) for double-slit interference, Eq. 34–2a. Also note that $D$ is a single slit width, whereas $d$ in Eq. 34–2 is the distance between two slits.

**FIGURE 35–5** Intensity in the diffraction pattern of a single slit as a function of $\sin\theta$. Note that the central maximum is not only much higher than the maxima to each side, but it is also twice as wide ($2\lambda/D$ wide) as compared to the others (only $\lambda/D$ wide each).

**⚠ CAUTION**

*Don't confuse Eqs. 35–2 for diffraction with Eqs. 34–2 for 2-slit interference: note the differences*

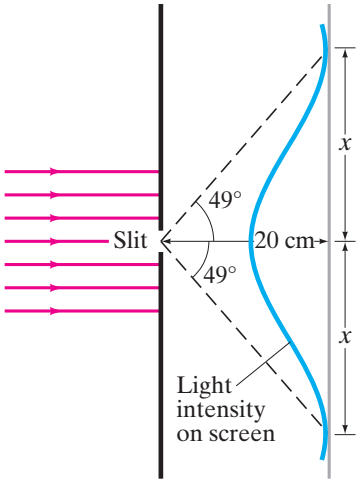


**FIGURE 35–6** Example 35–1.

**EXAMPLE 35–1** **Single-slit diffraction maximum.** Light of wavelength 750 nm passes through a slit $1.00 \times 10^{-3}$ mm wide. How wide is the central maximum (*a*) in degrees, and (*b*) in centimeters on a screen 20 cm away?

**APPROACH** The width of the central maximum goes from the first minimum on one side to the first minimum on the other side. We use Eq. 35–1 to find the angular position of the first single-slit diffraction minimum.

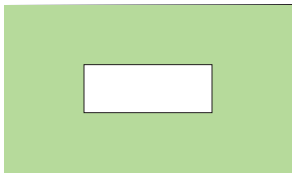
**SOLUTION** (*a*) The first minimum occurs at

$$\sin\theta = \frac{\lambda}{D} = \frac{7.50 \times 10^{-7}\,\text{m}}{1.00 \times 10^{-6}\,\text{m}} = 0.75.$$

So $\theta = 49°$. This is the angle between the center and the first minimum, Fig. 35–6. The angle subtended by the whole central maximum, between the minima above and below the center, is twice this, or 98°.

(*b*) The width of the central maximum is $2x$, where $\tan\theta = x/20\,\text{cm}$. So $2x = 2(20\,\text{cm})(\tan 49°) = 46\,\text{cm}$.

**NOTE** A large width of the screen will be illuminated, but it will not normally be very bright since the amount of light that passes through such a small slit will be small and it is spread over a large area. Note also that we *cannot* use the small-angle approximation here ($\theta \approx \sin\theta \approx \tan\theta$) because $\theta$ is large.



**EXERCISE A** In Example 35–1, red light ($\lambda = 750\,\text{nm}$) was used. If instead yellow light ($\lambda = 550\,\text{nm}$) had been used, would the central maximum be wider or narrower?

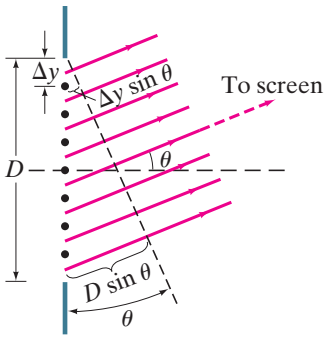
**CONCEPTUAL EXAMPLE 35–2** **Diffraction spreads.** Light shines through a small rectangular slit that is narrower in the vertical direction than the horizontal, Fig. 35–7. (*a*) Would you expect the diffraction pattern to be more spread out in the vertical direction or in the horizontal direction? (*b*) Should a rectangular loudspeaker horn at a stadium be tall and narrow, or wide and flat?

**RESPONSE** (*a*) From Eq. 35–1 we can see that if we make the slit width $D$ smaller, the pattern spreads out more ($\theta$ will be larger in Eq. 35–1). This is consistent with our study of waves in Chapter 15. The diffraction through the rectangular slit will be wider vertically, since the opening is smaller in that direction.

(*b*) For a stadium loudspeaker, the sound pattern desired is one spread out horizontally, so the horn should be tall and narrow (rotate Fig. 35–7 by 90°).

**FIGURE 35–7** Example 35–2.

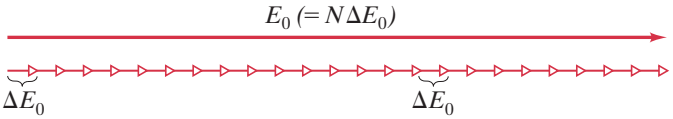
## *35–2 Intensity in Single-Slit Diffraction Pattern



We have determined the positions of the minima in the diffraction pattern produced by light passing through a single slit, Eq. 35–2a. We now discuss a method for predicting the amplitude and intensity at any point in the pattern using the phasor technique already discussed in Section 34–4.

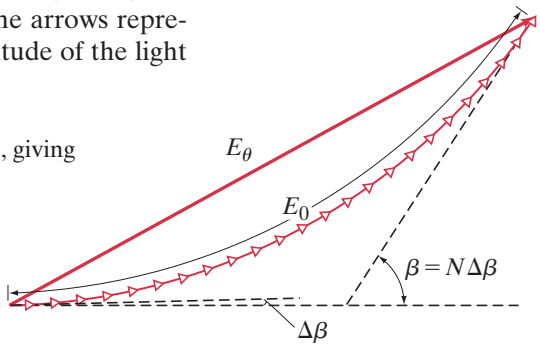
Let us consider the slit divided into $N$ very thin strips of width $\Delta y$ as indicated in Fig. 35–8. Each strip sends light in all directions toward a screen on the right. Again we take the rays heading for any particular point on the distant screen to be parallel, all making an angle $\theta$ with the horizontal as shown. We choose the strip width $\Delta y$ to be much smaller than the wavelength $\lambda$ of the monochromatic light falling on the slit, so all the light from a given strip is in phase. The strips are of equal size, and if the whole slit is uniformly illuminated, we can take the electric field wave amplitudes $\Delta E_0$ from each thin strip to be equal as long as $\theta$ is not too large. However, the separate amplitudes from the different strips will differ in phase. The phase difference in the light coming from adjacent strips will be (see Section 34–4, Eq. 34–4)

$$\Delta\beta = \frac{2\pi}{\lambda}\Delta y \sin\theta \qquad \textbf{(35–3)}$$



since the difference in path length is $\Delta y \sin\theta$.

**FIGURE 35–8** Slit of width $D$ divided into $N$ strips of width $\Delta y$.



The total amplitude on the screen at any angle $\theta$ will be the sum of the separate wave amplitudes due to each strip. These wavelets have the same amplitude $\Delta E_0$ but differ in phase. To obtain the total amplitude, we can use a phasor diagram as we did in Section 34–4 (Fig. 34–13). The phasor diagrams for four different angles $\theta$ are shown in Fig. 35–9. At the center of the screen, $\theta = 0$, the waves from each strip are all in phase ($\Delta\beta = 0$, Eq. 35–3), so the arrows representing each $\Delta E_0$ line up as shown in Fig. 35–9a. The total amplitude of the light arriving at the center of the screen is then $E_0 = N\,\Delta E_0$.

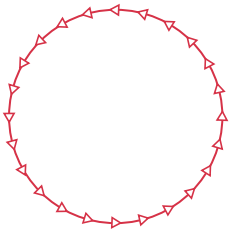


**FIGURE 35–9** Phasor diagram for single-slit diffraction, giving the total amplitude $E_\theta$ at four different angles $\theta$.

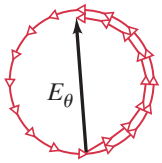

(a) At center, $\theta = 0$.

(b) Between center and first minimum (length of arc of tiny arrows = $E_0$).

(c) First minimum, $E_\theta = 0$ ($\beta = 2\pi = 360°$).

(d) Near secondary maximum.

At a small angle $\theta$, for a point on the distant screen not far from the center, Fig. 35–9b shows how the wavelets of amplitude $\Delta E_0$ add up to give $E_\theta$, the total amplitude on the screen at this angle $\theta$. Note that each wavelet differs in phase from the adjacent one by $\Delta\beta$. The phase difference between the wavelets from the top and bottom edges of the slit is

$$\beta = N\,\Delta\beta = \frac{2\pi}{\lambda} N\,\Delta y \sin\theta = \frac{2\pi}{\lambda} D \sin\theta \qquad \textbf{(35–4)}$$

where $D = N\,\Delta y$ is the total width of the slit. The "arc" of tiny arrows in Fig. 35–9b has length $N\Delta E_0$, and so equals $E_0$. But the amplitude of the total wave $E_\theta$ at angle $\theta$ is the *vector* sum of each wavelet amplitude and so is equal to the length of the straight arrow $E_\theta$. The arrow $E_\theta$ is shorter than the arc, so $E_\theta < E_0$.

For greater $\theta$, we eventually come to the case, illustrated in Fig. 35–9c, where the chain of arrows closes on itself. In this case the vector sum is zero, so $E_\theta = 0$ for this angle $\theta$. This corresponds to the first minimum. Since $\beta = N\,\Delta\beta$ is 360° or $2\pi$ in this case, we have from Eq. 35–3,

$$2\pi = N\,\Delta\beta = N\left(\frac{2\pi}{\lambda}\,\Delta y \sin\theta\right)$$

or, since the slit width $D = N\,\Delta y$,

$$\sin\theta = \frac{\lambda}{D}.$$

Thus the first minimum $(E_\theta = 0)$ occurs where $\sin\theta = \lambda/D$, which is the same result we obtained in the previous Section, Eq. 35–1.

For even greater values of $\theta$, the chain of arrows spirals beyond 360°. Figure 35–9d shows the case near the secondary maximum next to the first minimum. Here $\beta = N\,\Delta\beta \approx 360° + 180° = 540°$ or $3\pi$. When greater angles $\theta$ are considered, new maxima and minima occur. But since the total length of the coil remains constant, equal to $N\,\Delta E_0\,(= E_0)$, each succeeding maximum is smaller and smaller as the coil winds in on itself.

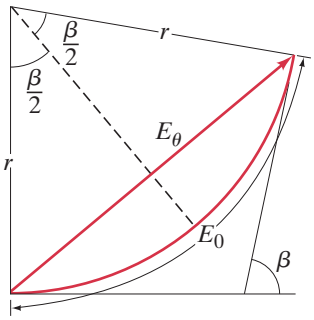

**FIGURE 35–10** Determining amplitude $E_\theta$ as a function of $\theta$ for single-slit diffraction.

To obtain a quantitative expression for the amplitude (and intensity) for any point on the screen (that is, for any angle $\theta$), we now consider the limit $N \to \infty$ so $\Delta y$ becomes the infinitesimal width $dy$. In this case, the diagrams of Fig. 35–9 become smooth curves, one of which is shown in Fig. 35–10. For any angle $\theta$, the wave amplitude on the screen is $E_\theta$, equal to the length $E_\theta$ of the straight arrow in Fig. 35–10. The length of the arc is $E_0$, as before. If $r$ is the radius of curvature of the arc, then

$$\frac{E_\theta}{2} = r \sin\frac{\beta}{2}.$$

Using radian measure for $\beta/2$, we also have

$$\frac{E_0}{2} = r\frac{\beta}{2}.$$

We combine these to obtain

$$E_\theta = E_0 \frac{\sin\beta/2}{\beta/2}. \qquad \textbf{(35–5)}$$

The angle $\beta$ is the phase difference between the waves from the top and bottom edges of the slit. The path difference for these two rays is $D\sin\theta$ (Fig. 35–8 and Eq. 35–4), so

$$\beta = \frac{2\pi}{\lambda} D \sin\theta. \qquad \textbf{(35–6)}$$

Intensity is proportional to the square of the wave amplitude, so the intensity $I_\theta$ at any angle $\theta$ is, from Eq. 35–5,

$$I_\theta = I_0\left(\frac{\sin\beta/2}{\beta/2}\right)^2 \qquad \textbf{(35–7)}$$

where $I_0\ (\propto E_0^2)$ is the intensity at $\theta = 0$ (the central maximum). We can combine Eqs. 35–7 and 35–6 (although it is often simpler to leave them as separate equations) to obtain

$$I_\theta = I_0\left[\frac{\sin\left(\frac{\pi D\sin\theta}{\lambda}\right)}{\left(\frac{\pi D\sin\theta}{\lambda}\right)}\right]^2. \qquad \textbf{(35–8)}$$

According to Eq. 35–8, minima $(I_\theta = 0)$ occur where $\sin(\pi D\sin\theta/\lambda) = 0$, which means $\pi D\sin\theta/\lambda$ must be $\pm\pi$, $\pm 2\pi$, $\pm 3\pi$, and so on, or

$$D\sin\theta = m\lambda, \qquad m = \pm 1, \pm 2, \pm 3, \cdots \qquad \text{[minima]}$$

which is what we have obtained previously, Eq. 35–2a. Notice that $m$ cannot be zero: when $\beta/2 = \pi D\sin\theta/\lambda = 0$, the denominator as well as the numerator in Eqs. 35–7 or 35–8 equals zero. We can evaluate the intensity in this case by taking the limit as $\theta \to 0$ (or $\beta \to 0$); for very small angles, $\sin\beta/2 \approx \beta/2$, so $(\sin\beta/2)/(\beta/2) \to 1$ and $I_\theta = I_0$, the *maximum* at the center of the pattern.

The intensity $I_\theta$ as a function of $\theta$, as given by Eq. 35–8, corresponds to the intensity pattern shown in Fig. 35–5.

**EXAMPLE 35–3** **ESTIMATE** **Intensity at secondary maxima.** Estimate the intensities of the first two secondary maxima to either side of the central maximum.

**APPROACH** The secondary maxima occur close to halfway between the minima, at about

$$\frac{\beta}{2} = \frac{\pi D\sin\theta}{\lambda} \approx \left(m + \tfrac{1}{2}\right)\pi. \qquad m = \pm 1, \pm 2, \pm 3, \cdots$$

The actual maxima are not quite at these points—their positions can be determined by differentiating Eq. 35–7 (see Problem 14)—but we are only seeking an estimate.

**SOLUTION** Using these values for $\beta$ in Eq. 35–7 or 35–8, with $\sin\left[\left(m+\frac{1}{2}\right)\pi\right]=1$, gives

$$I_\theta = \frac{I_0}{\left(m+\frac{1}{2}\right)^2\pi^2}. \qquad m = 1, 2, 3, \cdots$$

For $m = 1$ and 2, we get

$$I_\theta = \frac{I_0}{22.2} = 0.045I_0 \qquad [m = 1]$$

$$I_\theta = \frac{I_0}{61.7} = 0.016I_0. \qquad [m = 2]$$

The first maximum to the side of the central peak has only 1/22, or 4.5%, the intensity of the central peak, and succeeding ones are smaller still, just as we can see in Fig. 35–5 and the photo of Fig. 35–2c.

Diffraction by a circular opening produces a similar pattern (though circular rather than rectangular), and is of great practical importance because lenses are essentially circular apertures through which light passes. We will discuss this in Section 35–4 and see how diffraction limits the resolution (or sharpness) of images.

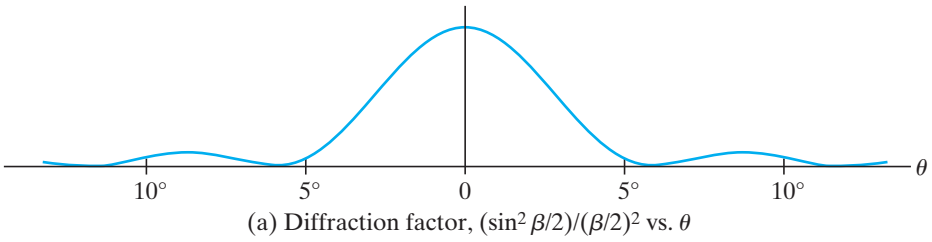
## *35–3 Diffraction in the Double-Slit Experiment

When we analyzed Young's double-slit experiment in Section 34–4, we assumed that the central portion of the screen was uniformly illuminated. This is equivalent to assuming the slits are infinitesimally narrow, so that the central diffraction peak is spread out over the whole screen. This can never be the case for real slits; diffraction reduces the intensity of the bright interference fringes to the side of center so they are not all of the same height as they were shown in Fig. 34–14. (They were shown more correctly in Fig. 34–9b.)

To calculate the intensity in a double-slit interference pattern including diffraction, let us assume the slits have equal widths $D$ and their centers are separated by a distance $d$. Since the distance to the screen is large compared to the slit separation $d$, the wave amplitude due to each slit is essentially the same at each point on the screen. Then the total wave amplitude at any angle $\theta$ will no longer be

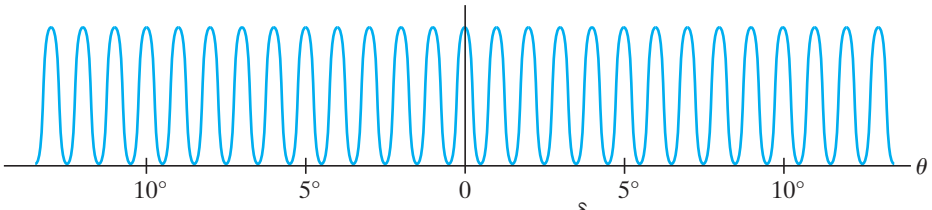
$$E_{\theta 0} = 2E_0\cos\frac{\delta}{2},$$

as was given by Eq. 34–5b (where $\delta = 2\pi d\sin\theta/\lambda$). Rather, this equation must be modified using Eq. 35–5 because each of the two slits exhibits its own diffraction, so that



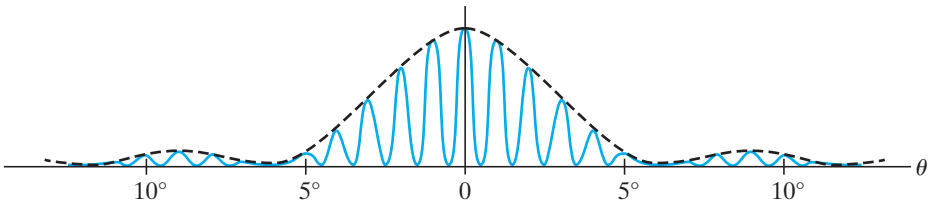
$$E_{\theta 0} = 2E_0\left(\frac{\sin\beta/2}{\beta/2}\right)\cos\frac{\delta}{2}.$$

Thus the intensity will be given by $(I \propto E^2)$



$$I_\theta = I_0\left(\frac{\sin\beta/2}{\beta/2}\right)^2\left(\cos\frac{\delta}{2}\right)^2 \qquad \textbf{(35–9)}$$

where $I_0 = 4E_0^2$, and from Eqs. 35–6 and 34–4 we have



$$\frac{\beta}{2} = \frac{\pi}{\lambda}D\sin\theta \qquad \text{and} \qquad \frac{\delta}{2} = \frac{\pi}{\lambda}d\sin\theta.$$

(a) Diffraction factor, $(\sin^2 \beta/2)/(\beta/2)^2$ vs. $\theta$

(b) Interference factor, $\cos^2 \frac{\delta}{2}$ vs. $\theta$

(c) Intensity, $I_\theta$ vs. $\theta$

**FIGURE 35–11**
(a) Diffraction factor,
(b) interference factor, and
(c) the resultant intensity $I_\theta$, plotted as a function of $\theta$ for $d = 6D = 60\lambda$.

Equation 35–9 for the intensity in a double-slit pattern, as we just saw, is

$$I_\theta = I_0\left(\frac{\sin\beta/2}{\beta/2}\right)^2\left(\cos\frac{\delta}{2}\right)^2. \qquad \textbf{(35–9)}$$

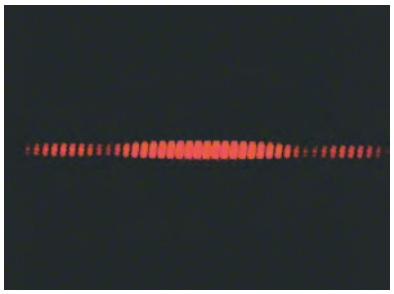
The first term in parentheses is sometimes called the "diffraction factor" and the second one the "interference factor." These two factors are plotted in Fig. 35–11a and b for the case when $d = 6D$, and $D = 10\lambda$. (Figure 35–11b is essentially the same as Fig. 34–14.) Figure 35–11c shows the product of these two curves (times $I_0$) which is the actual intensity as a function of $\theta$ (or as a function of position on the screen for $\theta$ not too large) as given by Eq. 35–9. As indicated by the dashed lines in Fig. 35–11c, the diffraction factor acts as a sort of envelope that limits the interference peaks.

**EXAMPLE 35–4** **Diffraction plus interference.** Show why the central diffraction peak in Fig. 35–11c contains 11 interference fringes.

**APPROACH** The first minimum in the diffraction pattern occurs where

$$\sin\theta = \frac{\lambda}{D}.$$

Since $d = 6D$,



$$d\sin\theta = 6D\left(\frac{\lambda}{D}\right) = 6\lambda.$$

**SOLUTION** From Eq. 34–2a, interference peaks (maxima) occur for $d\sin\theta = m\lambda$ where $m$ can be $0, 1, \cdots$ or any integer. Thus the diffraction minimum $(d\sin\theta = 6\lambda)$ coincides with $m = 6$ in the interference pattern, so the $m = 6$ peak won't appear. Hence the central diffraction peak encloses the central interference peak $(m = 0)$ and five peaks $(m = 1$ to $5)$ on each side for a total of 11. Since the sixth order doesn't appear, it is said to be a "missing order."

Notice from Example 35–4 that the number of interference fringes in the central diffraction peak depends only on the ratio $d/D$. It does not depend on wavelength $\lambda$. The actual spacing (in angle, or in position on the screen) does depend on $\lambda$. For the case illustrated, $D = 10\lambda$, and so the first diffraction minimum occurs at $\sin\theta = \lambda/D = 0.10$ or about 6°.

The decrease in intensity of the interference fringes away from the center, as graphed in Fig. 35–11, is shown in Fig. 35–12.

**FIGURE 35–12** Photographs of a double-slit interference pattern using a laser beam showing effects of diffraction. In both cases $d = 0.50$ mm, whereas $D = 0.040$ mm in (a) and 0.080 mm in (b).

(a)

(b)

## 35–4 Interference vs. Diffraction

The patterns due to interference and diffraction arise from the same phenomenon—the superposition of coherent waves of different phase. The distinction between them is thus not so much physical as for convenience of description, as in Section 35–3 where we analyzed the two-slit pattern in terms of interference and diffraction separately. In general, we use the word "diffraction" when referring to an analysis by superposition of many infinitesimal and usually contiguous sources, such as when we subdivide a source into infinitesimal parts. We use the term "interference" when we superpose the wave from a finite (and usually small) number of coherent sources.

**⚠ CAUTION**
*Diffraction and interference*

## 35–5 Limits of Resolution; Circular Apertures

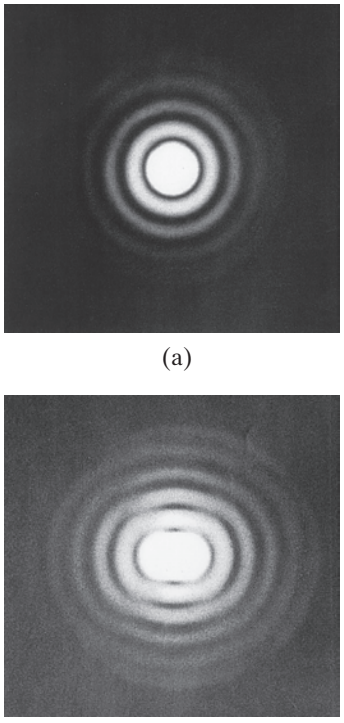
No lens can image a point object as a perfect point image. The image is always spread out a bit, as a blob, because of *aberrations* (Section 33–10) and *diffraction*.

The ability of a lens to produce distinct images of two point objects very close together is called the **resolution** of the lens. The closer the two images can be and still be seen as distinct (rather than overlapping blobs), the higher the resolution. The resolution of a camera lens, for example, is often specified as so many dots or lines per millimeter, as mentioned in Section 33–5.

In Section 35–1, we saw that because light travels as a wave, light from a point source passing through a slit is spread out into a diffraction pattern (Figs. 35–2 and 35–5). A lens, because it has edges, acts like a round slit. When a lens forms the image of a point object, the image is actually a tiny diffraction pattern. Thus *an image would be blurred even if lens aberrations were absent*.

In the analysis that follows, we assume that the lens is free of aberrations, so we can concentrate on diffraction effects and how much they limit the resolution of a lens. In Fig. 35–5 we saw that the diffraction pattern produced by light passing through a rectangular slit has a central maximum in which most of the light falls. This central peak falls to a minimum on either side of its center at an angle $\theta$ given by $\sin\theta = \lambda/D$ (this is Eq. 35–1), where $D$ is the slit width and $\lambda$ the wavelength of light used. $\theta$ is the *angular half-width* of the central maximum. For small angles (in radians), $\theta \approx \sin\theta$, so we can write

$$\theta \approx \frac{\lambda}{D}. \qquad \text{[slit]}$$



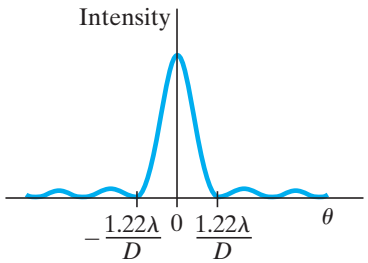
There are also low-intensity fringes beyond.

For a lens, or any circular hole, the image of a point object will consist of a *circular* central peak (called the *diffraction spot* or *Airy disk*) surrounded by faint circular fringes, as shown in Fig. 35–13a. The central maximum has an angular half width $\theta$ (in radians) given by

$$\theta \approx \frac{1.22\lambda}{D}, \qquad \text{[circular opening]}$$

where $D$ is the diameter of the circular opening. This is a *theoretical* result for a perfect circle or lens, obtained by integrating over the circular opening. The formula above differs from that for a slit (Eq. 35–1) by the factor 1.22. This factor appears because the width of a circular hole is not uniform (like a rectangular slit) but varies from its diameter $D$ at the center to zero at the edges. A mathematical analysis shows that the "average" width is $D/1.22$. Hence we get the equation above rather than Eq. 35–1. The intensity of light in the diffraction pattern from a point source of light passing through a circular opening is shown in Fig. 35–14. The image for a non-point source is a superposition of such patterns. Usually, we consider only the central spot, since the concentric rings are so much dimmer.

If two point objects are very close, the diffraction patterns of their images will overlap as shown in Fig. 35–13b. As the objects are moved closer, a separation is reached where you can't tell if there are two overlapping images or a single image.



(a)

(b)

**FIGURE 35–13** Photographs of images (greatly magnified) formed by a lens, showing the diffraction pattern of an image for: (a) a single point object; (b) two point objects whose images are barely resolved.

**FIGURE 35–14** Intensity of light across the diffraction pattern of a circular hole.

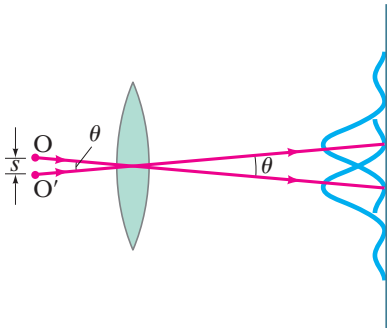


**FIGURE 35–15** The *Rayleigh criterion*. Two images are just resolvable when the center of the diffraction peak of one is directly over the first minimum in the diffraction pattern of the other. The two point objects O and O′ subtend an angle $\theta$ at the lens; only one ray (it passes through the center of the lens) is drawn for each object, to indicate the center of the diffraction pattern of its image.

The separation at which this happens may be judged differently by different observers. However, a generally accepted criterion is that proposed by Lord Rayleigh (1842–1919). This **Rayleigh criterion** states that *two images are just resolvable when the center of the diffraction disk of one image is directly over the first minimum in the diffraction pattern of the other*. This is shown in Fig. 35–15. Since the first minimum is at an angle $\theta = 1.22\lambda/D$ from the central maximum, Fig. 35–15 shows that two objects can be considered *just resolvable* if they are separated by at least an angle $\theta$ given by

$$\theta = \frac{1.22\lambda}{D}. \qquad \left[\begin{array}{l}\text{2 points just resolvable;}\\ \theta \text{ in radians}\end{array}\right] \qquad \textbf{(35–10)}$$

In this equation, $D$ is the diameter of the lens, and applies also to a mirror diameter. This is the limit on resolution set by the wave nature of light due to diffraction. A smaller angle means better resolution: you can make out closer objects. We see from Eq. 35–10 that using a shorter wavelength $\lambda$ can reduce $\theta$ and thus increase resolution.

**EXERCISE B** Green light (550 nm) passes through a 25-mm-diameter camera lens. What is the angular half-width of the resulting diffraction pattern? (*a*) $2.7 \times 10^{-5}$ degrees, (*b*) $1.5 \times 10^{-3}$ degrees, (*c*) 3.2°, (*d*) 27°, (*e*) $1.5 \times 10^{3}$ degrees.

(a)

(b)

**FIGURE 35–16** (a) Hubble Space Telescope, with Earth in the background. The flat orange panels are solar cells that collect energy from the Sun to power the equipment. (b) Hubble image looking deep into space, showing some of the most distant visible galaxies in the universe.

**EXAMPLE 35–5** **Hubble Space Telescope.** The Hubble Space Telescope (HST) is a reflecting telescope that was placed in orbit in 1990 above the Earth's atmosphere, so its resolution would not be limited by turbulence in the atmosphere (Fig. 35–16). It is still sending back remarkable images (Fig. 35–16b). Its objective diameter is 2.4 m. For visible light, say $\lambda = 550$ nm, estimate the improvement in resolution the Hubble offers over Earth-bound telescopes, which are limited in resolution by movement of the Earth's atmosphere to about half an arc second. (Each degree is divided into 60 minutes each containing 60 seconds, so $1° = 3600$ arc seconds.)

**APPROACH** Angular resolution for the Hubble is given (in radians) by Eq. 35–10. The resolution for Earth telescopes is given, and we first convert it to radians so we can compare.

**SOLUTION** Earth-bound telescopes are limited to an angular resolution of

$$\theta = \tfrac{1}{2}\left(\frac{1}{3600}\right)^{\circ}\left(\frac{2\pi \text{ rad}}{360^{\circ}}\right) = 2.4 \times 10^{-6}\,\text{rad}.$$

The Hubble, on the other hand, is limited by diffraction (Eq. 35–10) which for $\lambda = 550\,\text{nm}$ is

$$\theta = \frac{1.22\lambda}{D} = \frac{1.22(550 \times 10^{-9}\,\text{m})}{2.4\,\text{m}} = 2.8 \times 10^{-7}\,\text{rad},$$

thus giving almost ten times better resolution $(2.4 \times 10^{-6}\,\text{rad}/2.8 \times 10^{-7}\,\text{rad} \approx 9\times)$.

**EXAMPLE 35–6** **ESTIMATE** **Eye resolution.** You are in an airplane at an altitude of 10,000 m. If you look down at the ground, estimate the minimum separation $s$ between objects that you could distinguish. Could you count cars in a parking lot? Consider only diffraction, and assume your pupil is about 3.0 mm in diameter and $\lambda = 550\,\text{nm}$.

**PHYSICS APPLIED**
*How well the eye can see*

**APPROACH** We use the Rayleigh criterion, Eq. 35–10 and Fig. 35–15, to estimate $\theta$. The separation $s$ of objects is $s = \ell\theta$, where $\ell = 10^4\,\text{m}$ and $\theta$ is in radians.

**SOLUTION** In Eq. 35–10, we set $D = 3.0\,\text{mm}$ for the opening of the eye:

$$s = \ell\theta = \ell\frac{1.22\lambda}{D} = \frac{(10^4\,\text{m})(1.22)(550 \times 10^{-9}\,\text{m})}{3.0 \times 10^{-3}\,\text{m}} = 2.2\,\text{m}.$$

Yes, you could just resolve a car (roughly 2 m wide by 3 or 4 m long) and so, considering only diffraction, could count the number of cars in the lot.

**EXERCISE C** Someone claims a spy satellite camera can see 3-cm-high newspaper headlines from an altitude of 100 km. If diffraction were the only limitation ($\lambda = 550\,\text{nm}$), use Eq. 35–10 to determine what diameter lens the camera would have.

# 35–6 Resolution of Telescopes and Microscopes; the $\lambda$ Limit

You might think that a microscope or telescope could be designed to produce any desired magnification, depending on the choice of focal lengths and quality of the lenses. But this is not possible, because of diffraction. An increase in magnification above a certain point merely results in *magnification of the diffraction patterns*. This can be highly misleading since we might think we are seeing details of an object when we are really seeing details of the diffraction pattern.

**CAUTION**
*What may seem details under magnification may be only a diffraction pattern*

## Telescope Resolution

To examine this problem, we apply the Rayleigh criterion: two objects (or two nearby points on one object) are just resolvable if they are separated by an angle $\theta$ (Fig. 35–15) given by Eq. 35–10:

$$\theta = \frac{1.22\lambda}{D}.$$

*Telescope Resolution*

This formula is valid for either a microscope or a telescope, where $D$ is the diameter of the objective lens or mirror. For a telescope, the resolution is specified by stating $\theta$ as given by this equation.†

†Earth-bound telescopes with large-diameter objectives are usually limited not by diffraction but by other effects such as turbulence in the atmosphere. The resolution of a high-quality microscope, on the other hand, normally *is* limited by diffraction; microscope objectives are complex compound lenses containing many elements of small diameter (since $f$ is small), thus reducing aberrations.

**FIGURE 35–17** The 300-meter radiotelescope in Arecibo, Puerto Rico, uses radio waves (Fig. 31–12) instead of visible light.

**EXAMPLE 35–7 Telescope resolution (radio wave vs. visible light).** What is the theoretical minimum angular separation of two stars that can just be resolved by (*a*) the 200-inch telescope on Palomar Mountain (Fig. 33–38c); and (*b*) the Arecibo radiotelescope (Fig. 35–17), whose diameter is 300 m? Assume $\lambda = 550\,\text{nm}$ for the visible-light telescope in part (*a*), and $\lambda = 4\,\text{cm}$ (the shortest wavelength at which the radiotelescope has operated) in part (*b*).

**APPROACH** We apply the Rayleigh criterion (Eq. 35–10) for each telescope.

**SOLUTION** (*a*) With $D = 200\,\text{in.} = 5.1\,\text{m}$, we have from Eq. 35–10 that

$$\theta = \frac{1.22\lambda}{D} = \frac{(1.22)(5.50 \times 10^{-7}\,\text{m})}{(5.1\,\text{m})} = 1.3 \times 10^{-7}\,\text{rad},$$

or $0.75 \times 10^{-5}$ deg. (Note that this is equivalent to resolving two points less than 1 cm apart from a distance of 100 km!)

(*b*) For radio waves with $\lambda = 0.04\,\text{m}$ emitted by stars, the resolution is

$$\theta = \frac{(1.22)(0.04\,\text{m})}{(300\,\text{m})} = 1.6 \times 10^{-4}\,\text{rad}.$$

The resolution is less because the wavelength is so much larger, but the larger objective (300 m) collects more radiation and thus detects fainter objects.

**NOTE** In both cases, we determined the limit set by diffraction. The resolution for a visible-light Earth-bound telescope is not this good because of aberrations and, more importantly, turbulence in the atmosphere. In fact, large-diameter objectives are not justified by increased resolution, but by their greater *light-gathering ability*—they allow more light in, so fainter objects can be seen. Radiotelescopes are not hindered by atmospheric turbulence, and the resolution found in (*b*) is a good estimate.

## Microscope Resolving Power

For a microscope, it is more convenient to specify the actual distance, $s$, between two points that are just barely resolvable: see Fig. 35–15. Since objects are normally placed near the focal point of the microscope objective, the angle $\theta$ (in radians) subtended by two objects is $\theta = s/f$, so $s = f\theta$. If we combine this with Eq. 35–10, we obtain the **resolving power** (**RP**) of a microscope

$$\text{RP} = s = f\theta = \frac{1.22\lambda f}{D}, \qquad \textbf{(35–11)}$$

where $f$ is the objective lens' focal length (not frequency) and $D$ its diameter. The distance $s$ is called the resolving power of the lens because it is the minimum separation of two object points that can just be resolved—assuming the highest quality lens since this limit is imposed by the wave nature of light. A smaller RP means better resolution, better detail.

**EXERCISE D** What is the resolving power ($\lambda = 550\,\text{nm}$) of a microscope with a 5-mm-diameter objective which has $f = 9\,\text{mm}$? (*a*) 550 nm, (*b*) 750 nm, (*c*) 1200 nm, (*d*) 0.05 nm, (*e*) 0.005 nm.

## Ultimate Resolution Is $\lambda$

Diffraction sets an ultimate limit on the detail that can be seen on any object. In Eq. 35–11 for resolving power of a microscope, the focal length of the lens cannot practically be made less than (approximately) the radius of the lens, and even that is very difficult (see the lensmaker's equation, Eq. 33–4). In this best optimistic case, Eq. 35–11 gives, with $f \approx D/2$,

$$\text{RP} \approx \frac{\lambda}{2}. \qquad \textbf{(35–12)}$$

Thus we can say, to within a factor of 2 or so, that

*$\lambda$ limits resolution*

**it is not possible to resolve detail of objects smaller than the wavelength of the radiation being used.**

This is an important and useful rule of thumb.

Compound lenses in microscopes are now designed so well that the actual limit on resolution is often set by diffraction—that is, by the wavelength of the light used. To obtain greater detail, one must use radiation of shorter wavelength. The use of UV radiation can increase the resolution by a factor of perhaps 2. Far more important, however, was the discovery in the early twentieth century that electrons have wave properties (Chapter 37) and that their wavelengths can be very small. The wave nature of electrons is utilized in the electron microscope (Section 37–8), which can magnify 100 to 1000 times more than a visible-light microscope because of the much shorter wavelengths. X-rays, too, have very short wavelengths and are often used to study objects in great detail (Section 35–10).

## 35–7 Resolution of the Human Eye and Useful Magnification

The resolution of the human eye is limited by several factors, all of roughly the same order of magnitude. The resolution is best at the fovea (Section 33–6), where the cone spacing is smallest, about $3\,\mu\text{m}$ $(=3000\,\text{nm})$. The diameter of the pupil varies from about 1 mm to about 8 mm. So for $\lambda = 550\,\text{nm}$ (where the eye's sensitivity is greatest), the diffraction limit is about $\theta \approx 1.22\lambda/D \approx 8\times10^{-5}\,\text{rad}$ to $6\times10^{-4}\,\text{rad}$. The eye is about 2 cm long, giving a resolving power (Eq. 35–11) of $s \approx (2\times10^{-2}\,\text{m})(8\times10^{-5}\,\text{rad}) \approx 2\,\mu\text{m}$ at best, to about $10\,\mu\text{m}$ at worst (pupil small). Spherical and chromatic aberration also limit the resolution to about $10\,\mu\text{m}$. The net result is that the eye can just resolve objects whose angular separation is around

$$5\times10^{-4}\,\text{rad}. \qquad \left[\begin{array}{c}\text{best eye}\\ \text{resolution}\end{array}\right]$$

This corresponds to objects separated by 1 cm at a distance of about 20 m. (This contradicts, by a factor of 2, Example 35–6 which considered only diffraction.)

The typical near point of a human eye is about 25 cm. At this distance, the eye can just resolve objects that are $(25\,\text{cm})(5\times10^{-4}\,\text{rad}) \approx 10^{-4}\,\text{m} = \frac{1}{10}\,\text{mm}$ apart.[†] Since the best light microscopes can resolve objects no smaller than about 200 nm at best (Eq. 35–12 for violet light, $\lambda = 400\,\text{nm}$), the useful magnification [= (resolution by naked eye)/(resolution by microscope)] is limited to about

$$\frac{10^{-4}\,\text{m}}{200\times10^{-9}\,\text{m}} \approx 500\times. \qquad \left[\begin{array}{c}\text{maximum useful}\\ \text{microscope magnification}\end{array}\right]$$

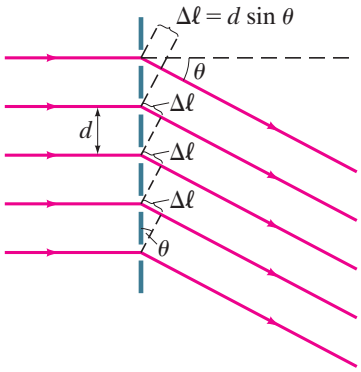
In practice, magnifications of about $1000\times$ are often used to minimize eyestrain. Any greater magnification would simply make visible the diffraction pattern produced by the microscope objective lens.

**EXERCISE E** Return to the Chapter-Opening Questions, page 1025, and answer them again now. Try to explain why you may have answered differently the first time.

## 35–8 Diffraction Grating

A large number of equally spaced parallel slits is called a **diffraction grating**, although the term "interference grating" might be as appropriate. Gratings can be made by precision machining of very fine parallel lines on a glass plate. The untouched spaces between the lines serve as the slits. Photographic transparencies of an original grating serve as inexpensive gratings. Gratings containing 10,000 lines or slits per centimeter are common, and are very useful for precise measurements of wavelengths. A diffraction grating containing slits is called a **transmission grating**. Another type of diffraction grating is the **reflection grating**, made by ruling fine lines on a metallic or glass surface from which light is reflected and analyzed. The analysis is basically the same as for a transmission grating, which we now discuss.

[†]A nearsighted eye that needs −8 or −10 D lenses can have a near point of 8 or 10 cm, and a higher resolution up close (without glasses) of a factor of $2\frac{1}{2}$ or 3, or $\approx \frac{1}{25}\,\text{mm} \approx 40\,\mu\text{m}$.



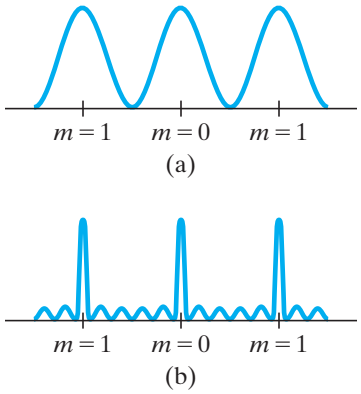


**FIGURE 35–18** Diffraction grating.

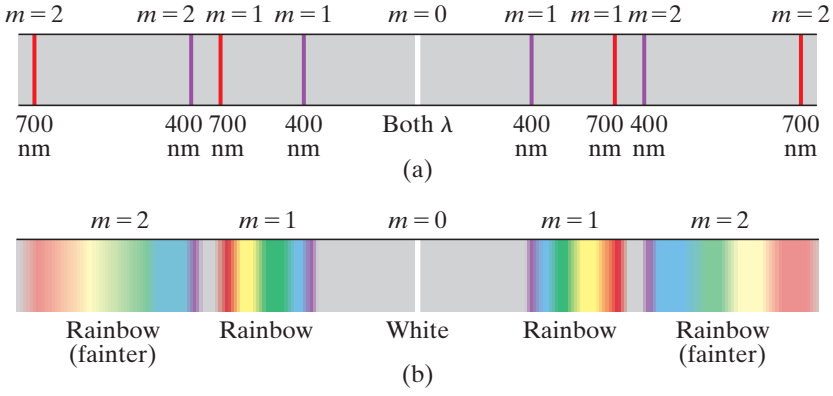
**⚠ CAUTION**

*Diffraction grating is analyzed using interference formulas, not diffraction formulas*

**FIGURE 35–19** Intensity as a function of viewing angle $\theta$ (or position on the screen) for (a) two slits, (b) six slits. For a diffraction grating, the number of slits is very large $(\approx 10^4)$ and the peaks are narrower still.

The analysis of a diffraction grating is much like that of Young's double-slit experiment. We assume parallel rays of light are incident on the grating as shown in Fig. 35–18. We also assume that the slits are narrow enough so that diffraction by each of them spreads light over a very wide angle on a distant screen beyond the grating, and interference can occur with light from all the other slits. Light rays that pass through each slit without deviation $(\theta = 0°)$ interfere constructively to produce a bright maximum at the center of the screen. Constructive interference also occurs at an angle $\theta$ such that rays from adjacent slits travel an extra distance of $\Delta\ell = m\lambda$, where $m$ is an integer. If $d$ is the distance *between* slits, then we see from Fig. 35–18 that $\Delta\ell = d \sin\theta$, and



$$\sin\theta = \frac{m\lambda}{d}, \qquad m = 0, 1, 2, \cdots \qquad \left[\begin{array}{c}\text{diffraction grating,}\\ \text{principal maxima}\end{array}\right] \qquad \textbf{(35–13)}$$

is the criterion to have a brightness maximum. This is the same equation as for the double-slit situation, and again $m$ is called the **order** of the pattern.

There is an important difference between a double-slit and a multiple-slit pattern. The bright maxima are much *sharper* and *narrower* for a grating. Why? Suppose the angle $\theta$ in Fig. 35–18 is increased just slightly beyond $\theta$ required for a maximum. For only two slits, the two waves will be only slightly out of phase, so nearly full constructive interference occurs. This means the maxima are wide (see Fig. 34–10). For a grating, the waves from two adjacent slits will also not be significantly out of phase. But waves from one slit and those from a second one a few hundred slits away may be exactly out of phase; all or nearly all the light can cancel in pairs in this way. For example, suppose the angle $\theta$ is very slightly different from its first-order maximum, so that the extra path length for a pair of adjacent slits is not exactly $\lambda$ but rather $1.0010\lambda$. The wave through one slit and another one 500 slits below will have a path difference of $1\lambda + (500)(0.0010\lambda) = 1.5000\lambda$, or $1\frac{1}{2}$ wavelengths, so the two will be out of phase and cancel. A pair of slits, one below each of these, will also cancel each other. That is, the light from slit 1 cancels with light from slit 501; light from slit 2 cancels with light from slit 502, and so on. Thus even for a tiny angle[†] corresponding to an extra path length of $\frac{1}{1000}\lambda$, there is much destructive interference, and so the maxima of a diffraction grating are very narrow. The more slits there are in a grating, the sharper will be the peaks (see Fig. 35–19). Because a grating produces much sharper lines than two slits alone, and also much brighter maxima because there are many more slits, a grating is a far more precise device for measuring wavelengths.

Suppose the light striking a diffraction grating is not monochromatic, but consists of two or more distinct wavelengths. Then for all orders other than $m = 0$, each wavelength will produce a maximum at a different angle (Eq. 35–13), forming a line on the screen as shown in Fig. 35–20a. If white light strikes a grating, the central $(m = 0)$ maximum will be a sharp white peak.

**FIGURE 35–20** Spectra produced by a grating: (a) two wavelengths, 400 nm and 700 nm; (b) white light. The second order will normally be dimmer than the first order. (Higher orders are not shown.) If the grating spacing is small enough, the second and higher orders will be missing.

[†]Depending on the total number of slits, there may or may not be complete cancellation for such an angle, so there will be very tiny peaks between the main maxima (see Fig. 35–19b), but they are usually much too small to be seen.

But for all other orders, there will be a distinct spectrum of colors spread out over a certain angular width, Fig. 35–20b. Because a diffraction grating spreads out light into its component wavelengths, the resulting pattern is called a **spectrum**.

**EXAMPLE 35–8** **Diffraction grating: line positions.** Determine the angular positions of the first- and second-order lines (maxima) for light of wavelength 400 nm and 700 nm incident on a grating containing 10,000 slits per centimeter. (Sometimes we say "lines per cm".)

**APPROACH** First we find the distance $d$ between grating slits: if the grating has $N$ slits in 1 m, then the distance between slits is $d = 1/N$ meters. Then we use Eq. 35–13, $\sin\theta = m\lambda/d$, to get the angles for the two wavelengths for $m = 1$ and 2.

**SOLUTION** The grating contains $1.00 \times 10^4$ slits/cm $= 1.00 \times 10^6$ slits/m, which means the distance between slits is $d = (1/1.00 \times 10^6)\,\text{m} = 1.00 \times 10^{-6}\,\text{m} = 1.00\,\mu\text{m}$. In first order $(m = 1)$, the angles are

$$\sin\theta_{400} = \frac{m\lambda}{d} = \frac{(1)(400 \times 10^{-9}\,\text{m})}{1.00 \times 10^{-6}\,\text{m}} = 0.400$$

$$\sin\theta_{700} = \frac{(1)(700 \times 10^{-9}\,\text{m})}{1.00 \times 10^{-6}\,\text{m}} = 0.700$$

so $\theta_{400} = 23.6°$ and $\theta_{700} = 44.4°$. In second order,

$$\sin\theta_{400} = \frac{2\lambda}{d} = \frac{(2)(400 \times 10^{-9}\,\text{m})}{1.00 \times 10^{-6}\,\text{m}} = 0.800$$

$$\sin\theta_{700} = \frac{(2)(700 \times 10^{-9}\,\text{m})}{1.00 \times 10^{-6}\,\text{m}} = 1.40$$

so $\theta_{400} = 53.1°$. But the second order does not exist for $\lambda = 700\,\text{nm}$ because $\sin\theta$ cannot exceed 1. No higher orders will appear.

**NOTE** The grating of Fig. 35–20 must have $d > 1.00\,\mu\text{m}$ since red is visible in both spectra for $m = 2$. $\text{Sin}\,\theta \le 1$ only if $d \ge 1.40 \times 10^{-6}\,\text{m}$ (see equation just above), so a grating must have fewer than 7140 slits/cm if the second order is to be visible.

**EXAMPLE 35–9** **Spectra overlap.** White light containing wavelengths from 400 nm to 750 nm strikes a grating containing 4000 slits/cm. Show that the blue at $\lambda = 450\,\text{nm}$ of the third-order spectrum overlaps the red at 700 nm of the second order.

**APPROACH** We use $\sin\theta = m\lambda/d$ to calculate the angular positions of the $m = 3$ blue maximum and the $m = 2$ red one.

**SOLUTION** The grating spacing is $d = (1/4000)\,\text{cm} = 2.50 \times 10^{-6}\,\text{m}$. The blue of the third order occurs at an angle $\theta$ given by

$$\sin\theta = \frac{m\lambda}{d} = \frac{(3)(450 \times 10^{-9}\,\text{m})}{(2.50 \times 10^{-6}\,\text{m})} = 0.540.$$

Red in second order occurs at

$$\sin\theta = \frac{(2)(7.00 \times 10^{-7}\,\text{m})}{(2.50 \times 10^{-6}\,\text{m})} = 0.560,$$

which is a greater angle. So the second order overlaps into the beginning of the third-order spectrum.

**EXERCISE F** You are shown the spectra produced by red light shining through two different gratings. The maxima in spectrum A are farther apart than those in spectrum B. Which grating has more slits/cm?

## 35–9 The Spectrometer and Spectroscopy

A **spectrometer** or **spectroscope**, Fig. 35–21, is a device to measure wavelengths accurately using a diffraction grating (or a prism) to separate different wavelengths of light. Light from a source passes through a narrow slit S in the "collimator." The slit is at the focal point of the lens L, so parallel light falls on the grating. The movable telescope can bring the rays to a focus. Nothing will be seen in the viewing telescope unless it is positioned at an angle $\theta$ that corresponds to a diffraction peak (first order is usually used) of a wavelength emitted by the source. The angle $\theta$ can be measured to very high accuracy, so the wavelength can be determined to high accuracy using Eq. 35–13:

$$\lambda = \frac{d}{m}\sin\theta,$$

where $m$ is an integer representing the order, and $d$ is the distance between grating slits. The bright line you see in a spectrometer corresponding to a discrete particular wavelength is actually an image of the slit S. A narrower slit results in dimmer light, but we can measure the angular position more precisely. If the light contains a continuous range of wavelengths, then a continuous spectrum is seen in the spectroscope.

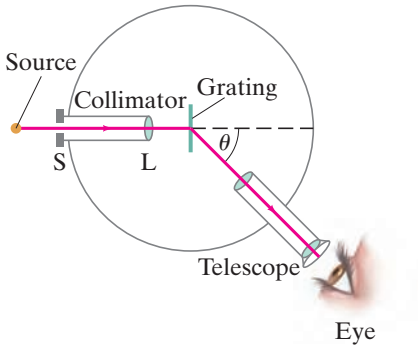


**FIGURE 35–21** Spectrometer or spectroscope.

The spectrometer in Fig. 35–21 uses a transmission grating. Others may use a reflection grating, or sometimes a prism. A prism works because of dispersion (Section 32–6), bending light of different wavelengths into different angles. A prism is not a linear device and must be calibrated because $\lambda$ is not proportional to $\sin\theta$; see Fig. 32–28.

An important use of a spectrometer is for the identification of atoms or molecules. When a gas is heated or an electric current is passed through it, the gas emits a characteristic **line spectrum**. That is, only certain discrete wavelengths of light are emitted, and these are different for different elements and compounds.[†] Figure 35–22 shows the line spectra for a number of elements in the gas state. Line spectra occur only for gases at high temperatures and low pressure and density. The light from heated solids, such as a lightbulb filament, and even from a dense gaseous object such as the Sun, produces a **continuous spectrum** including a wide range of wavelengths.

Figure 35–22 also shows the Sun's "continuous spectrum," which contains a number of *dark* lines (only the most prominent are shown), called **absorption lines**. Atoms and molecules can absorb light at the same wavelengths at which they emit light.

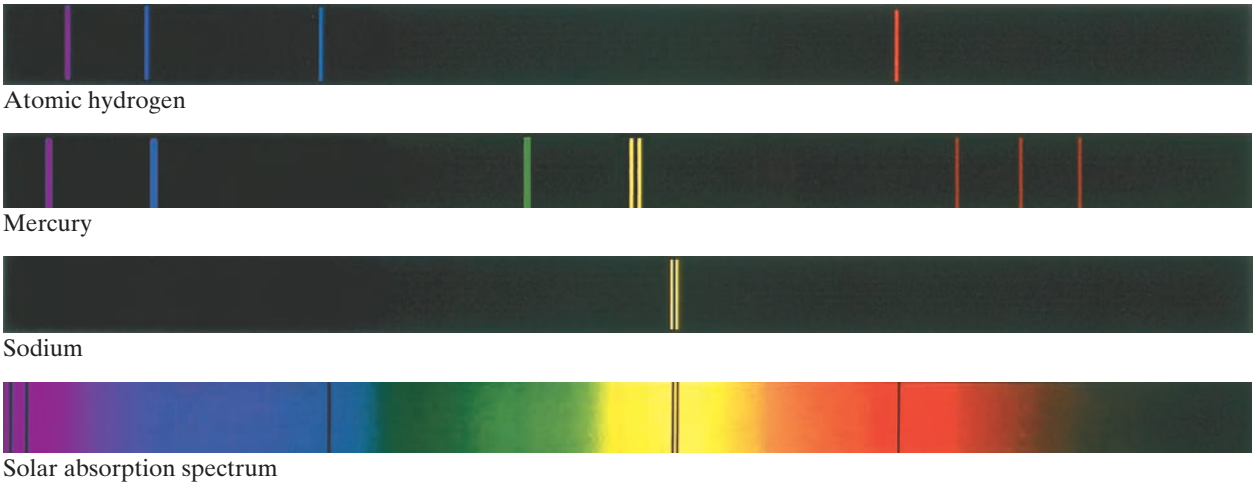

**FIGURE 35–22** Line spectra for the gases indicated, and the spectrum from the Sun showing absorption lines.

[†]Why atoms and molecules emit line spectra was a great mystery for many years and played a central role in the development of modern quantum theory, as we shall see in Chapter 37.

The Sun's absorption lines are due to absorption by atoms and molecules in the cooler outer atmosphere of the Sun, as well as by atoms and molecules in the Earth's atmosphere. A careful analysis of all the Sun's thousands of absorption lines reveals that at least two-thirds of all elements are present in the Sun's atmosphere. The presence of elements in the atmosphere of nearby planets, in interstellar space, and in stars, is also determined by spectroscopy.

Spectroscopy is useful for determining the presence of certain types of molecules in laboratory specimens where chemical analysis would be difficult. For example, biological DNA and different types of protein absorb light in particular regions of the spectrum (such as in the UV). The material to be examined, which is often in solution, is placed in a monochromatic light beam whose wavelength is selected by the placement angle of a diffraction grating or prism. The amount of absorption, as compared to a standard solution without the specimen, can reveal not only the presence of a particular type of molecule, but also its concentration.

**PHYSICS APPLIED**
*Chemical and biochemical analysis by spectroscopy*

Light emission and absorption also occur outside the visible part of the spectrum, such as in the UV and IR regions. Glass absorbs light in these regions, so reflection gratings and mirrors (in place of lenses) are used. Special types of film or sensors are used for detection.

**EXAMPLE 35–10** **Hydrogen spectrum.** Light emitted by hot hydrogen gas is observed with a spectroscope using a diffraction grating having $1.00 \times 10^4$ slits/cm. The spectral lines nearest to the center $(0°)$ are a violet line at 24.2°, a blue line at 25.7°, a blue-green line at 29.1°, and a red line at 41.0° from the center. What are the wavelengths of these spectral lines of hydrogen?

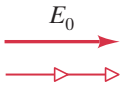
**APPROACH** We get the wavelengths from the angles by using $\lambda = (d/m)\sin\theta$ where $d$ is the spacing between slits, and $m$ is the order of the spectrum (Eq. 35–13).

**SOLUTION** Since these are the closest lines to $\theta = 0°$, this is the first-order spectrum $(m = 1)$. The slit spacing is $d = 1/(1.00 \times 10^4\,\text{cm}^{-1}) = 1.00 \times 10^{-6}\,\text{m}$. The wavelength of the violet line is

$$\lambda = \left(\frac{d}{m}\right)\sin\theta = \left(\frac{1.00 \times 10^{-6}\,\text{m}}{1}\right)\sin 24.2° = 4.10 \times 10^{-7}\,\text{m} = 410\,\text{nm}.$$

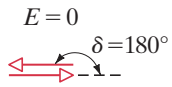
The other wavelengths are:

$$\text{blue:} \quad \lambda = (1.00 \times 10^{-6}\,\text{m})\sin 25.7° = 434\,\text{nm},$$



$$\text{blue-green:} \quad \lambda = (1.00 \times 10^{-6}\,\text{m})\sin 29.1° = 486\,\text{nm},$$

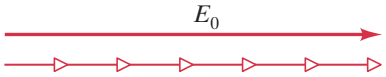
$$\text{red:} \quad \lambda = (1.00 \times 10^{-6}\,\text{m})\sin 41.0° = 656\,\text{nm}.$$



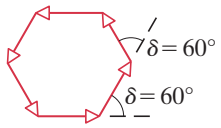
**NOTE** In an unknown mixture of gases, these four spectral lines need to be seen to identify that the mixture contains hydrogen.

## *35–10 Peak Widths and Resolving Power for a Diffraction Grating

We now look at the pattern of maxima produced by a multiple-slit grating using phasor diagrams. We can determine a formula for the width of each peak, and we will see why there are tiny maxima between the principal maxima, as indicated in Fig. 35–19b. First of all, it should be noted that the two-slit and six-slit patterns shown in Fig. 35–19 were drawn assuming very narrow slits so that diffraction does not limit the height of the peaks. For real diffraction gratings, this is not normally the case: the slit width $D$ is often not much smaller than the slit separation $d$, and diffraction thus limits the intensity of the peaks so the central peak $(m = 0)$ is brighter than the side peaks. We won't worry about this effect on intensity except to note that if a diffraction minimum coincides with a particular order of the interference pattern, that order will not appear. (For example, if $d = 2D$, all the even orders, $m = 2, 4, \cdots$, will be missing. Can you see why? *Hint*: See Example 35–4.)



(a) Central maximum: $\theta = 0, \delta = 0$



(b) Minimum: $\delta = 180°$

**FIGURE 35–23** Phasor diagram for two slits (a) at the central maximum, (b) at the nearest minimum.

**FIGURE 35–24** Phasor diagram for six slits (a) at the central maximum, (b) at the nearest minimum.

(a) Central maximum: $\theta = 0, \delta = 0$

(b) Minimum: $\delta = 60°, E_\theta = 0$

**FIGURE 35–25** Phasor diagram for the secondary peak.

Figures 35–23 and 35–24 show phasor diagrams for a two-slit and a six-slit grating, respectively. Each short arrow represents the amplitude of a wave from a single slit, and their vector sum (as phasors) represents the total amplitude for a given viewing angle $\theta$. Part (a) of each Figure shows the phasor diagram at $\theta = 0°$, at the center of the pattern, which is the central maximum $(m = 0)$. Part (b) of each Figure shows the condition for the adjacent minimum: where the arrows first close on themselves (add to zero) so the amplitude $E_\theta$ is zero. For two slits, this occurs when the two separate amplitudes are 180° out of phase. For six slits, it occurs when each amplitude makes a 60° angle with its neighbor. For two slits, the minimum occurs when the phase between slits is $\delta = 2\pi/2$ (in radians); for six slits it occurs when the phase $\delta$ is $2\pi/6$; and in the general case of $N$ slits, the minimum occurs for a phase difference between adjacent slits of

$$\delta = \frac{2\pi}{N}. \qquad \textbf{(35–14)}$$

What does this correspond to in $\theta$? First note that $\delta$ is related to $\theta$ by (Eq. 34–4)

$$\frac{\delta}{2\pi} = \frac{d \sin\theta}{\lambda} \quad \text{or} \quad \delta = \frac{2\pi}{\lambda} d \sin\theta. \qquad \textbf{(35–15)}$$

Let us call $\Delta\theta_0$ the angular position of the minimum next to the peak at $\theta = 0$. Then

$$\frac{\delta}{2\pi} = \frac{d \sin\Delta\theta_0}{\lambda}.$$

We insert Eq. 35–14 for $\delta$ and find

$$\sin\Delta\theta_0 = \frac{\lambda}{Nd}. \qquad \textbf{(35–16a)}$$

Since $\Delta\theta_0$ is usually small ($N$ is usually very large for a grating), $\sin\Delta\theta_0 \approx \Delta\theta_0$, so in the small angle limit we can write

$$\Delta\theta_0 = \frac{\lambda}{Nd}. \qquad \textbf{(35–16b)}$$

We can see from either of the last two relations that the larger $N$ is, the narrower will be the central peak. (For $N = 2$, $\sin\Delta\theta_0 = \lambda/2d$, which is what we obtained earlier for the double slit, Eq. 34–2b with $m = 0$.)

Either of Eqs. 35–16 shows why the peaks become narrower for larger $N$. The origin of the small secondary maxima between the principal peaks (see Fig. 35–19b) can be deduced from the diagram of Fig. 35–25. This is just a continuation of Fig. 35–24b (where $\delta = 60°$); but now the phase $\delta$ has been increased to almost 90°, where $E_\theta$ is a relative maximum. Note that $E_\theta$ is much less than $E_0$ (Fig. 35–24a), so the intensity in this secondary maximum is much smaller than in a principal peak. As $\delta$ (and $\theta$) is increased further, $E_\theta$ again decreases to zero (a "double circle"), then reaches another tiny maximum, and so on. Eventually the diagram unfolds again and when $\delta = 360°$, all the amplitudes again lie in a straight line (as in Fig. 35–24a) corresponding to the next principal maximum ($m = 1$ in Eq. 35–13).

Equation 35–16b gives the half-width of the central $(m = 0)$ peak. To determine the half-width of higher order peaks, $\Delta\theta_m$ for order $m$, we differentiate Eq. 35–15 so as to relate the change $\Delta\delta$ in $\delta$, to the change $\Delta\theta$ in the angle $\theta$:

$$\Delta\delta \approx \frac{d\delta}{d\theta}\Delta\theta = \frac{2\pi d}{\lambda}\cos\theta\,\Delta\theta.$$

If $\Delta\theta_m$ represents the half-width of a peak of order $m$ $(m = 1, 2, \cdots)$—that is, the angle between the peak maximum and the minimum to either side—then $\Delta\delta = 2\pi/N$ as given by Eq. 35–14. We insert this into the above relation and find

$$\Delta\theta_m = \frac{\lambda}{Nd\cos\theta_m}, \qquad \textbf{(35–17)}$$

where $\theta_m$ is the angular position of the $m^{\text{th}}$ peak as given by Eq. 35–13.

This derivation is valid only for small $\Delta\delta\ (=2\pi/N)$ which is indeed the case for real gratings since $N$ is on the order of $10^4$ or more.

An important property of any diffraction grating used in a spectrometer is its ability to resolve two very closely spaced wavelengths (wavelength difference $= \Delta\lambda$). The **resolving power** R of a grating is defined as

$$\mathrm{R} = \frac{\lambda}{\Delta\lambda}. \qquad \textbf{(35–18)}$$

With a little work, using Eq. 35–17, we can show that $\Delta\lambda = \lambda/Nm$ where $N$ is the total number of grating slits and $m$ is the order. Then we have

$$\mathrm{R} = \frac{\lambda}{\Delta\lambda} = Nm. \qquad \textbf{(35–19)}$$

The larger the value of R, the closer two wavelengths can be resolvable. If R is given, the minimum separation $\Delta\lambda$ between two wavelengths near $\lambda$, is (by Eq. 35–18)

$$\Delta\lambda = \frac{\lambda}{\mathrm{R}}.$$

**EXAMPLE 35–11** **Resolving two close lines.** Yellow sodium light, which consists of two wavelengths, $\lambda_1 = 589.00\,\mathrm{nm}$ and $\lambda_2 = 589.59\,\mathrm{nm}$, falls on a 7500-slit/cm diffraction grating. Determine (*a*) the maximum order $m$ that will be present for these sodium lines, (*b*) the width of grating necessary to resolve the two sodium lines.

**APPROACH** We first find $d = 1\,\mathrm{cm}/7500 = 1.33 \times 10^{-6}\,\mathrm{m}$, and then use Eq. 35–13 to find $m$. For (*b*) we use Eqs. 35–18 and 35–19.

**SOLUTION** (*a*) The maximum value of $m$ at $\lambda = 589\,\mathrm{nm}$, using Eq. 35–13 with $\sin\theta \leq 1$, is

$$m = \frac{d}{\lambda}\sin\theta \leq \frac{d}{\lambda} = \frac{1.33 \times 10^{-6}\,\mathrm{m}}{5.89 \times 10^{-7}\,\mathrm{m}} = 2.26,$$

so $m = 2$ is the maximum order present.

(*b*) The resolving power needed is

$$\mathrm{R} = \frac{\lambda}{\Delta\lambda} = \frac{589\,\mathrm{nm}}{0.59\,\mathrm{nm}} = 1000.$$

From Eq. 35–19, the total number $N$ of slits needed for the $m = 2$ order is $N = \mathrm{R}/m = 1000/2 = 500$, so the grating need only be $500/7500\,\mathrm{cm}^{-1} = 0.0667\,\mathrm{cm}$ wide. A typical grating is a few centimeters wide, and so will easily resolve the two lines.

## 35–11 X-Rays and X-Ray Diffraction

In 1895, W. C. Roentgen (1845–1923) discovered that when electrons were accelerated by a high voltage in a vacuum tube and allowed to strike a glass or metal surface inside the tube, fluorescent minerals some distance away would glow, and photographic film would become exposed. Roentgen attributed these effects to a new type of radiation (different from cathode rays). They were given the name **X-rays** after the algebraic symbol $x$, meaning an unknown quantity. He soon found that X-rays penetrated through some materials better than others, and within a few weeks he presented the first X-ray photograph (of his wife's hand). The production of X-rays today is usually done in a tube (Fig. 35–26) similar to Roentgen's, using voltages of typically 30 kV to 150 kV.

Investigations into the nature of X-rays indicated they were not charged particles (such as electrons) since they could not be deflected by electric or magnetic fields. It was suggested that they might be a form of invisible light. However, they showed no diffraction or interference effects using ordinary gratings.

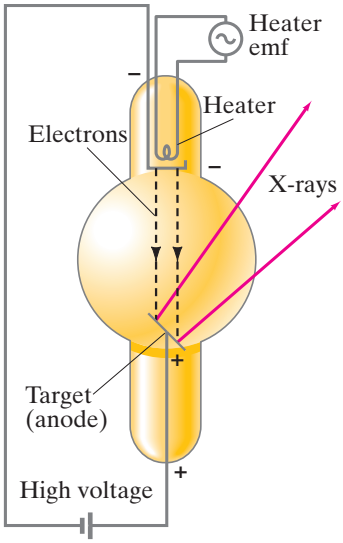


**FIGURE 35–26** X-ray tube. Electrons emitted by a heated filament in a vacuum tube are accelerated by a high voltage. When they strike the surface of the anode, the "target," X-rays are emitted.

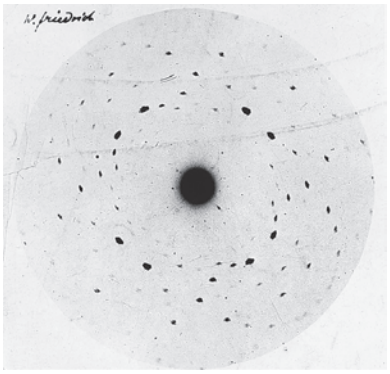

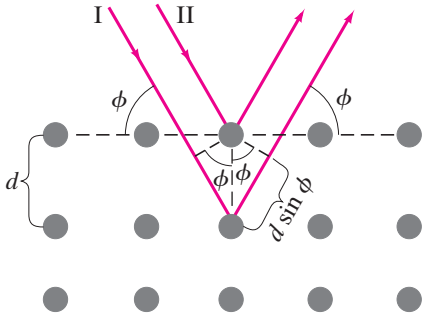

**FIGURE 35–27** This X-ray diffraction pattern is one of the first observed by Max von Laue in 1912 when he aimed a beam of X-rays at a zinc sulfide crystal. The diffraction pattern was detected directly on a photographic plate.

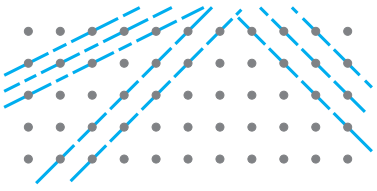
**FIGURE 35–28** X-ray diffraction by a crystal.

Indeed, if their wavelengths were much smaller than the typical grating spacing of $10^{-6}\,\text{m}$ $(=10^{3}\,\text{nm})$, no effects would be expected. Around 1912, Max von Laue (1879–1960) suggested that if the atoms in a crystal were arranged in a regular array (see Fig. 17–2a), such a crystal might serve as a diffraction grating for very short wavelengths on the order of the spacing between atoms, estimated to be about $10^{-10}\,\text{m}$ $(=10^{-1}\,\text{nm})$. Experiments soon showed that X-rays scattered from a crystal did indeed show the peaks and valleys of a diffraction pattern (Fig. 35–27). Thus it was shown, in a single blow, that X-rays have a wave nature and that atoms are arranged in a regular way in crystals. Today, X-rays are recognized as electromagnetic radiation with wavelengths in the range of about $10^{-2}\,\text{nm}$ to 10 nm, the range readily produced in an X-ray tube.

## X-Ray Diffraction



We saw in Section 35–5 that light of shorter wavelength provides greater resolution when we are examining an object microscopically. Since X-rays have much shorter wavelengths than visible light, they should in principle offer much greater resolution. However, there seems to be no effective material to use as lenses for the very short wavelengths of X-rays. Instead, the clever but complicated technique of **X-ray diffraction** (or **crystallography**) has proved very effective for examining the microscopic world of atoms and molecules. In a simple crystal such as NaCl, the atoms are arranged in an orderly cubical fashion, Fig. 35–28, with atoms spaced a distance $d$ apart. Suppose that a beam of X-rays is incident on the crystal at an angle $\phi$ to the surface, and that the two rays shown are reflected from two subsequent planes of atoms as shown. The two rays will constructively interfere if the extra distance ray I travels is a whole number of wavelengths farther than the distance ray II travels. This extra distance is $2d\,\sin\phi$. Therefore, constructive interference will occur when

$$m\lambda = 2d\sin\phi, \qquad m = 1, 2, 3, \cdots, \tag{35–20}$$

where $m$ can be any integer. (Notice that $\phi$ is *not* the angle with respect to the normal to the surface.) This is called the **Bragg equation** after W. L. Bragg (1890–1971), who derived it and who, together with his father W. H. Bragg (1862–1942), developed the theory and technique of X-ray diffraction by crystals in 1912–1913. If the X-ray wavelength is known and the angle $\phi$ is measured, the distance $d$ between atoms can be obtained. This is the basis for X-ray crystallography.

**EXERCISE G** When X-rays of wavelength $0.10\times10^{-9}\,\text{m}$ are scattered from a sodium chloride crystal, a second-order diffraction peak is observed at 21°. What is the spacing between the planes of atoms for this scattering?

**FIGURE 35–29** X-rays can be diffracted from many possible planes within a crystal.

Actual X-ray diffraction patterns are quite complicated. First of all, a crystal is a three-dimensional object, and X-rays can be diffracted from different planes at different angles within the crystal, as shown in Fig. 35–29. Although the analysis is complex, a great deal can be learned from X-ray diffraction about any substance that can be put in crystalline form.

X-ray diffraction has also been very useful in determining the structure of biologically important molecules, such as the double helix structure of DNA, worked out by James Watson and Francis Crick in 1953. See Fig. 35–30, and for models of the double helix, Figs. 21–48a and 21–49. Around 1960, the first detailed structure of a protein molecule, myoglobin, was elucidated with the aid of X-ray diffraction.

Soon the structure of an important constituent of blood, hemoglobin, was worked out, and since then the structures of a great many molecules have been determined with the help of X-rays.

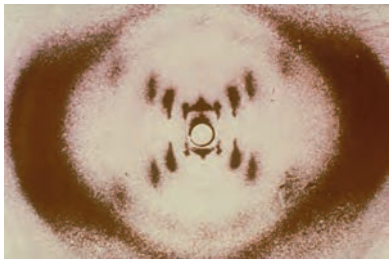


**FIGURE 35–30** X-ray diffraction photo of DNA molecules taken by Rosalind Franklin in the early 1950s. The cross of spots suggested that DNA is a helix.

# *35–12 X-Ray Imaging and Computed Tomography (CT Scan)

## *Normal X-Ray Image

For a conventional medical or dental X-ray photograph, the X-rays emerging from the tube (Fig. 35–26) pass through the body and are detected on photographic film, a digital sensor, or a fluorescent screen, Fig. 35–31. The rays travel in very nearly straight lines through the body with minimal deviation since at X-ray wavelengths there is little diffraction or refraction. There is absorption (and scattering), however; and the difference in absorption by different structures in the body is what gives rise to the image produced by the transmitted rays. The less the absorption, the greater the transmission and the darker the film. The image is, in a sense, a "shadow" of what the rays have passed through.

An X-ray image is *not* produced by focusing rays with lenses as for the optical instruments discussed earlier in Chapter 33.

**PHYSICS APPLIED**
*Normal X-ray image is a sort of shadow (no lenses are involved)*

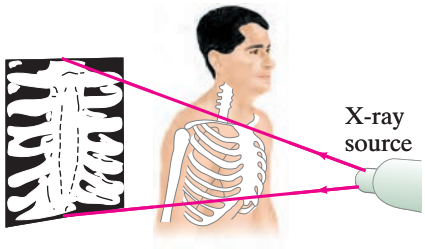

**FIGURE 35–31** Conventional X-ray imaging, which is essentially shadowing.

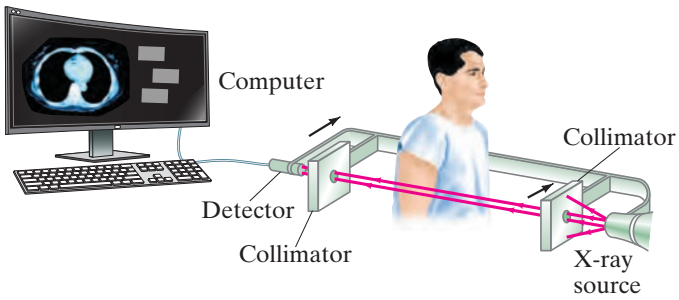
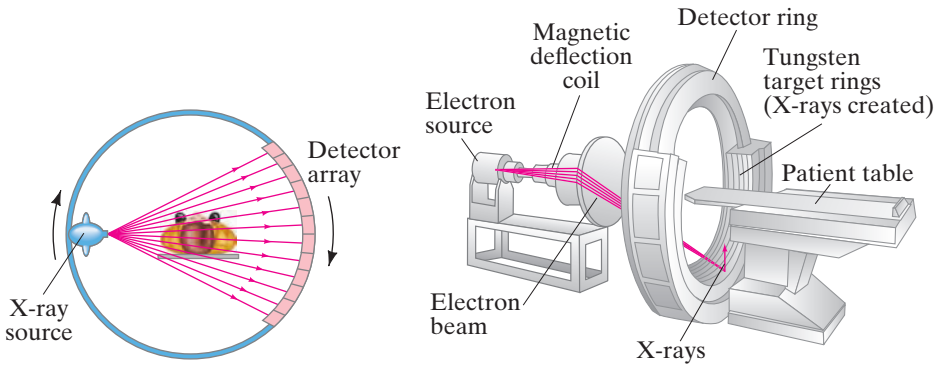
## *Tomography Images (CT)

In conventional X-ray images, a body's thickness is projected onto film or a sensor; structures overlap and in many cases are difficult to distinguish. In the 1970s, a revolutionary X-ray technique was developed called **computed tomography** (CT), which produces an image of a *slice* through the body. (The word **tomography** comes from the Greek: *tomos* = slice, *graph* = picture.) Structures and lesions previously impossible to visualize can now be seen with remarkable clarity. The principle behind CT is shown in Fig. 35–32: a thin collimated (parallel) beam of X-rays passes through the body to a detector that measures the transmitted intensity. Measurements are made at a large number of points as the source and detector are moved past the body together. The apparatus is then rotated slightly about the body axis and again scanned; this is repeated at (perhaps) 1° intervals for 180°. The intensity of the transmitted beam for the many points of each scan, and for each angle, is sent to a computer that reconstructs the image of the slice. Note that the imaged slice is perpendicular to the long axis of the body. For this reason, CT is sometimes called **computerized axial tomography** (CAT), although the abbreviation CAT, as in CAT scan, can also be read as **computer-assisted tomography**.

**PHYSICS APPLIED**
*Computed tomography images (CT or CAT scans)*





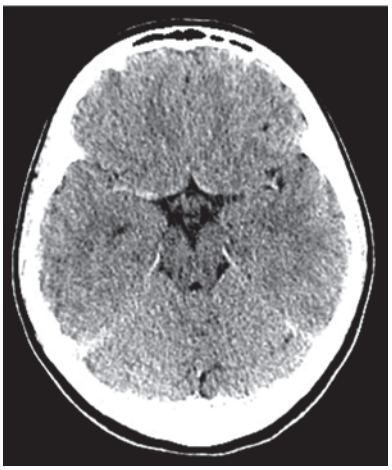


**FIGURE 35–32** Tomographic imaging: the X-ray source and detector move together across the body, the transmitted intensity being measured at a large number of points. Then the "source-detector" assembly is rotated slightly (say, 1°) around a vertical axis, and another scan is made. This process is repeated for perhaps 180°. The computer reconstructs the image of the slice and it is presented on a computer screen. Normally the patient is not standing but lying down.

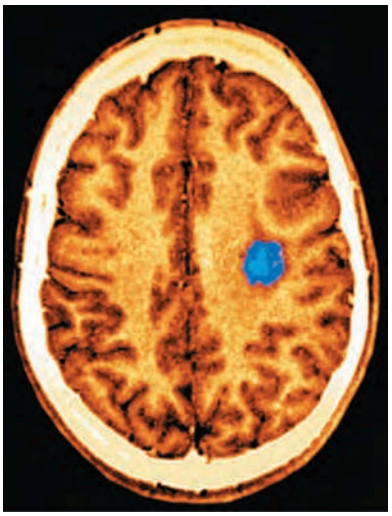

(a) (b)

**FIGURE 35–33** (a) Fan-beam scanner. Rays transmitted through the entire body are measured simultaneously at each angle. The source and detector rotate to take measurements at different angles. In another type of fan-beam scanner, there are detectors around the entire 360° of the circle which remain fixed as the source moves. (b) In still another type, a beam of electrons from a source is directed by magnetic fields at tungsten targets surrounding the patient.

(a)

(b)

**FIGURE 35–34** Two CT images, with different resolutions, each showing a cross section of a brain. Photo (a) is of low resolution; photo (b), of higher resolution, shows a brain tumor, and uses false color to highlight it.

The use of a single detector as in Fig. 35–32 would require a few minutes for the many scans needed to form a complete image. Much faster scanners use a fan beam, Fig. 35–33a, in which beams passing through the entire cross section of the body are detected simultaneously by many detectors. The source and detectors are then rotated about the patient, and an image requires only a few seconds. Even faster, and therefore useful for heart scans, are fixed source machines wherein an electron beam is directed (by magnetic fields) to tungsten targets surrounding the patient, creating the X-rays. See Fig. 35–33b.

## *Image Formation

But how is the image formed? We can think of the slice to be imaged as being divided into many tiny picture elements (or **pixels**), which could be squares (as in Fig. 34–36). For CT, the width of each pixel is chosen according to the width of the detectors and/or the width of the X-ray beams, and this determines the resolution of the image, which might be $\frac{1}{2}$ mm. An X-ray detector measures the intensity of the transmitted beam. Subtracting this value from the intensity of the beam at the source yields the total absorption (called a "projection") along that beam line. Complicated mathematical techniques are used to analyze all the absorption projections for the huge number of beam scans measured (see the next Subsection), obtaining the absorption at each pixel and assigning each a "grayness value" according to how much radiation was absorbed. The image is made up of tiny spots (pixels) of varying shades of gray. Often the amount of absorption is color-coded. The colors in the resulting **false-color** image have nothing to do, however, with the actual color of the object. The actual images are monochromatic (various shades of gray, depending on the absorption). Only *visible* light has color; X-rays do not.

Figure 35–34 illustrates what actual CT images look like. It is generally agreed that CT scanning has revolutionized some areas of medicine by providing much less invasive, and/or more accurate, diagnosis.

Computed tomography can also be applied to ultrasound imaging (Section 16–9) and to emissions from radioisotopes and nuclear magnetic resonance (Sections 42–9 and 42–10).

## *Tomographic Image Reconstruction

How can the "grayness" of each pixel be determined even though all we can measure is the total absorption along each beam line in the slice? It can be done only by using the many beam scans made at a great many different angles. Suppose the image is to be an array of $100 \times 100$ elements for a total of $10^4$ pixels. If we have 100 detectors and measure the absorption projections at 100 different angles, then we get $10^4$ pieces of information. From this information, an image can be reconstructed, but not precisely. If more angles are measured, the reconstruction of the image can be done more accurately.

To suggest how mathematical reconstruction is done, we consider a very simple case using the **iterative** technique ("to iterate" is from the Latin "to repeat"). Suppose our sample slice is divided into the simple $2 \times 2$ pixels as shown in Fig. 35–35. The number inside each pixel represents the amount of absorption by the material in that area (say, in tenths of a percent): that is, 4 represents twice as much absorption as 2. But we cannot directly measure these values—they are the unknowns we want to solve for. All we can measure are the *projections*—the total absorption along each beam line—and these are shown in Fig. 35–35 outside the yellow squares as the sum of the absorptions for the pixels along each line at four different angles. These projections (given at the tip of each arrow) are what we can measure, and we now want to work back from them to see how close we can get to the true absorption value for each pixel. We start our analysis with each pixel being assigned a zero value, Fig. 35–36a. In the iterative technique, we use the projections to estimate the absorption value in each square, and repeat for each angle. The angle 1 projections are 7 and 13 (Fig. 35–35). We divide each of these equally between their two squares: each square in the left column of Fig. 35–36a gets $3\frac{1}{2}$ (half of 7), and each square in the right column gets $6\frac{1}{2}$ (half of 13) as shown in Fig. 35–36b.

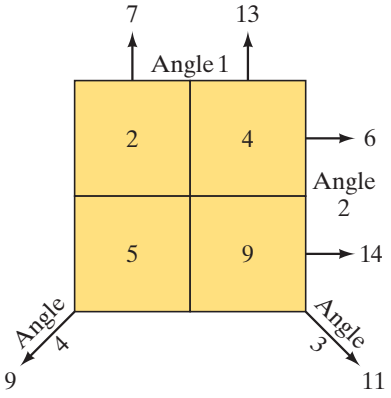

**FIGURE 35–35** A simple $2 \times 2$ image showing true absorption values (inside the squares) and measured projections.

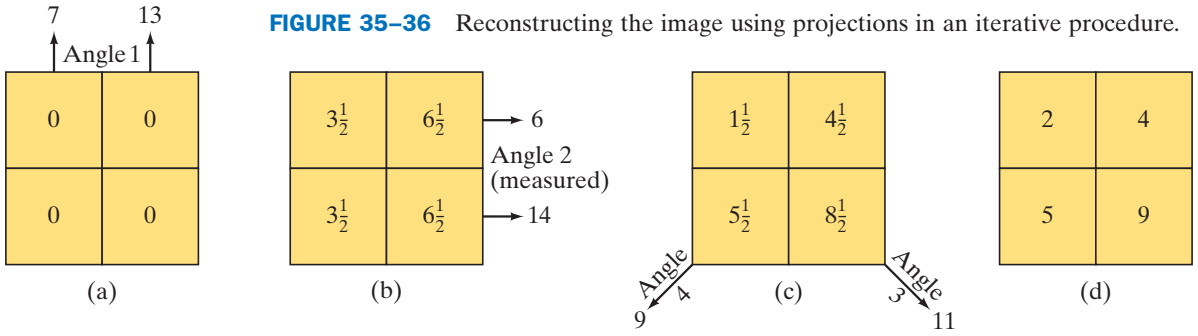

**FIGURE 35–36** Reconstructing the image using projections in an iterative procedure.

Next we use the projections at angle 2. We calculate the difference between the measured projections at angle 2 (6 and 14) and the projections based on the previous estimate (top row: $3\frac{1}{2} + 6\frac{1}{2} = 10$; same for bottom row). Then we distribute this difference equally to the squares in that row. For the top row, we have

$$3\tfrac{1}{2} + \frac{6 - 10}{2} = 1\tfrac{1}{2} \quad \text{and} \quad 6\tfrac{1}{2} + \frac{6 - 10}{2} = 4\tfrac{1}{2};$$

and for the bottom row,

$$3\tfrac{1}{2} + \frac{14 - 10}{2} = 5\tfrac{1}{2} \quad \text{and} \quad 6\tfrac{1}{2} + \frac{14 - 10}{2} = 8\tfrac{1}{2}.$$

These values are inserted as shown in Fig. 35–36c. Next, the projection at angle 3 (= 11), combined with the difference as above, gives

$$\text{(upper left)} \quad 1\tfrac{1}{2} + \frac{11 - 10}{2} = 2 \quad \text{and} \quad \text{(lower right)} \quad 8\tfrac{1}{2} + \frac{11 - 10}{2} = 9;$$

and then for angle 4 we have

$$\text{(lower left)} \quad 5\tfrac{1}{2} + \frac{9 - 10}{2} = 5 \quad \text{and} \quad \text{(upper right)} \quad 4\tfrac{1}{2} + \frac{9 - 10}{2} = 4.$$

The result, shown in Fig. 35–36d, corresponds exactly to the true values. (In real situations, the true values are not known, which is why these computer techniques are required.) To obtain these numbers exactly, we used six pieces of information (two each at angles 1 and 2, one each at angles 3 and 4). For the much larger number of pixels used for actual images, exact values are generally not attained. Many iterations may be needed, and the calculation is considered sufficiently precise when the difference between calculated and measured projections is sufficiently small. The above example illustrates the "convergence" of the process: the first iteration (b to c in Fig. 35–36) changed the values by 2, the last iteration (c to d) by only $\frac{1}{2}$.

## *35–13 Specialty Microscopes and Contrast

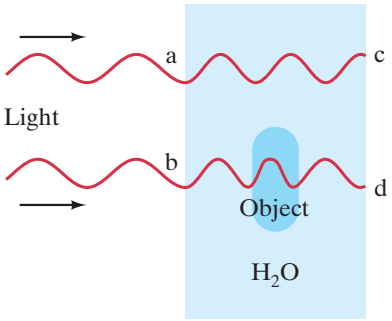

**FIGURE 35–37** Object—say, a bacterium—in a water solution.

All the resolving power a microscope can attain will be useless if the object to be seen cannot be distinguished from the background. The difference in brightness between the image of an object and the image of the surroundings is called **contrast**. Achieving high contrast is an important problem in microscopy and other forms of imaging. The problem arises in biology, for example, because cells consist largely of water and are almost uniformly transparent to light. We now briefly discuss two special types of microscope that can increase contrast: the interference and phase-contrast microscopes.

**PHYSICS APPLIED**
*Interference microscope*

An **interference microscope** makes use of the wave properties of light in a direct way to increase contrast in a transparent object. Consider a transparent object—say, a bacterium in water (Fig. 35–37). Coherent light enters uniformly from the left and is in phase at all points such as a and b. If the object is as transparent as the water, the beam leaving at d will be as bright as that at c. There will be no contrast and the object will not be seen. However, if the object's refractive index is slightly different from that of the surrounding medium, the wavelength within the object will be altered as shown. Hence light waves at points c and d will differ in phase, if not in amplitude. The interference microscope changes this difference in phase into a difference of amplitude which our eyes can detect. Light that passes through the sample is superimposed onto a reference beam that does not pass through the object, so that the beams interfere. One way of doing this is shown in Fig. 35–38. Light from a source is split into two equal beams by a half-silvered mirror, $MS_1$. One beam passes through the object, and the second (comparison beam) passes through an identical system without the object. The two meet again and are superposed by the half-silvered mirror $MS_2$ before entering the eyepiece and eye. The path length (and amplitude) of the comparison beam is adjustable so that the background can be dark; that is, full destructive interference occurs. Light passing through the object (beam bd in Fig. 35–37) will also interfere with the comparison beam. But because of its different phase, the interference will not be completely destructive. Thus it will appear brighter than the background. Where the object varies in thickness, the phase difference between beams ac and bd in Fig. 35–37 will be different, thus affecting the amount of interference. Hence *variation in the thickness of the object will appear as variations in brightness in the image*.

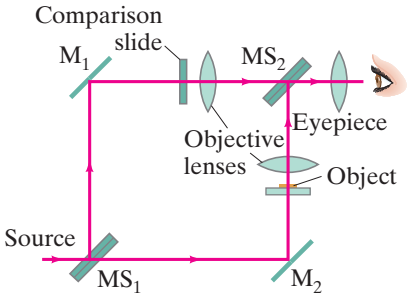

**FIGURE 35–38** Diagram of an interference microscope.

**PHYSICS APPLIED**
*Phase-contrast microscope*

A **phase-contrast microscope** also makes use of interference and differences in phase to produce a high-contrast image. Contrast is achieved by a circular glass *phase plate* that has a groove (or a raised portion) in the shape of a ring, positioned so undeviated source rays pass through it, but rays deviated by the object do not pass through this ring. Because the rays deviated by the object travel through a different thickness of glass than the undeviated source rays, the two can be out of phase and can interfere destructively at the object image plane. Thus the image of the object can contrast sharply with the background. Phase-contrast microscope images tend to have "halos" around them (as a result of diffraction from the phase-plate opening), so care must be taken in the interpretation of images.

# Summary

**Diffraction** refers to the fact that light, like other waves, bends around objects it passes, and spreads out after passing through narrow slits. This bending gives rise to a **diffraction pattern** due to interference between rays of light that travel different distances.

Light passing through a very narrow slit of width $D$ (on the order of the wavelength $\lambda$) will produce a pattern with a bright central maximum of half-width $\theta$ given by

$$\sin\theta = \frac{\lambda}{D}, \qquad \textbf{(35–1)}$$

flanked by fainter lines to either side.

The minima in the diffraction pattern occur at

$$D\sin\theta = m\lambda \qquad \textbf{(35–2)}$$

where $m = 1, 2, 3, \cdots$, but not $m = 0$ (for which the pattern has its strongest maximum).

[*The **intensity** at any point in the single-slit diffraction pattern can be calculated using **phasor** diagrams. The same technique can be used to determine the intensity of the pattern produced by two slits.]

[*The pattern for two-slit interference can be described as a series of maxima due to interference of light from the two slits, modified by an "envelope" due to diffraction at each slit.]

The wave nature of light limits the sharpness or **resolution** of images. Because of diffraction, it is *not possible to discern details smaller than the wavelength* of the radiation being used. The useful magnification of a light microscope is limited by diffraction to about $500\times$.

A **diffraction grating** consists of many parallel slits or lines, separated from each other by a distance $d$. The peaks of constructive interference occur at angles $\theta$ given by

$$\sin\theta = \frac{m\lambda}{d}, \qquad \textbf{(35–13)}$$

where $m = 0, 1, 2, \cdots$. The peaks of constructive interference are much brighter and sharper for a diffraction grating than for a two-slit apparatus. [*Peak width is inversely proportional to the total number of slits in the grating.]

A diffraction grating (or a prism) is used in a **spectrometer** to separate different colors and observe **line spectra**. For a given order $m$, $\theta$ depends on $\lambda$. Precise determination of wavelength can be done with a spectrometer by careful measurement of $\theta$.

**X-rays** are a form of electromagnetic radiation of very short wavelength. They are produced when high-speed electrons, accelerated by high voltage in an evacuated tube, strike a glass or metal target.

[***Computed tomography** (CT or CAT scan) uses many narrow X-ray beams through a section of the body to construct an image of that cross-section.]

# Questions

**1.** Radio waves and visible light are both electromagnetic waves. Why can a radio receive a signal behind a hill when we cannot see the transmitting antenna?

**2.** Hold one hand close to your eye and focus on a distant light source through a narrow slit between two fingers. (Adjust your fingers to obtain the best pattern.) Describe the pattern that you see.

**3.** Explain why diffraction patterns are more difficult to observe with an extended light source than for a point source. Compare also a monochromatic source to white light.

**4.** For diffraction by a single slit, what is the effect of increasing (*a*) the slit width, (*b*) the wavelength?

**5.** Describe the single-slit diffraction pattern produced when white light falls on a slit having a width of (*a*) 50 nm, (*b*) 50,000 nm.

**6.** What happens to the diffraction pattern of a single slit if the whole apparatus is immersed in (*a*) water, (*b*) a vacuum, instead of in air?

**7.** In the single-slit diffraction pattern, why does the first off-center maximum not occur at exactly $\sin\theta = \frac{3}{2}\lambda/D$?

**8.** Discuss the similarities, and differences, of double-slit interference and single-slit diffraction.

***9.** Figure 35–11 shows a two-slit interference pattern for the case when $d$ is larger than $D$. Can the reverse case occur, when $d$ is less than $D$?

***10.** When both diffraction and interference are taken into account in the double-slit experiment, discuss the effect of increasing (*a*) the wavelength, (*b*) the slit separation, (*c*) the slit width.

**11.** Does diffraction limit the resolution of images formed by (*a*) spherical mirrors, (*b*) plane mirrors?

**12.** Do diffraction effects occur for virtual as well as real images?

**13.** Give at least two advantages for the use of large reflecting mirrors in astronomical telescopes.

**14.** Atoms have diameters of about $10^{-8}$ cm. Can visible light be used to "see" an atom? Explain.

**15.** Which color of visible light would give the best resolution in a microscope? Explain.

**16.** Could a diffraction grating just as well be called an interference grating? Discuss.

**17.** Suppose light consisting of wavelengths between 400 nm and 700 nm is incident normally on a diffraction grating. For what orders (if any) would there be overlap in the observed spectrum? Does your answer depend on the slit spacing?

**18.** What is the difference in the interference patterns formed by two slits $10^{-4}$ cm apart as compared to a diffraction grating containing $10^4$ slits/cm?

**19.** By what factor can you improve resolution, other things being equal, if you use blue light ($\lambda = 450$ nm) rather than red (700 nm)?

**20.** The 300-meter radiotelescope in Arecibo, Puerto Rico (Fig. 35–17), is the world's largest radiotelescope, but many other radiotelescopes are also very large. Why are radiotelescopes so big? Why not make optical telescopes that are equally large? (The largest optical telescopes have diameters of about 10 meters.)

**21.** For a diffraction grating, what is the advantage of (*a*) many slits, (*b*) closely spaced slits?

**22.** White light strikes (*a*) a diffraction grating and (*b*) a prism. A rainbow appears on a wall just below the direction of the horizontal incident beam in each case. What is the color of the top of the rainbow in each case? Explain.

# MisConceptual Questions

**1.** Blue light of wavelength $\lambda$ passes through a single slit of width $D$ and forms a diffraction pattern on a screen. If we replace the blue light by red light of wavelength $2\lambda$, we can retain the original diffraction pattern if we change the slit width
(*a*) to $D/4$. (*c*) to $4D$. (*e*) not at all.
(*b*) to $D/2$. (*d*) to $2D$.

**2.** Imagine holding a circular disk in a beam of monochromatic light (Fig. 35–39). If diffraction occurs at the edge of the disk, the center of the shadow is
(*a*) darker than the rest of the shadow.
(*b*) a bright spot.
(*c*) bright or dark, depending on the wavelength.
(*d*) bright or dark, depending on the distance to the screen.

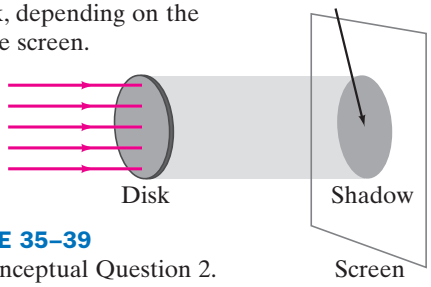

**FIGURE 35–39**
MisConceptual Question 2.

**3.** If you hold two fingers very close together and look at a bright light, you see lines between your fingers. What is happening?
(*a*) You are holding your fingers too close to your eye to be able to focus on it.
(*b*) You are seeing a diffraction pattern.
(*c*) This is a quantum-mechanical tunneling effect.
(*d*) The brightness of the light is overwhelming your eye.

**4.** A double-slit experiment yields an interference pattern due to the path length difference from light traveling through one slit versus the other. Why does a single slit show a diffraction pattern?
(*a*) There is a path length difference from waves originating at different parts of the slit.
(*b*) The wavelength of the light is shorter than the slit.
(*c*) The light passing through the slit interferes with light that does not pass through.
(*d*) The single slit must have something in the middle of it, causing it to act like a double slit.

**5.** Red light from a laser pointer shines directly on a narrow slit whose width is about 5 wavelengths of this light. A white screen is placed 0.1 m behind the slit. What is observed on the screen?
(*a*) Light that is more orange, because the wavelength shifts.
(*b*) Light that is closer to infrared, because the wavelength shifts.
(*c*) A tiny red rectangle.
(*d*) A red rectangle and dimmer red stripes on either side of it.
(*e*) No light, because the slits are too narrow.

**6.** A single-slit diffraction pattern is formed on a distant screen by a narrow vertical slit. If the width of the slit is reduced, what happens to the width of the central bright fringe?
(*a*) It becomes narrower.
(*b*) It becomes wider.
(*c*) It becomes brighter.
(*d*) It becomes taller.
(*e*) It doesn't change at all.

**7.** If someone is standing on a sidewalk around a corner from you, what is the main reason you can hear him speaking but can't see him?
(*a*) Sound travels farther in air than light does.
(*b*) Sound can travel through walls, but light cannot.
(*c*) Sound waves have long enough wavelengths to bend around a corner; light wavelengths are too short to bend much.
(*d*) Sound waves reflect off walls, but light cannot.

**8.** Light passes through a slit that is about $5 \times 10^{-3}$ m high and $5 \times 10^{-7}$ m wide. The central bright light visible on a distant screen will be
(*a*) about $5 \times 10^{-3}$ m high and about $5 \times 10^{-7}$ m wide.
(*b*) about $5 \times 10^{-3}$ m high and wider than $5 \times 10^{-7}$ m.
(*c*) about $5 \times 10^{-3}$ m high and narrower than $5 \times 10^{-7}$ m.
(*d*) taller than $5 \times 10^{-3}$ m high and wider than $5 \times 10^{-7}$ m.
(*e*) taller than $5 \times 10^{-3}$ m high and about $5 \times 10^{-7}$ m wide.

**9.** A point source of yellow light shines on a slit. If the width of the slit is increased by 20%, how will the diffraction pattern change?
(*a*) The pattern will shift to longer wavelengths.
(*b*) The pattern will shift to shorter wavelengths.
(*c*) The pattern spacing will spread out.
(*d*) The pattern spacing will be compressed.
(*e*) There will be no change.

**10.** Which of the following statements is true?
(*a*) A larger-diameter lens can better resolve two distant points.
(*b*) Red light can better resolve two distant points than blue light can.
(*c*) It is easier to resolve distant objects than nearer objects.
(*d*) Objects that are closer together are easier to resolve than objects that are farther apart.

**11.** It would be impossible to build a microscope that could use visible light to see the molecular structure of a crystal because
(*a*) lenses with enough magnification cannot be made.
(*b*) lenses cannot be ground with fine enough precision.
(*c*) lenses cannot be placed in the correct place with enough precision.
(*d*) diffraction limits the resolving power to about the size of the wavelength of the light used.
(*e*) More than one of the above is correct.

**12.** The size of the smallest object that can be clearly seen by the naked eye is determined by
(*a*) the diameter of the pupil.
(*b*) the light intensity.
(*c*) the eye's far point.
(*d*) the eye's near point.

**13.** The resolving power of a microscope is greatest when the object being observed is illuminated by
(*a*) ultraviolet light.
(*b*) infrared light.
(*c*) visible light.
(*d*) radio waves.

# Problems

[Note: Assume light passing through slits is in phase, unless stated otherwise.]

## 35–1 Single-Slit Diffraction

**1.** (I) If 680-nm light falls on a slit 0.0385 mm wide, what is the angular width of the central diffraction peak?

**2.** (I) Monochromatic light falls on a slit that is $2.60 \times 10^{-3}$ mm wide. If the angle between the first dark fringes on either side of the central maximum is 29.0° (dark fringe to dark fringe), what is the wavelength of the light used?

**3.** (II) When violet light of wavelength 415 nm falls on a single slit, it creates a central diffraction peak that is 9.60 cm wide on a screen that is 2.85 m away. How wide is the slit?

**4.** (II) Light of wavelength 580 nm falls on a slit that is $3.50 \times 10^{-3}$ mm wide. Estimate how far the first brightest diffraction fringe is from the strong central maximum if the screen is 10.0 m away.

**5.** (II) Consider microwaves which are incident perpendicular to a metal plate which has a 1.8-cm slit in it. Determine the angles at which there are diffraction minima for wavelengths of (*a*) 0.50 cm, (*b*) 1.0 cm, and (*c*) 3.0 cm.

**6.** (II) Monochromatic light of wavelength 633 nm falls on a slit. If the angle between the first bright fringes on either side of the central maximum is 32°, estimate the slit width.

**7.** (II) If a slit diffracts 580-nm light so that the diffraction maximum is 6.0 cm wide on a screen 2.50 m away, what will be the width of the diffraction maximum for light with a wavelength of 460 nm?

**8.** (II) (*a*) For a given wavelength $\lambda$, what is the minimum slit width for which there will be no diffraction minimum? (*b*) What is the minimum slit width so that no visible light exhibits a diffraction minimum?

**9.** (II) When blue light of wavelength 440 nm falls on a single slit, the first dark bands on either side of center are separated by 51.0°. Determine the width of the slit.

**10.** (II) A single slit 0.10 mm wide is illuminated by 450-nm light. What is the width of the central maximum in the diffraction pattern on a screen 5.0 m away?

**11.** (II) Coherent light from a laser diode is emitted through a rectangular area $3.0\,\mu\text{m} \times 1.5\,\mu\text{m}$ (horizontal-by-vertical). If the laser light has a wavelength of 680 nm, determine the angle between the first diffraction minima on either side, (*a*) above and below the central maximum, (*b*) to the left and right of the central maximum.

## *35–2 Intensity, Single-Slit Diffraction Pattern

***12.** (II) If you double the width of a single slit, the intensity of the light passing through the slit is doubled. (*a*) Show, however, that the intensity at the center of the screen increases by a factor of 4. (*b*) Explain why this does not violate conservation of energy.

***13.** (II) Light of wavelength 750 nm passes through a slit 1.0 $\mu$m wide and a single-slit diffraction pattern is formed vertically on a screen 25 cm away. Determine the light intensity $I$ 18 cm above the central maximum, expressed as a fraction of the central maximum's intensity $I_0$.

***14.** (III) (*a*) Explain why the secondary maxima in the single-slit diffraction pattern do not occur precisely at $\beta/2 = (m + \frac{1}{2})\pi$ where $m = 1, 2, 3, \cdots$. (*b*) By differentiating Eq. 35–7 with respect to $\beta$ show that the secondary maxima occur when $\beta/2$ satisfies the relation $\tan(\beta/2) = \beta/2$. (*c*) Carefully and precisely plot the curves $y = \beta/2$ and $y = \tan\beta/2$. From their intersections, determine the values of $\beta$ for the first and second secondary maxima. What is the percent difference from $\beta/2 = (m + \frac{1}{2})\pi$?

## *35–3 Intensity, Double-Slit Diffraction

***15.** (II) If a double-slit pattern contains exactly eleven fringes in the central diffraction peak, what can you say about the slit width and separation? Assume the first diffraction minimum occurs at an interference minimum.

***16.** (II) Design a double-slit apparatus so that the central diffraction peak contains precisely fifteen fringes. Assume the first diffraction minimum occurs at (*a*) an interference minimum, (*b*) an interference maximum.

***17.** (II) In a double-slit experiment, if the central diffraction peak contains 13 interference fringes (Fig. 35–11c), how many fringes are contained within each secondary diffraction peak (between $m = +1$ and $+2$ in Eq. 35–2a)? Assume the first diffraction minimum occurs at an interference minimum.

***18.** (II) Two 0.010-mm-wide slits are 0.030 mm apart (center to center). Determine (*a*) the spacing between interference fringes for 520-nm light on a screen 1.0 m away and (*b*) the distance between the two diffraction minima on either side of the central maximum of the envelope.

***19.** (II) Suppose $d = D$ in a double-slit apparatus, so that the two slits merge into one slit of width $2D$. Show that Eq. 35–9 reduces to the correct equation for single-slit diffraction.

***20.** (II) In a double-slit experiment, let $d = 5.00D = 40.0\lambda$. Compare (as a ratio) the intensity of the third-order interference maximum with that of the zero-order maximum.

***21.** (II) How many fringes are contained in the central diffraction peak for a double-slit pattern if (*a*) $d = 2.00D$, (*b*) $d = 4.50D$, (*c*) $d = 7.80D$, (*d*) $d = 16.0D$?

***22.** (III) (*a*) Derive an expression for the intensity in the interference pattern for three equally spaced slits. Express in terms of $\delta = 2\pi d \sin\theta/\lambda$ where $d$ is the distance between adjacent slits and assume the slit width $D \approx \lambda$. (*b*) Show that there is only one secondary maximum between principal peaks.

## 35–5 to 35–7 Resolution Limits

**23.** (I) What is the angular resolution limit (degrees) set by diffraction for the 100-inch (254-cm mirror diameter) Mt. Wilson telescope ($\lambda = 560$ nm)?

**24.** (I) What is the resolving power of a microscope ($\lambda = 550$ nm) with a 5-mm-diameter objective which has $f = 8$ mm?

**25.** (II) Two stars 18 light-years away are barely resolved by a 66-cm (mirror diameter) telescope. How far apart are the stars? Assume $\lambda = 550$ nm and that the resolution is limited by diffraction.

**26.** (II) The nearest neighboring star to the Sun is about 4 light-years away. If a planet happened to be orbiting this star at an orbital radius equal to that of the Earth–Sun distance, what minimum diameter would an Earth-based telescope's aperture have to be in order to obtain an image that resolved this star–planet system? Assume the light emitted by the star and planet has a wavelength of 550 nm.

**27.** (II) If you could shine a very powerful flashlight beam toward the Moon, estimate the diameter of the beam when it reaches the Moon. Assume that the beam leaves the flashlight through a 5.0-cm aperture, that its white light has an average wavelength of 550 nm, and that the beam spreads due to diffraction only.

**28.** (II) Suppose that you wish to construct a telescope that can resolve features 6.5 km across on the Moon, 384,000 km away. You have a 2.0-m-focal-length objective lens whose diameter is 11.0 cm. What focal-length eyepiece is needed if your eye can resolve objects 0.10 mm apart at a distance of 25 cm? What is the resolution limit set by the size of the objective lens (that is, by diffraction)? Use $\lambda = 560$ nm.

**29.** (II) The normal lens on a 35-mm camera has a focal length of 50.0 mm. Its aperture diameter varies from a maximum of 25 mm $(f/2)$ to a minimum of 3.0 mm $(f/16)$. Determine the resolution limit set by diffraction for $(f/2)$ and $(f/16)$. Specify as the number of lines per millimeter resolved on the detector or film. Take $\lambda = 560$ nm.

**30.** (II) A microscope 14.0 cm long has an objective lens of diameter 6.0 mm and focal length 8.25 mm. Its magnifying power is approximately 275×. What is its resolving power?

**31.** (II) Two ants stand 2 cm apart. (*a*) Assuming diffraction-limited vision, at what distance could a human eye with a pupil diameter of 4 mm tell that there are two separate ants? Assume light of 550-nm wavelength. (*b*) Does this result agree with your everyday experience? Explain.

**32.** (II) When driving at night, your eyes' pupils have dilated to a 7.5-mm diameter. If your vision is diffraction limited, what would be the greatest distance at which you could resolve the two headlights of an oncoming car, which are spaced 1.5 m apart? Assume a wavelength of 550 nm for the light.

## 35–8 and 35–9 Diffraction Grating, Spectroscopy

**33.** (I) At what angle will 480-nm light produce a second-order maximum when falling on a grating whose slits are $1.25 \times 10^{-3}$ cm apart?

**34.** (I) A source produces first-order lines when incident normally on a 12,000-slit/cm diffraction grating at angles 28.8°, 36.7°, 38.6°, and 47.9°. What are the wavelengths?

**35.** (I) A 3800-slit/cm grating produces a third-order fringe at a 35.0° angle. What wavelength of light is being used?

**36.** (I) A grating has 6300 slits/cm. How many spectral orders can be seen (400 to 700 nm) when it is illuminated by white light?

**37.** (II) How many slits per centimeter does a grating have if the third order occurs at an 18.0° angle for 650-nm light?

**38.** (II) White light containing wavelengths from 410 nm to 750 nm falls on a grating with 7800 slits/cm. How wide is the first-order spectrum on a screen 2.50 m away?

**39.** (II) A diffraction grating has $6.5 \times 10^5$ slits/m. Find the angular spread in the second-order spectrum between red light of wavelength $7.0 \times 10^{-7}$ m and blue light of wavelength $4.5 \times 10^{-7}$ m.

**40.** (II) A tungsten–halogen bulb emits a continuous spectrum of ultraviolet, visible, and infrared light in the wavelength range 360 nm to 2000 nm. Assume that the light from a tungsten–halogen bulb is incident on a diffraction grating with slit spacing $d$ and that the first-order brightness maximum for the wavelength of 1200 nm occurs at angle $\theta$. What other wavelengths within the spectrum of incident light will produce a brightness maximum at this same angle $\theta$? [Optical filters are used to deal with this bothersome effect when a continuous spectrum of light is measured by a spectrometer.]

**41.** (II) Show that the second- and third-order spectra of white light produced by a diffraction grating always overlap. What wavelengths overlap?

**42.** (II) Two first-order spectrum lines are measured by a 9350-slit/cm spectrometer at angles, on each side of center, of $+26°38'$, $+41°02'$ and $-26°18'$, $-40°27'$. Calculate the wavelengths based on these data.

**43.** (II) Suppose the angles measured in Problem 42 were produced when the spectrometer (but not the source) was submerged in water. What then would be the wavelengths (in air)?

**44.** (II) The first-order line of 589-nm light falling on a diffraction grating is observed at a 15.5° angle. How far apart are the slits? At what angle will the third order be observed?

**45.** (II) Red laser light from a He–Ne laser $(\lambda = 632.8\text{ nm})$ creates a second-order fringe at 53.2° after passing through a grating. What is the wavelength $\lambda$ of light that creates a first-order fringe at 21.2°?

**46.** (II) Two (and only two) full spectral orders can be seen on either side of the central maximum when white light is sent through a diffraction grating. What is the maximum number of slits per cm for the grating?

**47.** (II) White light passes through a 640-slit/mm diffraction grating. First-order and second-order visible spectra ("rainbows") appear on the wall 32 cm away as shown in Fig. 35–40. Determine the widths $\ell_1$ and $\ell_2$ of the two "rainbows" (400 nm to 700 nm). In which order is the "rainbow" dispersed over a larger distance?

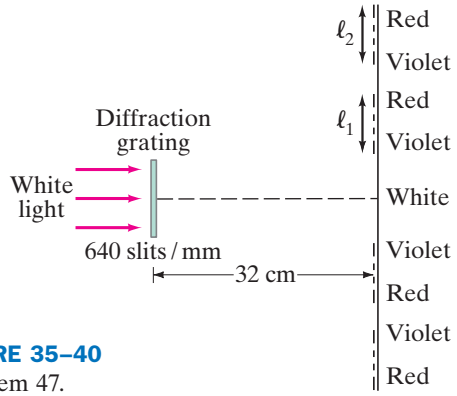

**FIGURE 35–40**
Problem 47.

**48.** (II) **Missing orders** occur for a diffraction grating when a diffraction minimum coincides with an interference maximum. Let $D$ be the width of each slit and $d$ the separation of slits. (*a*) Show that if $d = 2D$, all even orders $(m = 2, 4, 6, \cdots)$ are missing. (*b*) Show there will be missing orders whenever

$$\frac{d}{D} = \frac{m_1}{m_2}$$

where $m_1$ and $m_2$ are integers. (*c*) Discuss the case $d = D$, the limit in which the space between slits becomes negligible.

**49.** (II) Monochromatic light falls on a transmission diffraction grating at an angle $\phi$ to the normal. (*a*) Show that Eq. 35–13 for diffraction maxima must be replaced by

$$d(\sin\phi + \sin\theta) = \pm m\lambda. \qquad m = 0, 1, 2, \cdots.$$

(*b*) Explain the $\pm$ sign. (*c*) Green light with a wavelength of 550 nm is incident at an angle of 15° to the normal on a diffraction grating with 4500 slits/cm. Find the angles at which the first-order maxima occur.

### *35–10 Grating, Peak Widths, Resolving Power

***50.** (II) A 6500-slit/cm diffraction grating is 3.26 cm wide. If light with wavelengths near 624 nm falls on the grating, how close can two wavelengths be if they are to be resolved in any order? What order gives the best resolution?

***51.** (II) A diffraction grating has 15,000 rulings in its 1.9 cm width. Determine (*a*) its resolving power in first and second orders, and (*b*) the minimum wavelength resolution ($\Delta\lambda$) it can yield for $\lambda = 410$ nm.

***52.** (II) Let 580-nm light be incident normally on a diffraction grating for which $d = 3.00D = 1050$ nm. (*a*) How many orders (principal maxima) are present? (*b*) If the grating is 1.80 cm wide, what is the full angular width of each principal maximum?

### 35–11 X-Ray Diffraction

**53.** (II) X-rays of wavelength 0.138 nm fall on a crystal whose atoms, lying in planes, are spaced 0.315 nm apart. At what angle $\phi$ (relative to the surface, Fig. 35–28) must the X-rays be directed if the first diffraction maximum is to be observed?

**54.** (II) First-order Bragg diffraction is observed at 23.6° relative to the crystal surface, with spacing between atoms of 0.24 nm. (*a*) At what angle will second order be observed? (*b*) What is the wavelength of the X-rays?

**55.** (II) If X-ray diffraction peaks corresponding to the first three orders ($m = 1, 2,$ and 3) are measured, can both the X-ray wavelength $\lambda$ and lattice spacing $d$ be determined? Prove your answer.

### *35–12 X-Ray Imaging and CT

***56.** (II) (*a*) Suppose for a conventional X-ray image that the X-ray beam consists of parallel rays. What would be the magnification of the image? (*b*) Suppose, instead, that the X-rays come from a point source (as in Fig. 35–31) that is 15 cm in front of a human body which is 25 cm thick, and the film is pressed against the person's back. Determine and discuss the range of magnifications that result.

## General Problems

**57.** The wings of a certain beetle have a series of parallel lines across them. When normally incident 520-nm light is reflected from the wing, the wing appears bright when viewed at an angle of 56°. How far apart are the lines?

**58.** A teacher stands well back from an outside doorway 0.88 m wide, and blows a whistle of frequency 820 Hz. Ignoring reflections, estimate at what angle(s) it is *not* possible to hear the whistle clearly on the playground outside the doorway. Assume 340 m/s for the speed of sound.

**59.** Light is incident on a diffraction grating with 8200 slits/cm and the pattern is viewed on a screen located 2.5 m from the grating. The incident light beam consists of two wavelengths, $\lambda_1 = 4.4 \times 10^{-7}$ m and $\lambda_2 = 6.8 \times 10^{-7}$ m. Calculate the linear distance between the first-order bright fringes of these two wavelengths on the screen.

**60.** When yellow sodium light, $\lambda = 589$ nm, falls on a diffraction grating, its first-order peak on a screen 62.0 cm away falls 3.32 cm from the central peak. Another source produces a line 3.71 cm from the central peak. What is its wavelength? How many slits/cm are on the grating?

**61.** Two of the lines of the atomic hydrogen spectrum have wavelengths of 656 nm and 410 nm. If these fall at normal incidence on a grating with 8500 slits/cm, what will be the angular separation of the two wavelengths in the first-order spectrum?

**62.** (*a*) How far away can a human eye distinguish two car headlights 2.0 m apart? Consider only diffraction effects and assume an eye pupil diameter of 6.0 mm and a wavelength of 560 nm. (*b*) What is the minimum angular separation an eye could resolve when viewing two stars, considering only diffraction effects? In reality, it is about 1′ of arc. Why is it not equal to your answer in (*b*)?

**63.** A laser beam passes through a slit of width 1.0 cm and is pointed at the Moon, which is approximately 380,000 km from the Earth. Assume the laser emits waves of wavelength 633 nm (the red light of a He–Ne laser). Estimate the width of the beam when it reaches the Moon due to diffraction.

**64.** A He–Ne gas laser which produces monochromatic light of wavelength $\lambda = 6.328 \times 10^{-7}$ m is used to calibrate a reflection grating in a spectroscope. The first-order diffraction line is found at an angle of 18.5° to the incident beam. How many lines per meter are imprinted on this reflecting diffraction grating?

**65.** A 1.0-cm-diameter lens with a focal length of 35 cm uses blue light (450 nm) to image two objects 18 m away that are very close together. What is the closest those objects can be to each other and still be imaged as separate objects?

**66.** Red light from three separate sources passes through a diffraction grating with $3.30 \times 10^5$ slits/m. The wavelengths of the three lines are $6.56 \times 10^{-7}$ m (hydrogen), $6.50 \times 10^{-7}$ m (neon), and $6.97 \times 10^{-7}$ m (argon). Calculate the angles for the first-order diffraction line of each source.

**67.** The Earth and Moon are separated by about $400 \times 10^6$ m. When Mars is $8 \times 10^{10}$ m from Earth, could a person standing on Mars resolve the Earth and its Moon as two separate objects without a telescope? Assume a pupil diameter of 5 mm and $\lambda = 550$ nm.

**68.** You want to design a spy satellite to photograph license plate numbers. Assuming it is necessary to resolve points separated by 2 cm with 550-nm light, and that the satellite orbits at a height of 130 km, what minimum lens aperture (diameter) is required?

**69.** What is the highest spectral order that can be seen if a grating with 6800 slits per cm is illuminated with 633-nm laser light? Assume normal incidence.

**70.** A parallel beam of light containing two wavelengths, 420 nm and 680 nm, enters a borate flint glass equilateral prism (Fig. 35–41). (*a*) What is the angle between the two beams leaving the prism? (See Section 32–6.) (*b*) Repeat part (*a*) for a diffraction grating with 5800 slits/cm. (*c*) Discuss two advantages of a diffraction grating, including one that you see from your results.

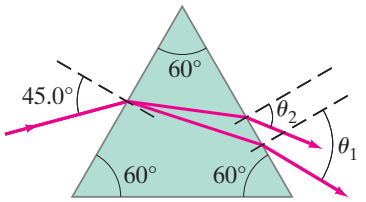

**FIGURE 35–41**
Problem 70.

**71.** Mizar, the second star from the end of the Big Dipper's handle, appears to have a companion star, Alcor. From Earth, Mizar and Alcor have an angular separation of 12 arc minutes ($1 \text{ arc min} = \frac{1}{60}$ of $1°$). Using Example 35–6, estimate the angular resolution of the human eye (in arc min). From your estimate, explain if these two stars can be resolved by the naked eye.

**72.** The entrance to a boy's bedroom consists of two doorways, each 1.0 m wide, which are separated by a distance of 3.0 m. The boy's mother yells at him through the two doors as shown in Fig. 35–42, telling him to clean up his room. Her voice has a frequency of 400 Hz. Later, when the mother discovers the room is still a mess, the boy says he never heard her telling him to clean his room. The velocity of sound is 340 m/s. (*a*) Find all of the angles $\theta$ (Fig. 35–42) at which no sound will be heard within the bedroom when the mother yells. Assume sound is fully absorbed when it strikes a bedroom wall. (*b*) If the boy was at the position shown when his mother yelled, does he have a good explanation for not having heard her? Explain.

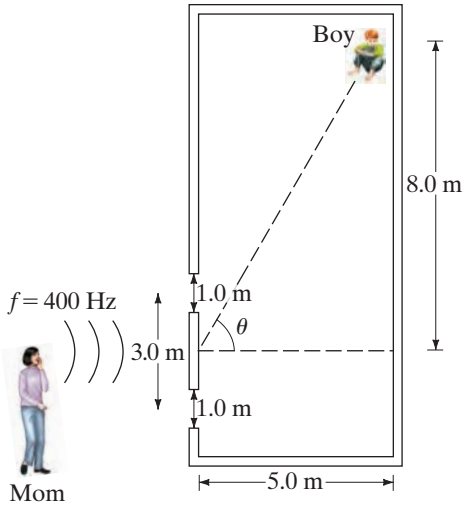

**FIGURE 35–42**
Problem 72.

**73.** How many slits per centimeter must a grating have if there is to be no second-order spectrum for any visible wavelength?

**74.** Spy planes fly at extremely high altitudes (25 km) to avoid interception. If their cameras are to discern features as small as 5 cm, what is the minimum aperture of the camera lens to afford this resolution? (Use $\lambda = 580$ nm.)

**75.** X-rays of wavelength 0.0973 nm are directed at an unknown crystal. The second diffraction maximum is recorded when the X-rays are directed at an angle of 21.8° relative to the crystal surface. What is the spacing between crystal planes parallel to the surface?

**76.** X-rays of wavelength 0.10 nm fall on a microcrystalline powder sample. The sample is located 15 cm from a photographic sensor. The crystal structure of the sample has an atomic spacing of 0.22 nm. Calculate the radii of the diffraction rings corresponding to first- and second-order scattering. Note in Fig. 35–28 that the X-ray beam is deflected through an angle $2\phi$.

**77.** The Hubble Space Telescope, with an objective diameter of 2.4 m, is viewing the Moon. Estimate the minimum distance between two objects on the Moon that the Hubble can distinguish. Consider diffraction of light with wavelength 550 nm. Assume the Hubble is near the Earth.

**78.** A slit of width $D = 22\ \mu$m is cut through a thin aluminum plate. Light with wavelength $\lambda = 620$ nm passes through this slit and forms a single-slit diffraction pattern on a screen a distance $\ell = 2.0$ m away. Defining $x$ to be the distance between the two first minima on either side of the center in this diffraction pattern ($m = +1$ and $m = -1$), find the change $\Delta x$ in this distance when the temperature $T$ of the metal plate is changed by an amount $\Delta T = 55$ C°. [*Hint*: Since $\lambda \ll D$, the first minima occur at a small angle.]

**79.** A satellite dish is about 0.5 m in diameter. According to the user's manual, the dish has to be pointed in the direction of the satellite, but an error of about 2° to either side is allowed without loss of reception. Estimate the wavelength of the electromagnetic waves received by the dish.

## ANSWERS TO EXERCISES

**A:** Narrower.
**B:** (*b*).
**C:** 2 m.
**D:** (*c*).
**E:** (*c*) By the equation just above; (*c*) by the $\lambda$ rule.
**F:** A.
**G:** 0.28 nm.

(a) (b)

(a) That is me standing on the corner, with messy hair and nerdy eyeglasses. I am talking to my girlfriend sitting on her Vespa. She is glamorous; she could be a model. As we chat, I notice a UPS truck zooming by which looks quite a bit shorter than when it is parked. (b) My girlfriend takes off, turning right and going around the block, and then comes speeding past me on her scooter at 60 or 70 km/hr. She looks so skinny now. I hate it when she drives that fast. Oh, I need to mention that in my fantasy universe the speed limit of light is only 100 km/h.

One of the predictions of Einstein's special theory of relativity is that objects moving at high speed, near the speed of light, would look shorter than when they are at rest. This effect is called "length contraction". Special relativity predicts other strange and wonderful effects as well.

CHAPTER 36

# The Special Theory of Relativity

**CHAPTER-OPENING QUESTION—Guess now!**

A rocket is headed away from Earth at a speed of 0.80$c$. The rocket fires a small payload at a speed of 0.70$c$ (relative to the rocket) aimed away from Earth. How fast is the payload moving relative to Earth?

**(a)** 1.50$c$.
**(b)** a little less than 1.50$c$.
**(c)** a little over $c$.
**(d)** a little under $c$.
**(e)** 0.75$c$.

Physics at the end of the nineteenth century looked back on a period of great progress. The theories developed over the preceding three centuries had been very successful in explaining a wide range of natural phenomena. Newtonian mechanics beautifully explained the motion of objects on Earth and in the heavens. Furthermore, it formed the basis for successful treatments of fluids, wave motion, and sound. Kinetic theory explained the behavior of gases and other materials. Maxwell's theory of electromagnetism embodied all of electric and magnetic phenomena, and it predicted the existence of electromagnetic waves that would behave just like light—so light came to be thought of as an electromagnetic wave. Indeed, it seemed that the natural world, as seen through the eyes of physicists, was very well explained. A few puzzles remained, but it was felt that these would soon be explained using already known principles.

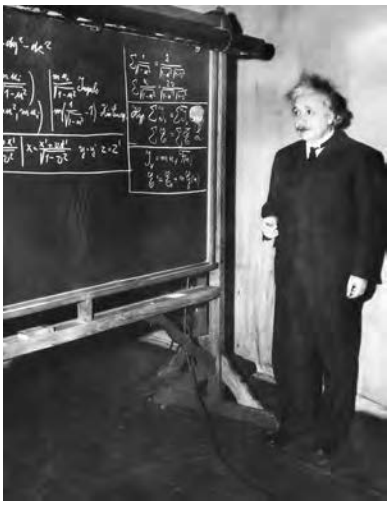

**FIGURE 36–1** Albert Einstein (1879–1955), one of the great minds of the twentieth century, was the creator of the special and general theories of relativity.

It did not turn out so simply. Instead, these puzzles were to be solved only by the introduction, in the early part of the twentieth century, of two revolutionary new theories that changed our whole conception of nature: the *theory of relativity* and *quantum theory*.

Physics as it was known at the end of the nineteenth century (what we've covered up to now in this book) is referred to as **classical physics**. The new physics that grew out of the great revolution at the turn of the twentieth century is now called **modern physics**. In this Chapter, we present the special theory of relativity, which was first proposed by Albert Einstein (1879–1955; Fig. 36–1) in 1905. In Chapter 37, we introduce the equally momentous quantum theory.

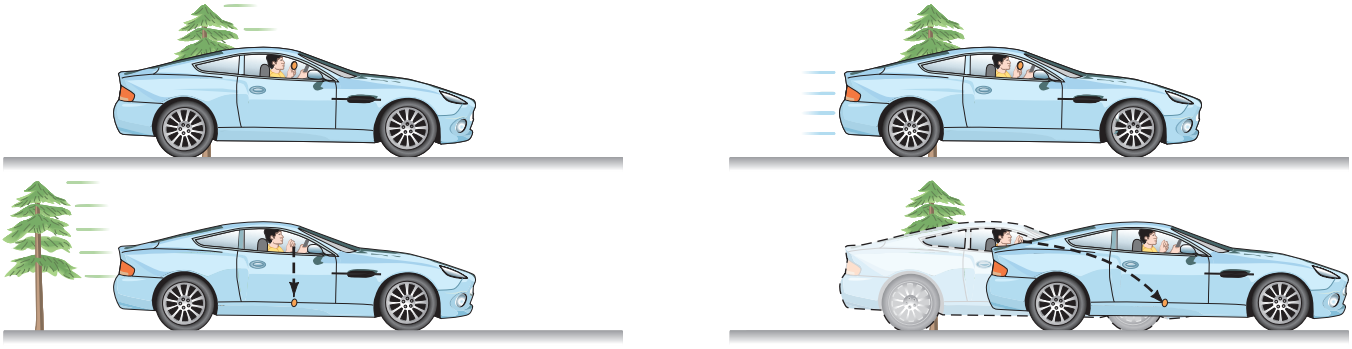
## 36–1 Galilean–Newtonian Relativity

Einstein's special theory of relativity deals with how we observe events, particularly how objects and events are observed from different frames of reference.[†] This subject had already been explored by Galileo and Newton.

The special theory of relativity deals with events that are observed and measured from so-called **inertial reference frames** (Sections 4–2 and 11–8), which are reference frames in which Newton's first law is valid: if an object experiences no net force, the object either remains at rest or continues in motion with constant speed in a straight line. It is usually easiest to analyze events when they are observed and measured by observers at rest in an inertial frame. The Earth, though not quite an inertial frame (it rotates), is close enough that for most purposes we can approximate it as an inertial frame. Rotating or otherwise accelerating frames of reference are noninertial frames,[‡] and won't concern us in this Chapter (they are dealt with in Einstein's general theory of relativity).

**PROBLEM SOLVING**
*A reference frame moving at constant velocity relative to an inertial frame is itself an inertial frame*

A reference frame that moves with constant velocity with respect to an inertial frame is itself also an inertial frame, since Newton's laws hold in it as well. When we say that we observe or make measurements from a certain reference frame, it means that we are at rest in that reference frame.



Both Galileo and Newton were aware of what we now call the **relativity principle** applied to mechanics: that *the basic laws of physics are the same in all inertial reference frames*. You may have recognized its validity in everyday life. For example, objects move in the same way in a smoothly moving (constant-velocity) train or airplane as they do on Earth. (This assumes no vibrations or rocking which would make the reference frame noninertial.) When you walk, drink a cup of soup, play pool, or drop a pencil on the floor while traveling in a train, airplane, or ship moving at *constant velocity*, the objects move just as they do when you are at rest on Earth. Suppose you are in a car traveling rapidly at constant velocity. If you drop a coin from above your head inside the car, how will it fall? It falls straight downward with respect to the car, and hits the floor directly below the point of release, Fig. 36–2a. This is just how objects fall on the Earth—straight down—and thus our experiment in the moving car is in accord with the relativity principle. (If you drop the coin out the car's window, this won't happen because the moving air drags the coin backward relative to the car.)

**CAUTION**
*Laws are the same, but paths may be different in different reference frames*

Note in this example, however, that to an observer on the Earth, the coin follows a curved path, Fig. 36–2b. The actual path followed by the coin is different as viewed from different frames of reference. This does not violate the relativity principle because this principle states that the *laws* of physics are the same in all inertial frames. The same law of gravity, and the same laws of motion, apply in both reference frames. The acceleration of the coin is the same in both reference frames.

[†]On a rotating platform (say a merry-go-round), for example, a ball at rest starts moving outward even though no object exerts a force on it. This is therefore not an inertial frame. See Section 11–8.

[‡]A reference frame is a set of coordinate axes fixed to some object such as the Earth, a train, or the Moon. See Section 2–1.

(a)
Reference frame = car

(b)
Reference frame = Earth

**FIGURE 36–2** A coin is dropped by a person inside a moving car. The upper views show the moment of the coin's release, the lower views are a short time later. (a) In the reference frame of the car, the coin falls straight down (and the tree moves to the left). (b) In a reference frame fixed on the Earth, the coin has an initial velocity (= to car's) and follows a curved (parabolic) path.

The difference in Figs. 36–2a and b is that in the Earth's frame of reference, the coin has an initial velocity (equal to that of the car). The laws of physics therefore predict it will follow a parabolic path like any projectile (Chapter 3). In the car's reference frame, there is no initial velocity, and the laws of physics predict that the coin will fall straight down. The laws are the same in both reference frames, although the specific paths are different.

Galilean–Newtonian relativity involves certain unprovable assumptions that make sense from everyday experience. It is assumed that the lengths of objects are the same in one reference frame as in another, and that time passes at the same rate in different reference frames. In classical mechanics, then, space and time intervals are considered to be **absolute**: their measurement does not change from one reference frame to another. The mass of an object, as well as all forces, are assumed to be unchanged by a change in inertial reference frame.

**CAUTION**
*Length and time intervals are absolute (pre-relativity)*

The position of an object, however, is different when specified in different reference frames, and so is velocity. For example, a person may walk inside a bus toward the front with a speed of 2 m/s. But if the bus moves 10 m/s with respect to the Earth, the person is then moving with a speed of 12 m/s with respect to the Earth. The acceleration of an object, however, is the same in any inertial reference frame according to classical mechanics. This is because the change in velocity, and the time interval, will be the same. For example, the person in the bus may accelerate from 0 to 2 m/s in 1.0 seconds, so $a = 2\,\text{m/s}^2$ in the reference frame of the bus. With respect to the Earth, the velocity changes from 10 m/s to 12 m/s so the acceleration is $(12\,\text{m/s} - 10\,\text{m/s})/(1.0\,\text{s}) = 2\,\text{m/s}^2$, which is the same.

**CAUTION**
*Position and velocity are different in different reference frames, but length is the same (classical)*

Since neither $F$, $m$, nor $a$ changes from one inertial frame to another, then Newton's second law, $F = ma$, does not change. Thus Newton's second law satisfies the relativity principle. The other laws of mechanics also satisfy the relativity principle.

That the laws of mechanics are the same in all inertial reference frames implies that no one inertial frame is special in any sense. We express this important conclusion by saying that **all inertial reference frames are equivalent** for the description of mechanical phenomena. No one inertial reference frame is any better than another. A reference frame fixed to a car or an aircraft traveling at constant velocity is as good as one fixed on the Earth. When you travel smoothly at constant velocity in a car or airplane, it is just as valid to say you are at rest and the Earth is moving, as it is to say the reverse.[†] There is no experiment you can do to tell which frame is "really" at rest and which is moving. Thus, there is no way to single out one particular reference frame as being at absolute rest.

**CAUTION**
*There is no reference frame truly at rest*

A complication arose, however, in the last half of the nineteenth century. Maxwell's comprehensive and successful theory of electromagnetism (Chapter 31) predicted that light is an electromagnetic wave. Maxwell's equations gave the velocity of light $c$ as $3.00 \times 10^8\,\text{m/s}$; and this is just what is measured. The question then arose: in what reference frame does light have precisely the value predicted by Maxwell's theory? It was assumed that light would have a different speed in different frames of reference.

[†]We are ignoring the rotation and curvature of the Earth, and using the reasonable approximation that Earth is an inertial reference frame.

For example, if observers could travel on a rocket ship at a speed of $1.0 \times 10^8$ m/s away from a source of light, we might expect them to measure the speed of the light reaching them to be $(3.0 \times 10^8 \text{ m/s}) - (1.0 \times 10^8 \text{ m/s}) = 2.0 \times 10^8$ m/s. But Maxwell's equations have no provision for relative velocity. They predicted the speed of light to be $c = 3.0 \times 10^8$ m/s, which seemed to imply that there must be some preferred reference frame where $c$ would have this value.

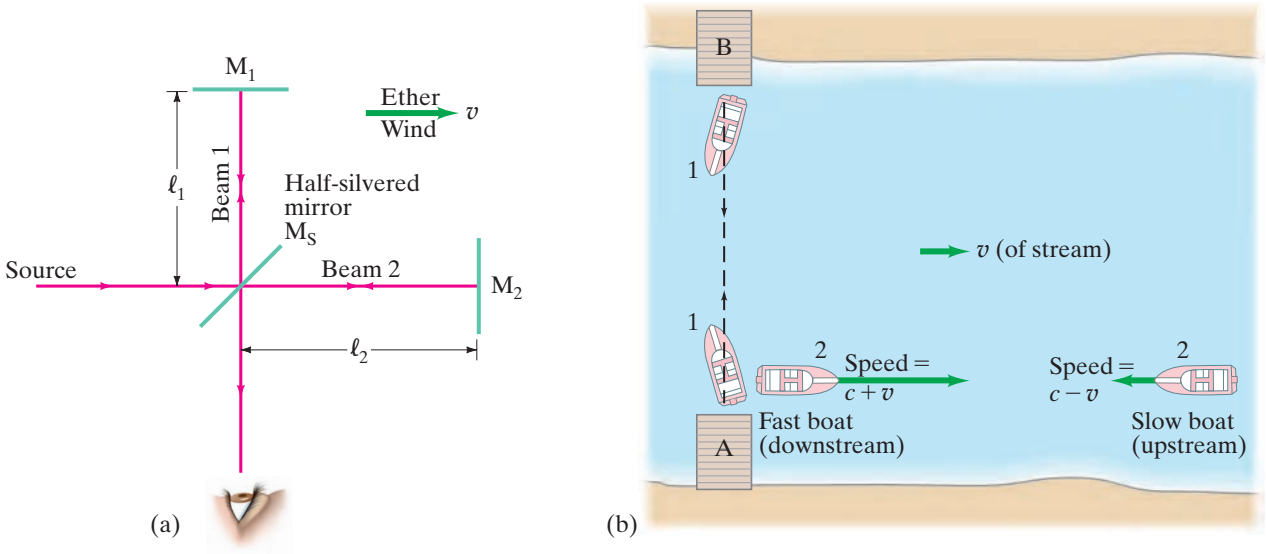
We discussed in Chapters 15 and 16 that waves can travel on water and along ropes or strings, and sound waves travel in air and other materials. Nineteenth-century physicists viewed the material world in terms of the laws of mechanics, so it was natural for them to assume that light too must travel in some *medium*. They called this transparent medium the **ether** and assumed it permeated all space.[†] It was therefore assumed that the velocity of light given by Maxwell's equations must be with respect to the ether.

At first it appeared that Maxwell's equations did *not* satisfy the relativity principle. They were simplest in the frame where $c = 3.00 \times 10^8$ m/s in a reference frame at rest in the ether. In any other reference frame, extra terms were needed to account for the relative velocity. Thus, although other laws of physics obeyed the relativity principle, the laws of electricity and magnetism apparently did not. Einstein's second postulate (Section 36–3) resolved this problem: Maxwell's equations do satisfy relativity.

Scientists soon set out to determine the speed of the Earth relative to this absolute frame, whatever it might be. A number of clever experiments were designed. The most direct were performed by A. A. Michelson and E. W. Morley in the 1880s. They measured the difference in the speed of light in different directions using Michelson's interferometer (Section 34–6). They expected to find a difference depending on the orientation of their apparatus with respect to the ether. For just as a boat has different speeds relative to the land when it moves upstream, downstream, or across the stream, so too light would be expected to have different speeds depending on the velocity of the ether past the Earth.

Strange as it may seem, they detected no difference at all. This was a great puzzle. A number of explanations were put forth over a period of years, but they led to contradictions or were otherwise not generally accepted. This **null result** was one of the great puzzles at the end of the nineteenth century.

Then in 1905, Albert Einstein proposed a radical new theory that reconciled these many problems in a simple way. But at the same time, as we shall see, it completely changed our ideas of space and time.



## 36–2 The Michelson–Morley Experiment

The Michelson–Morley experiment was designed to measure the speed of the *ether*—the medium in which light was assumed to travel—with respect to the Earth. The experimenters thus hoped to find an absolute reference frame, one that could be considered to be at rest.

One of the possibilities nineteenth-century scientists considered was that the ether is fixed relative to the Sun, for even Newton had taken the Sun as the center of the universe. If this were the case (there was no guarantee, of course), the Earth's speed of about $3 \times 10^4$ m/s in its orbit around the Sun could produce a change of 1 part in $10^4$ in the speed of light $(3.0 \times 10^8 \text{ m/s})$. Direct measurement of the speed of light to this precision was not possible. But A. A. Michelson, later with the help of E. W. Morley, was able to use his interferometer (Section 34–6) to measure the difference in the speed of light in different directions to this precision.

[†]The medium for light waves could not be air, since light travels from the Sun to Earth through nearly empty space. Therefore, another medium was postulated, the ether. The ether was not only transparent but, because of difficulty in detecting it, was assumed to have zero density.

This famous experiment is based on the principle shown in Fig. 36–3. Part (a) is a diagram of the Michelson interferometer, and it is assumed that the "ether wind" is moving with speed $v$ to the right. (Alternatively, the Earth is assumed to move to the left with respect to the ether at speed $v$.) The light from a source is split into two beams by a half-silvered mirror $M_S$. One beam travels to mirror $M_1$ and the other to mirror $M_2$. The beams are reflected by $M_1$ and $M_2$ and are joined again after passing through $M_S$. The now superposed beams interfere with each other and the resultant is viewed by the observer's eye as an interference pattern (discussed in Section 34–6).

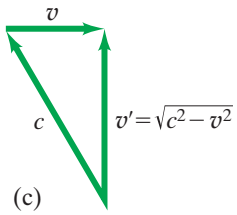


**FIGURE 36–3** The Michelson–Morley experiment. (a) Michelson interferometer. (b) Boat analogy: boat 1 goes across the stream and back; boat 2 goes downstream and back upstream (boat has speed $c$ relative to the water). (c) Calculation of the velocity of boat (or light beam) traveling perpendicular to the current (or ether wind).

Whether constructive or destructive interference occurs at the center of the interference pattern depends on the relative phases of the two beams after they have traveled their separate paths. Let us consider an analogy of a boat traveling up and down, and across, a river, whose current moves with speed $v$, as shown in Fig. 36–3b. In still water, the boat can travel with speed $c$ (not the speed of light in this case).

First we consider beam 2 in Fig. 36–3a, which travels parallel to the "ether wind." In its journey from $M_S$ to $M_2$, the light would travel with speed $c + v$, according to classical physics, just as for a boat traveling downstream (see Fig. 36–3b) we add the speed of the river water to the boat's own speed (relative to the water) to get the boat's speed relative to the shore. Since the beam travels a distance $\ell_2$, the time it takes to go from $M_S$ to $M_2$ would be $t = \ell_2/(c + v)$. To make the return trip from $M_2$ to $M_S$, the light moves against the ether wind (like the boat going upstream), so its relative speed is expected to be $c - v$. The time for the return trip would be $\ell_2/(c - v)$. The total time for beam 2 to travel from $M_S$ to $M_2$ and back to $M_S$ is

$$t_2 = \frac{\ell_2}{c + v} + \frac{\ell_2}{c - v} = \frac{\ell_2(c - v) + \ell_2(c + v)}{(c + v)(c - v)} = \frac{2\ell_2}{c(1 - v^2/c^2)}.$$

Now let us consider beam 1, which travels crosswise to the ether wind. Here the boat analogy (Fig. 36–3b) is especially helpful. The boat is to go from wharf A to wharf B directly across the stream. If it heads directly across, the stream's current will drag it downstream. To reach wharf B, the boat must head at an angle upstream. The precise angle depends on the magnitudes of $c$ and $v$, but is of no interest to us in itself. Part (c) of Fig. 36–3 shows how to calculate the velocity $v'$ of the boat relative to Earth as it crosses the stream. Since $c$, $v$, and $v'$ form a right triangle, we have that $v' = \sqrt{c^2 - v^2}$. The boat has the same speed when it returns.

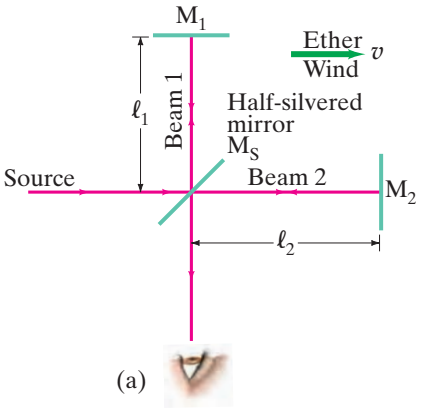

**FIGURE 36–3a** (Repeated.)

If we now apply these principles to light beam 1 in Fig. 36–3a, we expect the beam to travel with speed $\sqrt{c^2 - v^2}$ in going from $M_S$ to $M_1$ and back again. The total distance traveled is $2\ell_1$, so the time required for beam 1 to make the round trip would be $2\ell_1/\sqrt{c^2 - v^2}$, or

$$t_1 = \frac{2\ell_1}{c\sqrt{1 - v^2/c^2}}.$$

Notice that the denominator in this equation for $t_1$ involves a square root, whereas that for $t_2$ does not.

If $\ell_1 = \ell_2 = \ell$, we see that beam 2 will lag behind beam 1 by an amount

$$\Delta t = t_2 - t_1 = \frac{2\ell}{c}\left(\frac{1}{1 - v^2/c^2} - \frac{1}{\sqrt{1 - v^2/c^2}}\right).$$

If $v = 0$, then $\Delta t = 0$, and the two beams will return in phase since they were initially in phase. But if $v \neq 0$, then $\Delta t \neq 0$, and the two beams will return out of phase. If this change of phase, from the condition $v = 0$ to that for $v \neq 0$, could be measured, then $v$ could be determined. But the Earth cannot be stopped. Furthermore, we should not be too quick to assume that lengths are not affected by motion and therefore we should not assume $\ell_1 = \ell_2$.

Michelson and Morley realized that they could detect the difference in phase (assuming that $v \neq 0$) if they rotated their apparatus by 90°, for then the interference pattern between the two beams should change. In the rotated position, beam 1 would now move parallel to the ether and beam 2 perpendicular to it. Thus the roles could be reversed, and in the rotated position the times (designated by primes, $'$) would be

$$t_1' = \frac{2\ell_1}{c(1 - v^2/c^2)} \quad \text{and} \quad t_2' = \frac{2\ell_2}{c\sqrt{1 - v^2/c^2}}.$$

The time lag between the two beams in the nonrotated position (unprimed) would be

$$\Delta t = t_2 - t_1 = \frac{2\ell_2}{c(1 - v^2/c^2)} - \frac{2\ell_1}{c\sqrt{1 - v^2/c^2}}.$$

In the rotated position, the time difference would be

$$\Delta t' = t_2' - t_1' = \frac{2\ell_2}{c\sqrt{1 - v^2/c^2}} - \frac{2\ell_1}{c(1 - v^2/c^2)}.$$

When the rotation is made, the fringes of the interference pattern that reach the eye (Section 34–6) will shift an amount determined by the difference:

$$\Delta t - \Delta t' = \frac{2}{c}(\ell_1 + \ell_2)\left(\frac{1}{1 - v^2/c^2} - \frac{1}{\sqrt{1 - v^2/c^2}}\right).$$

This expression can be considerably simplified if we assume that $v/c \ll 1$. In this case we can use the binomial expansion (Appendix A), so

$$\frac{1}{1 - v^2/c^2} \approx 1 + \frac{v^2}{c^2} \quad \text{and} \quad \frac{1}{\sqrt{1 - v^2/c^2}} \approx 1 + \frac{1}{2}\frac{v^2}{c^2}.$$

Then

$$\Delta t - \Delta t' \approx \frac{2}{c}(\ell_1 + \ell_2)\left(1 + \frac{v^2}{c^2} - 1 - \frac{1}{2}\frac{v^2}{c^2}\right)$$

$$\approx (\ell_1 + \ell_2)\frac{v^2}{c^3}.$$

We assume $v = 3.0 \times 10^4$ m/s, the speed of the Earth in its orbit around the Sun, in this equation. In Michelson and Morley's experiments, the arms $\ell_1$ and $\ell_2$ were about 11 m long so $\ell_1 + \ell_2 = 22$ m. The time difference would then be about

$$(22\text{ m})(3.0 \times 10^4\text{ m/s})^2/(3.0 \times 10^8\text{ m/s})^3 \approx 7.3 \times 10^{-16}\text{ s}.$$

For visible light of wavelength $\lambda = 5.5 \times 10^{-7}$ m, say, the frequency would be $f = c/\lambda = (3.0 \times 10^8\text{ m/s})/(5.5 \times 10^{-7}\text{ m}) = 5.5 \times 10^{14}$ Hz, which means that wave

crests pass by a point every $1/(5.5\times10^{14}\,\text{Hz}) = 1.8\times10^{-15}\,\text{s}$. Thus, with a time difference of $7.3\times10^{-16}\,\text{s}$, Michelson and Morley should have noted a movement in the interference pattern of $(7.3\times10^{-16}\,\text{s})/(1.8\times10^{-15}\,\text{s}) = 0.4$ fringe. They could easily have detected this, since their apparatus was capable of observing a fringe shift as small as 0.01 fringe.

But they found *no significant fringe shift whatever*! They set their apparatus at various orientations. They made observations day and night so that they would be at various orientations with respect to the Sun (due to the Earth's rotation). They tried at different seasons of the year (the Earth at different locations due to its orbit around the Sun). Never did they observe a significant fringe shift.

This **null result** was one of the great puzzles of physics at the end of the nineteenth century. To explain it was a difficult challenge. One possibility to explain the null result was put forth independently by G. F. Fitzgerald and H. A. Lorentz (in the 1890s) in which they proposed that any length (including the arm of an interferometer) contracts by a factor $\sqrt{1 - v^2/c^2}$ in the direction of motion through the ether. According to Lorentz, this could be due to the ether affecting the forces between the molecules of a substance, which were assumed to be electrical in nature. This theory was eventually replaced by the far more comprehensive theory proposed by Albert Einstein in 1905—the special theory of relativity.

## 36–3 Postulates of the Special Theory of Relativity

The problems that existed at the start of the twentieth century with regard to electromagnetic theory and Newtonian mechanics were beautifully resolved by Einstein's introduction of the special theory of relativity in 1905. Unaware of the Michelson–Morley null result, Einstein was motivated by certain questions regarding electromagnetic theory and light waves. For example, he asked himself: "What would I see if I rode a light beam?" The answer was that instead of a traveling electromagnetic wave, he would see alternating electric and magnetic fields at rest whose magnitude changed in space, but did not change in time. Such fields, he realized, had never been detected and indeed were not consistent with Maxwell's electromagnetic theory. He argued, therefore, that it was unreasonable to think that the speed of light relative to any observer could be reduced to zero, or in fact reduced at all. This idea became the second postulate of his theory of relativity.

In his famous 1905 paper, Einstein proposed doing away with the idea of the ether and the accompanying assumption of a preferred or absolute reference frame at rest. This proposal was embodied in two postulates. The first was an extension of the Galilean–Newtonian relativity principle to include not only the laws of mechanics but also those of the rest of physics, including electricity and magnetism:

***First postulate (the relativity principle)*: The laws of physics have the same form in all inertial reference frames.**

RELATIVITY PRINCIPLE

The first postulate can also be stated as: *There is no experiment you can do in an inertial reference frame to determine if you are at rest or moving uniformly at constant velocity*. The second postulate is consistent with the first:

***Second postulate (constancy of the speed of light)*: Light propagates through empty space with a definite speed *c* independent of the speed of the source or observer.**

SPEED OF LIGHT PRINCIPLE

These two postulates form the foundation of Einstein's **special theory of relativity**. It is called "special" to distinguish it from his later "general theory of relativity," which deals with noninertial (accelerating) reference frames (Chapter 44). The special theory, which is what we discuss here, deals only with inertial frames.

The second postulate may seem hard to accept, for it seems to violate common sense. First of all, we have to think of light traveling through empty space. Giving up the ether is not too hard, however, since it had never been detected. But the second postulate also tells us that the speed of light in vacuum is always the same, $3.00\times10^8\,\text{m/s}$, no matter what the speed of the observer or the source. Thus, a person traveling toward or away from a source of light will measure the same speed for that light as someone at rest with respect to the source.

This conflicts with our everyday experience: we would expect to have to add in the velocity of the observer. On the other hand, perhaps we can't expect our everyday experience to be helpful when dealing with the high velocity of light. Furthermore, the null result of the Michelson–Morley experiment is fully consistent with the second postulate.

Einstein's proposal has a certain beauty. By doing away with the idea of an absolute reference frame, it was possible to reconcile classical mechanics with Maxwell's electromagnetic theory. The speed of light predicted by Maxwell's equations *is* the speed of light in vacuum in *any* reference frame.

Einstein's theory required us to give up common sense notions of space and time, and in the following Sections we will examine some strange but interesting consequences of special relativity. Our arguments for the most part will be simple ones. We will use a technique that Einstein himself did: we will imagine very simple experimental situations in which little mathematics is needed. In this way, we can see many of the consequences of relativity theory without getting involved in detailed calculations. Einstein called these **thought experiments**.

## 36–4 Simultaneity

An important consequence of the theory of relativity is that we can no longer regard time as an absolute quantity. No one doubts that time flows onward and never turns back. But according to relativity the time interval between two events, and even whether or not two events are simultaneous, depends on the observer's reference frame. By an **event**, which we use a lot here, we mean something that happens at a particular place and at a particular time.

**CAUTION**
*Event = at one place, at one time*

Two events are said to occur simultaneously if they occur at exactly the same time. But how do we know if two events occur precisely at the same time? If they occur at the same point in space—such as two apples falling on your head at the same time—it is easy. But if the two events occur at widely separated places, it is more difficult to know whether the events are simultaneous since we have to take into account the time it takes for the light from each event to reach us. Because light travels at finite speed, a person who sees two events must calculate back to find out when they actually occurred. For example, if two events are *observed* to occur at the same time, but one actually took place farther from the observer than the other, then the more distant one must have occurred earlier, and the two events were not simultaneous.

We now imagine a simple thought experiment. Assume an observer, called O, is located exactly halfway between points A and B where two events occur, Fig. 36–4. Suppose the two events are lightning that strikes the points A and B, as shown. For brief events like lightning, only short pulses of light (blue in Fig. 36–4) will travel outward from A and B and reach O. Observer O "sees" the events when the pulses of light reach point O. If the two pulses reach O at the same time, then the two events had to be simultaneous. This is because (i) the two light pulses travel at the same speed (postulate 2), and (ii) the distance OA equals OB, so the time for the light to travel from A to O and from B to O must be the same. Observer O can then definitely state that the two events occurred simultaneously. On the other hand, if O sees the light from one event earlier than from the other, then the former event occurred first.

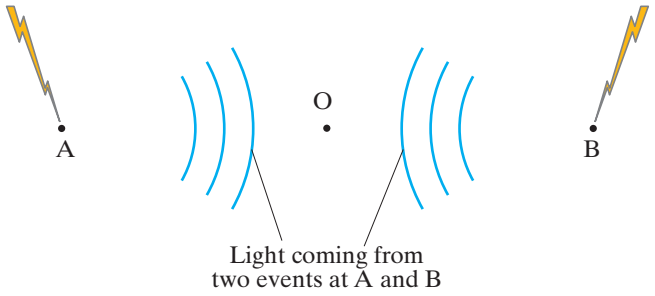

**FIGURE 36–4** A moment after lightning strikes at points A and B, the pulses of light (shown as blue waves) are traveling toward the observer O, but O "sees" the lightning only when the light reaches O. Note: OA = OB.

The question we really want to examine is this: if two events are simultaneous to an observer in one reference frame, are they also simultaneous to another observer moving with respect to the first? Let us call the observers $O_1$ and $O_2$ and assume they are fixed in reference frames 1 and 2 that move with speed $v$ relative to one another. These two reference frames can be thought of as two rockets or two trains, Fig. 36–5. In Fig. 36–5a, $O_2$ says that $O_1$ is moving to the right with speed $v$. But $O_1$ sees that $O_2$ is moving to the left with speed $v$, as in Fig. 36–5b. Both viewpoints are legitimate according to the relativity principle. **There is no third point of view that will tell us which one is "really" moving**.

Now suppose that observers $O_1$ and $O_2$ observe and measure two lightning strikes. The lightning bolts mark both trains where they strike: at $A_1$ and $B_1$ on $O_1$'s train, and at $A_2$ and $B_2$ on $O_2$'s train, Fig. 36–6a. For simplicity, we assume that $O_1$ is exactly halfway between $A_1$ and $B_1$, and $O_2$ is halfway between $A_2$ and $B_2$. Let us first put ourselves in $O_2$'s reference frame, so we observe $O_1$ moving to the right with speed $v$. Let us also assume that the two events occur *simultaneously* in $O_2$'s frame, and just at the instant when $O_1$ and $O_2$ are opposite each other, Fig. 36–6a. A short time later, Fig. 36–6b, the light from $A_2$ and from $B_2$ reaches $O_2$ at the same time (we assumed this). Since $O_2$ knows (or measures) the distances $O_2A_2$ and $O_2B_2$ as equal, $O_2$ knows the two events are simultaneous in the $O_2$ reference frame.

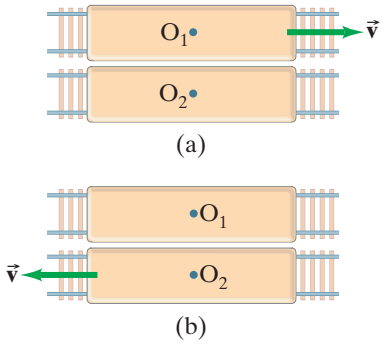

**FIGURE 36–5** Observers $O_1$ and $O_2$, on two different trains (two different reference frames), are moving with relative speed $v$. (a) $O_2$ says that $O_1$ is moving to the right. (b) $O_1$ says $O_2$ is moving to the left. Both viewpoints are legitimate: it all depends on your reference frame.

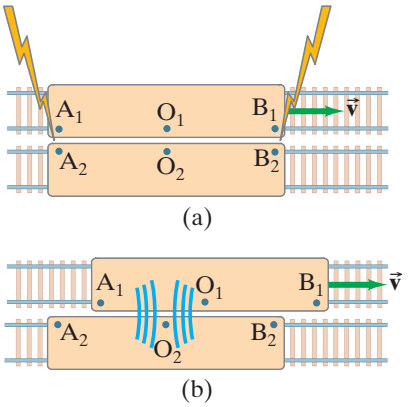

**FIGURE 36–6** Thought experiment on simultaneity. In both (a) and (b) we are in the reference frame of observer $O_2$, who sees the reference frame of $O_1$ moving to the right. In (a), one lightning bolt strikes the two reference frames at $A_1$ and $A_2$, and a second lightning bolt strikes at $B_1$ and $B_2$. (b) A moment later, the light (shown in blue) from the two events reaches $O_2$ at the same time. So according to observer $O_2$, the two bolts of lightning struck simultaneously. But in $O_1$'s reference frame, the light from $B_1$ has already reached $O_1$, whereas the light from $A_1$ has not yet reached $O_1$. So in $O_1$'s reference frame, the event at $B_1$ must have preceded the event at $A_1$. Simultaneity in time is not absolute.

But what does observer $O_1$ observe and measure? From our $(O_2)$ reference frame, we can predict what $O_1$ will observe. We see that $O_1$ moves to the right during the time the light is traveling to $O_1$ from $A_1$ and $B_1$. As shown in Fig. 36–6b, we can see from our $O_2$ reference frame that the light from $B_1$ has already passed $O_1$, whereas the light from $A_1$ has not yet reached $O_1$. That is, $O_1$ observes the light coming from $B_1$ before observing the light coming from $A_1$. Given (i) that light travels at the same speed $c$ in any direction and in any reference frame, and (ii) that the distance $O_1A_1$ equals $O_1B_1$, then observer $O_1$ can only conclude that the event at $B_1$ occurred before the event at $A_1$. The two events are *not* simultaneous for $O_1$, even though they are simultaneous for $O_2$.

We thus find that two events which take place at different locations and are simultaneous to one observer, are actually not simultaneous to a second observer who moves relative to the first.

It may be tempting to ask: "Which observer is right, $O_1$ or $O_2$?" The answer, according to relativity, is that they are *both* right. There is no "best" reference frame we can choose to determine which observer is right. Both frames are equally good. We can only conclude that *simultaneity is not an absolute concept*, but is relative. We are not aware of this lack of agreement on simultaneity in everyday life because the effect would be noticeable only when the relative speed of the two reference frames is very large (near $c$), or the distances involved are very large.

**EXERCISE A** Examine the experiment of Fig. 36–6 from $O_1$'s reference frame. In this case, $O_1$ will be at rest and will see event $B_1$ occur before $A_1$. Will $O_1$ recognize that $O_2$, who is moving with speed $v$ to the left, will see the two events as simultaneous? [*Hint*: Draw a diagram equivalent to Fig. 36–6.]

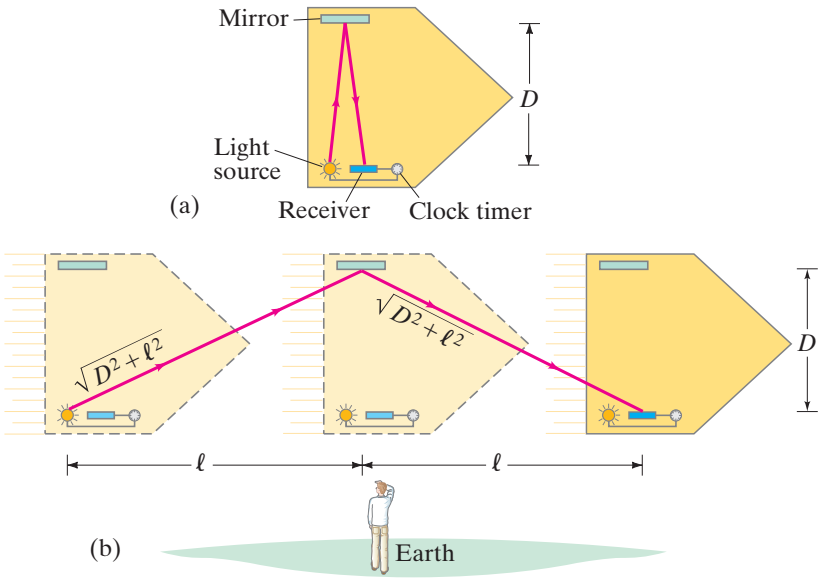

**FIGURE 36–7** Time dilation can be shown by a thought experiment: the time it takes for light to travel across a spaceship and back is longer for the observer on Earth (b) than for the observer on the spaceship (a).

## 36–5 Time Dilation and the Twin Paradox

The fact that two events simultaneous to one observer may not be simultaneous to a second observer suggests that time itself is not absolute. Could it be that time passes differently in one reference frame than in another? This is, indeed, just what Einstein's theory of relativity predicts, as the following thought experiment shows.

Figure 36–7 shows a spaceship traveling past Earth at high speed. The point of view of an observer on the spaceship is shown in part (a), and that of an observer on Earth in part (b). Both observers have accurate clocks. The person on the spaceship (Fig. 36–7a) flashes a light and measures the time it takes the light to travel directly across the spaceship and return after reflecting from a mirror that is a distance $D$ away (the rays are drawn at a slight angle for clarity). In the reference frame of the spaceship, the light travels a distance $2D$ at speed $c$. So the time required to go across and back, $\Delta t_0$, is

$$\Delta t_0 = \frac{2D}{c}.$$

The observer on Earth, Fig. 36–7b, observes the same process. But to this observer, the spaceship is moving. So the light travels the diagonal path shown going across the spaceship, reflecting off the mirror, and returning to the sender. Although the light travels at the same speed to this observer (the second postulate), it travels a greater distance. Hence the time required, as measured by the observer on Earth, will be *greater* than that measured by the observer on the spaceship.

Let us determine the time interval $\Delta t$ measured by the observer on Earth between sending and receiving the light. In time $\Delta t$, the spaceship travels a distance $2\ell = v\,\Delta t$ where $v$ is the speed of the spaceship (Fig. 36–7b). The light travels a total distance on its diagonal path (Pythagorean theorem) of $2\sqrt{D^2 + \ell^2}$, where $\ell = v\,\Delta t/2$. Therefore

$$c\,\Delta t = 2\sqrt{D^2 + \ell^2} = 2\sqrt{D^2 + v^2(\Delta t)^2/4}.$$

We square both sides, to find

$$c^2(\Delta t)^2 = 4D^2 + v^2(\Delta t)^2,$$

and solve for $(\Delta t)^2$:

$$(\Delta t)^2 = \frac{4D^2}{c^2 - v^2}.$$

We take the square root to get

$$\Delta t = \frac{2D}{c\sqrt{1 - v^2/c^2}}.$$

We combine this equation for $\Delta t$ with the formula for $\Delta t_0$ above,

$$\Delta t_0 = \frac{2D}{c},$$

and obtain

$$\Delta t = \frac{\Delta t_0}{\sqrt{1 - v^2/c^2}}. \qquad \textbf{(36–1a)}$$

TIME DILATION

Since $\sqrt{1 - v^2/c^2}$ is always less than 1, we see that $\Delta t > \Delta t_0$. That is, the time interval between the two events (the sending of the light, and its reception on the spaceship) is *greater* for the observer on Earth than for the observer on the spaceship. This is a general result of the theory of relativity, and is known as **time dilation**. The time dilation effect can be stated as

**clocks moving relative to an observer are measured to run more slowly, as compared to clocks at rest.**

However, we should not think that the clocks are somehow at fault.

**Time is actually measured to pass more slowly in any moving reference frame as compared to your own.**

This remarkable result is an inevitable outcome of the two postulates of the special theory of relativity.

The factor $1/\sqrt{1 - v^2/c^2}$ occurs so often in relativity that we often give it the shorthand symbol $\gamma$ (the Greek letter "gamma"), and write Eq. 36–1a as

$$\Delta t = \gamma\, \Delta t_0 \qquad \textbf{(36–1b)}$$

where

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}}. \qquad \textbf{(36–2)}$$

Note that $\gamma$ is never less than one, and has no units. At speeds we normally experience, $\gamma = 1$ to many decimal places, and exceeds 1.00 significantly only at very high speeds, much above about $10^6$ m/s (for which $\gamma = 1.000006$).

The concept of time dilation may be hard to accept, for it contradicts our experience. We can see from Eqs. 36–1 that the time dilation effect is indeed negligible unless $v$ is reasonably close to $c$. If $v$ is much less than $c$, then the term $v^2/c^2$ is much smaller than the 1 in the denominator of Eq. 36–1a, and then $\Delta t \approx \Delta t_0$ (see Example 36–2). The speeds we experience in everyday life are much smaller than $c$, so it is little wonder we don't ordinarily notice time dilation. But experiments that have tested the time dilation effect have confirmed Einstein's predictions. In 1971, for example, extremely precise atomic clocks were flown around the Earth in jet planes. The speed of the planes $(10^3\ \text{km/h})$ was much less than $c$, so the clocks had to be accurate to nanoseconds $(10^{-9}\ \text{s})$ in order to detect any time dilation. They were this accurate, and they confirmed Eqs. 36–1 to within experimental error. Time dilation had been confirmed decades earlier, however, by observations on "elementary particles" which have very small masses (typically $10^{-30}$ to $10^{-27}$ kg) and so require little energy to be accelerated to speeds close to the speed of light, $c$. Many of these elementary particles are not stable and decay after a time into lighter particles. One example is the muon, whose mean lifetime is 2.2 $\mu$s when at rest. Careful experiments showed that when a muon is traveling at high speeds, its lifetime is measured to be longer than when it is at rest, just as predicted by the time dilation formula.

**EXAMPLE 36–1 Lifetime of a moving muon.** (*a*) What will be the mean lifetime of a muon as measured in the laboratory if it is traveling at $v = 0.60c = 1.80 \times 10^8\,\text{m/s}$ with respect to the laboratory? A muon's mean lifetime at rest is $2.20\,\mu\text{s} = 2.20 \times 10^{-6}\,\text{s}$. (*b*) How far does a muon travel in the laboratory, on average, before decaying?

**APPROACH** If an observer were to move along with the muon (the muon would be at rest to this observer), the muon would have a mean life of $2.20 \times 10^{-6}\,\text{s}$. To an observer in the lab, the muon lives longer because of time dilation. We find the mean lifetime using Eq. 36–1a and the average distance using $d = v\,\Delta t$.

**SOLUTION** (*a*) From Eq. 36–1a with $v = 0.60c$, we have

$$\Delta t = \frac{\Delta t_0}{\sqrt{1 - v^2/c^2}} = \frac{2.20 \times 10^{-6}\,\text{s}}{\sqrt{1 - 0.36c^2/c^2}} = \frac{2.20 \times 10^{-6}\,\text{s}}{\sqrt{0.64}} = 2.8 \times 10^{-6}\,\text{s}.$$

(*b*) Relativity predicts that a muon with speed $1.80 \times 10^8\,\text{m/s}$ would travel an average distance $d = v\,\Delta t = (1.80 \times 10^8\,\text{m/s})(2.8 \times 10^{-6}\,\text{s}) = 500\,\text{m}$ before decaying and disappearing into lighter particles. This is the average distance that is measured experimentally in the laboratory.

**NOTE** At a speed of $1.8 \times 10^8\,\text{m/s}$, classical physics would tell us that with a mean life of $2.2\,\mu\text{s}$, an average muon would on average travel $d = vt = (1.8 \times 10^8\,\text{m/s})(2.2 \times 10^{-6}\,\text{s}) = 400\,\text{m}$. This is shorter than the average distance measured.

**EXERCISE B** What is the muon's mean lifetime (Example 36–1) if it is traveling at $v = 0.90c$? (*a*) 0.42 $\mu$s; (*b*) 2.3 $\mu$s; (*c*) 5.0 $\mu$s; (*d*) 5.3 $\mu$s; (*e*) 12.0 $\mu$s.

**CAUTION**
*Proper time $\Delta t_0$ is for two events at the same point in space*

We need to clarify how to use Eq. 36–1, $\Delta t = \gamma\,\Delta t_0$, and the meaning of $\Delta t$ and $\Delta t_0$. The equation is true only when $\Delta t_0$ represents the time interval between the two events *in a reference frame where an observer at rest sees the two events occur at the same point in space*. (This is the case in Fig. 36–7a where the two events are the light flash being sent and being received at the same point in the spaceship.) This time interval, $\Delta t_0$, is called the **proper time**. Then $\Delta t$ in Eqs. 36–1 represents the time interval between the two events as measured in a reference frame *moving* with speed $v$ with respect to the first. In Example 36–1 above, $\Delta t_0$ (and not $\Delta t$) was set equal to $2.2 \times 10^{-6}\,\text{s}$ because it is only in the rest frame of the muon that the two events ("birth" and "decay") occur at the same point in space. The proper time $\Delta t_0$ is the shortest time between two events any observer can measure. In any other moving reference frame, the time $\Delta t$ is greater.

**CAUTION**
*Proper time is shortest: $\Delta t > \Delta t_0$*

**EXAMPLE 36–2 Time dilation at 100 km/h.** Let us check time dilation for everyday speeds. A car traveling 100 km/h covers a certain distance in 10.00 s according to the driver's watch. What does an observer at rest on Earth measure for the time interval?

**APPROACH** The car's speed relative to Earth, written in meters per second, is $100\,\text{km/h} = (1.00 \times 10^5\,\text{m})/(3600\,\text{s}) = 27.8\,\text{m/s}$. The driver is at rest in the reference frame of the car, so we set $\Delta t_0 = 10.00\,\text{s}$ in the time dilation formula.

**SOLUTION** We use Eq. 36–1a:

$$\Delta t = \frac{\Delta t_0}{\sqrt{1 - \dfrac{v^2}{c^2}}} = \frac{10.00\,\text{s}}{\sqrt{1 - \left(\dfrac{27.8\,\text{m/s}}{3.00 \times 10^8\,\text{m/s}}\right)^2}}$$

$$= \frac{10.00\,\text{s}}{\sqrt{1 - (8.59 \times 10^{-15})}}.$$

If you put these numbers into a calculator, you will obtain $\Delta t = 10.00\,\text{s}$, because the denominator differs from 1 by such a tiny amount. The time measured by an observer fixed on Earth would show no difference from that measured by the driver, even with the best instruments. A computer that could calculate to a large number of decimal places would reveal a slight difference between $\Delta t$ and $\Delta t_0$.

We can estimate the difference using the binomial expansion (Appendix A–2),

**PROBLEM SOLVING**
*Use of the binomial expansion*

$$(1 \pm x)^n \approx 1 \pm nx. \qquad [\text{for } x \ll 1]$$

In our time dilation formula, we have the factor $\gamma = \left(1 - v^2/c^2\right)^{-\frac{1}{2}}$. Thus

$$\Delta t = \gamma\,\Delta t_0 = \Delta t_0\left(1 - \frac{v^2}{c^2}\right)^{-\frac{1}{2}} \approx \Delta t_0\left(1 + \frac{1}{2}\frac{v^2}{c^2}\right)$$

$$\approx 10.00\,\text{s}\left[1 + \frac{1}{2}\left(\frac{27.8\,\text{m/s}}{3.00 \times 10^8\,\text{m/s}}\right)^2\right]$$

$$\approx 10.00\,\text{s} + 4 \times 10^{-14}\,\text{s}.$$

So the difference between $\Delta t$ and $\Delta t_0$ is predicted to be $4 \times 10^{-14}\,\text{s}$, an extremely small amount.

**EXERCISE C** A certain atomic clock keeps precise time on Earth. If the clock is taken on a spaceship traveling at a speed $v = 0.60c$, does this clock now run slow according to the people (*a*) on the spaceship, (*b*) on Earth?

**EXAMPLE 36–3** **Reading a magazine on a spaceship.** A passenger on a fictional high-speed spaceship traveling between Earth and Jupiter at a steady speed of $0.75c$ reads a magazine which takes 10.0 min according to her watch. (*a*) How long does this take as measured by Earth-based clocks? (*b*) How much farther is the spaceship from Earth at the end of reading the magazine than it was at the beginning?

**APPROACH** (*a*) The time interval in one reference frame is related to the time interval in the other by Eq. 36–1a or b. (*b*) At constant speed, distance is speed × time. Because there are two time intervals ($\Delta t$ and $\Delta t_0$) we will get two distances, one for each reference frame. [This surprising result is explored in the next Section (36–6).]

**SOLUTION** (*a*) The given 10.0-min time interval is the proper time $\Delta t_0$—starting and finishing the magazine happen at the same place on the spaceship. Earth clocks measure

$$\Delta t = \frac{\Delta t_0}{\sqrt{1 - (v^2/c^2)}} = \frac{10.00\,\text{min}}{\sqrt{1 - (0.75)^2}} = 15.1\,\text{min}.$$

(*b*) In the Earth frame, the spaceship travels a distance $D = v\,\Delta t = (0.75c)\,(15.1\,\text{min}) = (0.75)\,(3.00 \times 10^8\,\text{m/s})\,(15.1\,\text{min} \times 60\,\text{s/min}) = 2.04 \times 10^{11}\,\text{m}$. In the spaceship's frame, the Earth is moving away from the spaceship at $0.75c$, but the time is only 10.0 min, so the distance is measured to be $D_0 = v\,\Delta t_0 = (0.75)\,(3.00 \times 10^8\,\text{m/s})\,(600\,\text{s}) = 1.35 \times 10^{11}\,\text{m}$.

Values for $\gamma = 1/\sqrt{1 - v^2/c^2}$ at a few speeds $v$ are given in Table 36–1.

**TABLE 36–1 Values of $\gamma$**

| $v$ | $\gamma$ |
|---|---|
| 0 | 1.00000. . . |
| $0.01c$ | 1.00005 |
| $0.10c$ | 1.005 |
| $0.50c$ | 1.15 |
| $0.90c$ | 2.3 |
| $0.99c$ | 7.1 |

## Space Travel?

Time dilation has aroused interesting speculation about space travel. According to classical (Newtonian) physics, to reach a star 100 light-years away would not be possible for ordinary mortals (1 light-year is the distance light can travel in 1 year $= 3.0 \times 10^8\ \text{m/s} \times 3.16 \times 10^7\ \text{s} = 9.5 \times 10^{15}\ \text{m}$). Even if a spaceship could travel at close to the speed of light, it would take over 100 years to reach such a star. But time dilation tells us that the time involved could be less. In a spaceship traveling at $v = 0.999c$, the time for such a trip would be only about $\Delta t_0 = \Delta t\sqrt{1 - v^2/c^2} = (100\ \text{yr})\sqrt{1 - (0.999)^2} = 4.5\ \text{yr}$. Thus time dilation allows such a trip, but the enormous practical problems of achieving such speeds may not be possible to overcome, certainly not in the near future.

When we talk in this Chapter and in the Problems about spaceships moving at speeds close to $c$, it is for understanding and for fun, but not realistic, although for tiny elementary particles such high speeds *are* realistic.

In this example, 100 years would pass on Earth, whereas only 4.5 years would pass for the astronaut on the trip. Is it just the clocks that would slow down for the astronaut? No.

> *All processes, including aging and other life processes, run more slowly for the astronaut as measured by an Earth observer. But to the astronaut, time would pass in a normal way.*

The astronaut would experience 4.5 years of normal sleeping, eating, reading, and so on. And people on Earth would experience 100 years of ordinary activity.

## Twin Paradox

Not long after Einstein proposed the special theory of relativity, an apparent paradox was pointed out. According to this **twin paradox**, suppose one of a pair of 20-year-old twins takes off in a spaceship traveling at very high speed to a distant star and back again, while the other twin remains on Earth. According to the Earth twin, the astronaut twin will age less. Whereas 20 years might pass for the Earth twin, perhaps only 1 year (depending on the spacecraft's speed) would pass for the traveler. Thus, when the traveler returns, the earthbound twin could expect to be 40 years old whereas the traveling twin would be only 21.

This is the viewpoint of the twin on the Earth. But what about the traveling twin? If all inertial reference frames are equally good, won't the traveling twin make all the same claims the Earth twin does, only in reverse? From the reference frame of the spacecraft, the Earth is moving away at high speed, so can't the astronaut twin claim that time passes more slowly on Earth and the twin on Earth will age less? This is the opposite of what the Earth twin predicts. They cannot both be right, for after all the spacecraft returns to Earth and a direct comparison of ages and clocks can be made.

There is, however, no contradiction here. One of the viewpoints is indeed incorrect. The consequences of the special theory of relativity—in this case, time dilation—can be applied only by observers in an *inertial reference frame*. The Earth is such a frame (or nearly so), whereas the spacecraft is not. The spacecraft accelerates at the start and end of its trip and when it turns around at the far point of its journey. Part of the time, the astronaut twin may be in an inertial frame (and is justified in saying the Earth twin's clocks run slow). But during the accelerations, the twin on the spacecraft is not in an inertial frame. So she cannot use special relativity to predict their relative ages when she returns to Earth. The Earth twin stays in the same inertial frame, and we can thus trust her predictions based on special relativity. Thus, there is no paradox. The prediction of the Earth twin that the traveling twin ages less is the correct one.

## *Global Positioning System (GPS)

PHYSICS APPLIED
*Global positioning system (GPS)*

Airplanes, cars, boats, and hikers use **global positioning system (GPS)** receivers to tell them quite accurately where they are at a given moment (Fig. 36–8). There are more than 30 global positioning system satellites that send out precise time signals using atomic clocks. Your receiver compares the times received from at least four satellites, all of whose times are carefully synchronized to within 1 part in $10^{13}$. By comparing the time differences with the known satellite positions and the fixed speed of light, the receiver can determine how far it is from each satellite and thus where it is on the Earth. It can do this to an accuracy of a few meters, if it has been constructed to make corrections due to relativity, such as the one we discuss next.

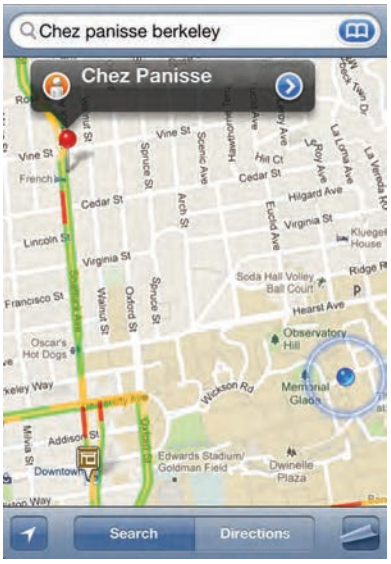

**FIGURE 36–8** A visiting professor of physics uses the GPS on her smart phone to find a restaurant (red dot). Her location in the physics department is the blue dot. Traffic on some streets is also shown (green = good, orange = slow, red = heavy traffic) which comes in part by tracking cell phone movements.

**CONCEPTUAL EXAMPLE 36–4** **A relativity correction to GPS.** GPS satellites move at about $4\,\text{km/s} = 4000\,\text{m/s}$. Show that a good GPS receiver needs to correct for time dilation if it is to produce results consistent with atomic clocks accurate to 1 part in $10^{13}$.

**RESPONSE** Let us calculate the magnitude of the time dilation effect by inserting $v = 4000\,\text{m/s}$ into Eq. 36–1a:

$$\Delta t = \frac{1}{\sqrt{1 - \frac{v^2}{c^2}}}\Delta t_0 = \frac{1}{\sqrt{1 - \left(\frac{4\times10^3\,\text{m/s}}{3\times10^8\,\text{m/s}}\right)^2}}\Delta t_0$$

$$= \frac{1}{\sqrt{1 - 1.8\times10^{-10}}}\Delta t_0.$$

We use the binomial expansion: $(1 \pm x)^n \approx 1 \pm nx$ for $x \ll 1$ (see Appendix A–2) which here is $(1-x)^{-\frac{1}{2}} \approx 1 + \frac{1}{2}x$. That is

$$\Delta t = \left(1 + \tfrac{1}{2}(1.8\times10^{-10})\right)\Delta t_0 = \left(1 + 9\times10^{-11}\right)\Delta t_0.$$

The time "error" divided by the time interval is

$$\frac{(\Delta t - \Delta t_0)}{\Delta t_0} = 1 + 9\times10^{-11} - 1 = 9\times10^{-11} \approx 1\times10^{-10}.$$

Time dilation, if not accounted for, would introduce an error of about 1 part in $10^{10}$, which is 1000 times greater than the precision of the atomic clocks. Not good! By not correcting for time dilation means a receiver could give much poorer position accuracy.

**NOTE** GPS devices must make other corrections as well, including effects associated with general relativity.

## 36–6 Length Contraction

Time intervals are not the only things different in different reference frames. Space intervals—lengths and distances—are different as well, according to the special theory of relativity, and we illustrate this with a thought experiment.

Observers on Earth watch a spacecraft traveling at speed $v$ away from Earth to Neptune, Fig. 36–9a. The distance between the planets, as measured by the Earth observers, is $\ell_0$. The time required for the trip, measured from Earth, is

$$\Delta t = \frac{\ell_0}{v}. \qquad \text{[Earth observer]}$$

In Fig. 36–9b we see the point of view of observers on the spacecraft. In this frame of reference, the spaceship is at rest; Earth and Neptune move† with speed $v$ (but opposite direction).

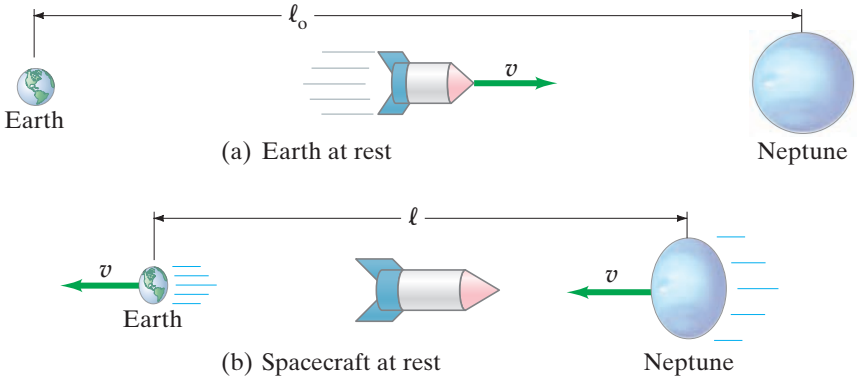

**FIGURE 36–9** (a) A spaceship traveling at very high speed $v$ from Earth to the planet Neptune, as seen from Earth's frame of reference. (b) According to an observer on the spaceship, Earth and Neptune are moving at the very high speed $v$: Earth leaves the spaceship, and a time $\Delta t_0$ later Neptune arrives at the spaceship.

The time between departure of Earth and arrival of Neptune, as observed from the spacecraft, is the "proper time" $\Delta t_0$ (page 1066) because these two events occur at the same point in space (i.e., at the spacecraft). Therefore the time interval is less for the spacecraft observers than for the Earth observers. That is, because of time dilation (Eq. 36–1a), the time for the trip as viewed by the spacecraft is

$$\Delta t_0 = \Delta t\sqrt{1 - v^2/c^2} = \Delta t/\gamma. \qquad \text{[spacecraft observer]}$$

Because the spacecraft observers measure the same speed but less time between these two events, they also measure the distance as less. If we let $\ell$ be the distance between the planets as viewed by the spacecraft observers (Fig. 36–9b), then $\ell = v\,\Delta t_0$, which we can rewrite as $\ell = v\,\Delta t_0 = v\,\Delta t\sqrt{1 - v^2/c^2} = \ell_0\sqrt{1 - v^2/c^2}$. Thus we have the important result that

*LENGTH CONTRACTION*

$$\ell = \ell_0\sqrt{1 - v^2/c^2} \qquad \textbf{(36–3a)}$$

or

$$\ell = \ell_0/\gamma. \qquad \textbf{(36–3b)}$$

This is a general result of the special theory of relativity and applies to lengths of objects as well as to distance between objects. The result can be stated most simply in words as:

> **the length of an object moving relative to an observer is measured to be shorter along its direction of motion than when it is at rest.**

**CAUTION**

*Proper length is measured in reference frame where the two positions are at rest*

This is called **length contraction**. The length $\ell_0$ in Eqs. 36–3 is called the **proper length**. It is the length of the object (or distance between two points whose positions are measured at the same time) as determined by *observers at rest* with respect to the object. Equations 36–3 give the length $\ell$ that will be measured by observers when the object travels past them at speed $v$.

It is important to note that length contraction occurs *only along the direction of motion*. For example, the moving spaceship in Fig. 36–9a is shortened in length, but its height is the same as when it is at rest.

Length contraction, like time dilation, is not noticeable in everyday life because the factor $\sqrt{1 - v^2/c^2}$ in Eq. 36–3a differs significantly from 1.00 only when $v$ is very large (Table 36–1 on page 1067).

†We assume $v$ is much greater than the relative speed of Neptune and Earth (which we thus ignore).

**EXAMPLE 36–5** **Painting's contraction.** A rectangular painting measures 1.00 m tall and 1.50 m wide, Fig. 36–10a. It is hung on the side wall of a spaceship which is moving past the Earth at a speed of $0.90c$. (*a*) What are the dimensions of the picture according to the captain of the spaceship? (*b*) What are the dimensions as seen by an observer on the Earth?

**APPROACH** We apply the length contraction formula in part (*b*) to the dimension parallel to the motion; $v$ is the speed of the painting relative to the Earth observer.

**SOLUTION** (*a*) The painting is at rest $(v = 0)$ on the spaceship so it (as well as everything else in the spaceship) looks perfectly normal to everyone on the spaceship. The captain sees a 1.00-m by 1.50-m painting.

(*b*) Only the dimension in the direction of motion is shortened, so the height is unchanged at 1.00 m, Fig. 36–10b. The length, however, is contracted to

$$\ell = \ell_0\sqrt{1 - v^2/c^2} = (1.50\,\text{m})\sqrt{1 - (0.90)^2} = 0.65\,\text{m}.$$

So the picture has dimensions $1.00\,\text{m} \times 0.65\,\text{m}$ to an observer on Earth.

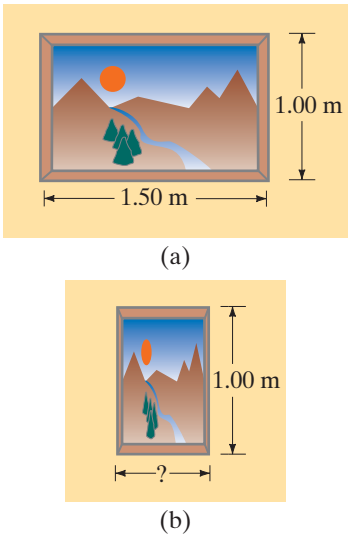

**FIGURE 36–10** Example 36–5.

**EXAMPLE 36–6** **A fantasy supertrain.** A very fast train with a "proper length" of $\ell_0 = 500\,\text{m}$ (measured by people at rest on the train) is passing through a tunnel that is 200 m long according to observers on the ground. Let us imagine the train's speed to be so great that the train fits completely within the tunnel as seen by observers on the ground. That is, the engine is just about to emerge from one end of the tunnel at the time the last car disappears into the other end. What is the train's speed?

**APPROACH** Since the train just fits inside the tunnel, its length measured by the person on the ground is $\ell = 200\,\text{m}$. The length contraction formula, Eq. 36–3a or b, can thus be used to solve for $v$.

**SOLUTION** Substituting $\ell = 200\,\text{m}$ and $\ell_0 = 500\,\text{m}$ into Eq. 36–3a gives

$$200\,\text{m} = 500\,\text{m}\sqrt{1 - v^2/c^2}.$$

Dividing both sides by 500 m and squaring, we get

$$(0.40)^2 = 1 - v^2/c^2$$

or $v = c\sqrt{1 - (0.40)^2} = 0.92c$.

**NOTE** No real train could go this fast. But it is fun to think about.

**NOTE** An observer on the *train* would *not* see the two ends of the train inside the tunnel at the same time. Recall that observers moving relative to each other do not agree about simultaneity. (See Example 36–7, next.)

**EXERCISE D** What is the length of the tunnel as measured by observers on the train in Example 36–6?

**CONCEPTUAL EXAMPLE 36–7** **Resolving the train and tunnel length.** Observers at rest on the Earth see a very fast 200-m-long train pass through a 200-m-long tunnel (as in Example 36–6) so that the train momentarily disappears from view inside the tunnel. Observers on the train measure the train's length to be 500 m and the tunnel's length to be only 80 m (Exercise D, using Eq. 36–3a). Clearly a 500-m-long train cannot fit inside an 80-m-long tunnel. How is this apparent inconsistency explained?

**RESPONSE** Events simultaneous in one reference frame may not be simultaneous in another. Let the engine emerging from one end of the tunnel be "event A," and the last car disappearing into the other end of the tunnel "event B." To observers in the Earth frame, as we stated in Example 36–6, events A and B are simultaneous. To observers on the train, however, the events are not simultaneous. In the train's frame, event A occurs before event B. As the engine emerges from the tunnel, observers on the train observe the last car as still $500\,\text{m} - 80\,\text{m} = 420\,\text{m}$ from the entrance to the tunnel. What a kick—not our usual way of thinking.

## 36–7 Four-Dimensional Space–Time

Let us imagine a person is on a train moving at a very high speed, say 0.65$c$, Fig. 36–11. This person begins a meal at 7:00 and finishes at 7:15, according to a clock on the train. The two events, beginning and ending the meal, take place at the same point on the train, so the "proper time" between these two events is 15 min. To observers on Earth, the plate is moving and the meal will take longer—20 min according to Eqs. 36–1. Let us assume that the meal was served on a 20-cm-diameter plate (its "proper length"). To observers on the Earth, the plate is moving and is only 15 cm wide (length contraction). Thus, to observers on the Earth, the meal looks smaller but lasts longer.

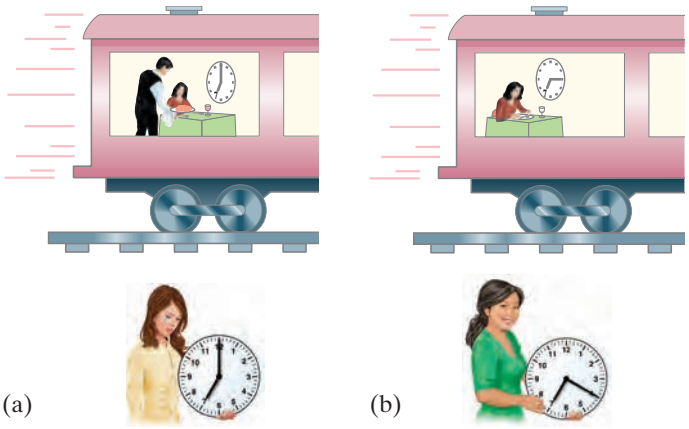

**FIGURE 36–11** According to an accurate clock on a fast-moving train, a person (a) begins dinner at 7:00 and (b) finishes at 7:15. At the beginning of the meal, two observers on Earth set their watches to correspond with the clock on the train. These observers measure the eating time as 20 minutes.

**CAUTION**
*Space and time "exchanged"*

In a sense the two effects, time dilation and length contraction, balance each other. When viewed from the Earth, what an object seems to lose in size it gains in length of time it lasts. Space, or length, is exchanged for time.

Considerations like this led to the idea of **four-dimensional space–time**: space takes up three dimensions and time is a fourth dimension. Space and time are intimately connected. Just as when we squeeze a balloon we make one dimension larger and another smaller, so when we examine objects and events from different reference frames, a certain amount of space is exchanged for time, or vice versa.

Although the idea of four dimensions may seem strange, it refers to the idea that any object or event is specified by four quantities—three to describe where in space, and one to describe when in time. The really unusual aspect of four-dimensional space–time is that space and time can intermix: a little of one can be exchanged for a little of the other when the reference frame is changed.

[In Galilean–Newtonian relativity, the time interval between two events, $\Delta t$, and the distance between two events or points, $\Delta x$, are invariant quantities no matter what inertial reference frame they are viewed from. Neither of these quantities is invariant according to Einstein's relativity. But there is an invariant quantity in four-dimensional space–time, called the **space–time interval**, which is $(\Delta s)^2 = (c\,\Delta t)^2 - (\Delta x)^2$.]

## 36–8 Galilean and Lorentz Transformations

We examine in detail the mathematics of relating quantities in one inertial reference frame to the equivalent quantities in another. In particular, we will see how positions and velocities *transform* (that is, change) from one inertial reference frame to the other.

We begin with the classical or Galilean viewpoint. Consider two inertial reference frames S and S′ which are each characterized by a set of coordinate axes, Fig. 36–12. The axes $x$ and $y$ ($z$ is not shown) refer to S, and $x'$ and $y'$ refer to S′. The $x'$ and $x$ axes overlap one another, and we assume that frame S′ moves to the right in the $x$ direction at constant speed $v$ with respect to S.

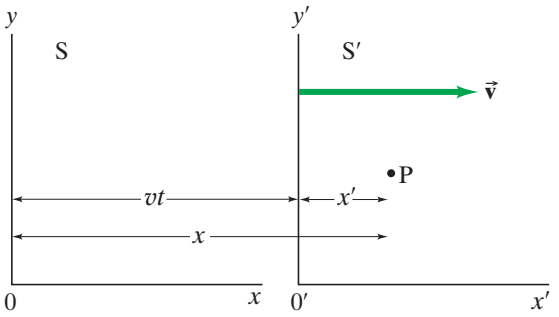

**FIGURE 36–12** Inertial reference frame S′ moves to the right at constant speed $v$ with respect to frame S.

We assume that we, as observers, are at rest in S. For simplicity let us assume the origins 0 and 0′ of the two reference frames are superimposed at time $t = 0$. That is, $x = x'$ at $t = 0$ for all positions.

Now consider an event that occurs at some point P (Fig. 36–12) represented by the coordinates $x', y', z'$ in reference frame S′ at the time $t'$. What will be the coordinates of P in S? Since S and S′ overlap precisely initially, after a time $t'$, S′ will have moved a distance $vt'$. Therefore, at time $t'$, $x = x' + vt'$. The $y$ and $z$ coordinates, on the other hand, are not altered by motion along the $x$ axis, as we saw on page 1070. Thus $y = y'$ and $z = z'$. Finally, since time is assumed to be absolute in Galilean–Newtonian physics, clocks in the two frames will agree with each other, so $t = t'$. We summarize these in the following **Galilean transformation equations**:

$$\begin{aligned} x &= x' + vt' \\ y &= y' \\ z &= z' \\ t &= t'. \end{aligned} \qquad \text{[Galilean]} \quad \textbf{(36–4)}$$

These equations give the coordinates of an event in the S frame when those in the S′ frame are known. If those in the S frame are known, then the S′ coordinates are obtained from

$$x' = x - vt, \qquad y' = y, \qquad z' = z, \qquad t' = t. \qquad \text{[Galilean]}$$

These four equations are the "inverse" transformation. They can be obtained from Eqs. 36–4 (1) by solving Eqs. 36–4 for $x'$, and (2) by exchanging primed and unprimed quantities and replacing $v$ by $-v$. This makes sense because looking from the S′ frame, S moves to the left (negative $x$ direction) with speed $v$.

Next suppose the point P in Fig. 36–12 represents a particle that is moving. Let the components of its velocity vector in S′ be $u'_x, u'_y, u'_z$. (We use $u$ to distinguish it from the relative velocity of the two frames, $v$.) Now $u'_x = dx'/dt'$, $u'_y = dy'/dt'$ and $u'_z = dz'/dt'$. The velocity of P as seen from S will have components $u_x, u_y$, and $u_z$. We can show how these are related to the velocity components in S′ by differentiating Eqs. 36–4. For $u_x$ we get

$$u_x = \frac{dx}{dt} = \frac{d(x' + vt')}{dt'} = u'_x + v$$

since $v$ is assumed constant. For the other components, $u'_y = u_y$ and $u'_z = u_z$, so we have

$$\begin{aligned} u_x &= u'_x + v \\ u_y &= u'_y \\ u_z &= u'_z. \end{aligned} \qquad \text{[Galilean]} \quad \textbf{(36–5)}$$

These are known as the **Galilean velocity transformation equations**. We see that the $y$ and $z$ components of velocity are unchanged, but the $x$ components differ by $v$. This is just what we have used before when dealing with relative velocity (Section 3–9). For example, if S′ is a train and S the Earth, and the train moves with speed $v$ with respect to Earth, a person walking toward the front of the train with speed $u'_x$ will have a speed with respect to the Earth of $u_x = u'_x + v$.

The Galilean transformations, Eqs. 36–4 and 36–5, give quite accurate results only when the velocities involved are much less than the speed of light, $c$. We can see, for example, that the first of Eqs. 36–5 will not work for the speed of light, $c$, which is the same in all inertial reference frames (the second postulate of special relativity). That is, light traveling in S′ with speed $u'_x = c$ will have speed $c + v$ in S, according to Eqs. 36–5, whereas the theory of relativity insists it must be $c$ also in S. Clearly, then, a new set of transformation equations is needed to deal with relativistic velocities.

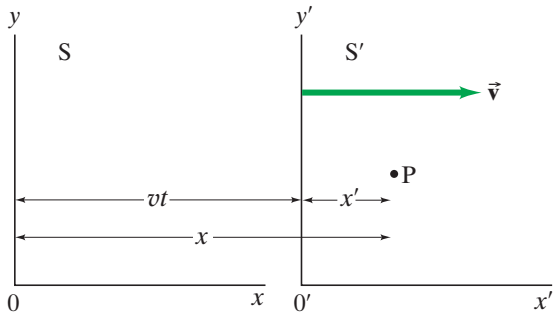

**FIGURE 36–12** (Repeated.) Inertial reference frame S′ moves to the right at constant speed $v$ with respect to frame S.

We can derive the required equations, again looking at Fig. 36–12. We hope it will work out to be simple, and assume the transformation is linear and for $x$ is of the form

$$x = \gamma(x' + vt'). \qquad \textbf{(i)}$$

[We are NOT assuming $\gamma$ is given by Eq. 36–2, $1/\sqrt{1 - v^2/c^2}$, as in Section 36–5. Our minds are open. Let's see.] That is, we modify the first of Eqs. 36–4 by multiplying by a factor $\gamma$ which is yet to be determined. We assume the $y$ and $z$ equations are unchanged

$$y = y', \qquad z = z'$$

because there is no length contraction in these directions. We will not assume a form for $t$, but will derive it. The inverse equations must have the same form with $v$ replaced by $-v$. (The principle of relativity demands it, since S′ moving to the right with respect to S is equivalent to S moving to the left with respect to S′.) Therefore

$$x' = \gamma(x - vt). \qquad \textbf{(ii)}$$

Suppose a light pulse leaves the common origin of S and S′ at time $t = t' = 0$. Then after a time $t$ it will have traveled along the $x$ axis a distance $x = ct$ (in S), or $x' = ct'$ (in S′). Therefore, from Eqs. (i) and (ii) above,

$$ct = x = \gamma(ct' + vt') = \gamma(c + v)t', \qquad \textbf{(iii)}$$

$$ct' = x' = \gamma(ct - vt) = \gamma(c - v)t. \qquad \textbf{(iv)}$$

From Eq. (iv), $t' = \gamma(c - v)(t/c)$, and we substitute this into Eq. (iii) and find $ct = \gamma(c + v)\gamma(c - v)(t/c) = \gamma^2(c^2 - v^2)t/c$. We cancel out the $t$ on each side and solve for $\gamma$ to find

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}}.$$

We have found that $\gamma$ is, in fact, the value for $\gamma$ we used before, Eq. 36–2.

Now that we have found $\gamma$, we need only find the relation between $t$ and $t'$. To do so, we combine $x' = \gamma(x - vt)$ with $x = \gamma(x' + vt')$:

$$x' = \gamma(x - vt) = \gamma[\gamma(x' + vt') - vt].$$

We solve for $t$, doing some algebra, and find $t = \gamma(t' + vx'/c^2)$. In summary,

$$\begin{aligned} x &= \frac{1}{\sqrt{1 - v^2/c^2}}(x' + vt') \\ y &= y' \\ z &= z' \\ t &= \frac{1}{\sqrt{1 - v^2/c^2}}\left(t' + \frac{vx'}{c^2}\right). \end{aligned} \qquad \textbf{(36–6)}$$

*LORENTZ TRANSFORMATIONS*

These are the **Lorentz transformation equations**. They were first proposed, in a slightly different form, by Lorentz in 1904 to explain the null result of the Michelson–Morley experiment and to make Maxwell's equations take the same form in all inertial reference frames. A year later, Einstein derived them independently based on his theory of relativity. Notice that not only is the $x$ equation modified as compared to the Galilean transformation, but so is the $t$ equation. Indeed, we see directly in this last equation how the space and time coordinates mix.

## Deriving Length Contraction

We now derive the length contraction formula, Eq. 36–3, from the Lorentz transformation equations. We consider two reference frames S and S′ as in Fig. 36–12.

Let an object of length $\ell_0$ be at rest on the $x$ axis in S. The coordinates of its two end points are $x_1$ and $x_2$, so that $x_2 - x_1 = \ell_0$. At any instant in S′, the end points will be at $x_1'$ and $x_2'$ as given by the Lorentz transformation equations. The length measured in S′ is $\ell = x_2' - x_1'$. An observer in S′ measures this length by measuring $x_2'$ and $x_1'$ at the same time (in the S′ reference frame), so $t_2' = t_1'$. Then, from the first of Eqs. 36–6,

$$\ell_0 = x_2 - x_1 = \frac{1}{\sqrt{1 - v^2/c^2}}(x_2' + vt_2' - x_1' - vt_1'),$$

and with $t_2' = t_1'$, we have

$$\ell_0 = \frac{1}{\sqrt{1 - v^2/c^2}}(x_2' - x_1') = \frac{\ell}{\sqrt{1 - v^2/c^2}},$$

or

$$\ell = \ell_0\sqrt{1 - v^2/c^2},$$

which is Eq. 36–3a, the length contraction formula.

## Deriving Time Dilation

We now derive the time-dilation formula, Eq. 36–1a, from the Lorentz transformation equations.

The time $\Delta t_0$ between two events that occur at the same place $(x_2' = x_1')$ in S′ is measured to be $\Delta t_0 = t_2' - t_1'$. Since $x_2' = x_1'$, then from the last of Eqs. 36–6, the time $\Delta t$ between the events as measured in S is

$$\begin{aligned} \Delta t = t_2 - t_1 &= \frac{1}{\sqrt{1 - v^2/c^2}}\left(t_2' + \frac{vx_2'}{c^2} - t_1' - \frac{vx_1'}{c^2}\right) \\ &= \frac{1}{\sqrt{1 - v^2/c^2}}(t_2' - t_1') = \frac{\Delta t_0}{\sqrt{1 - v^2/c^2}}, \end{aligned}$$

which is Eq. 36–1a, the time-dilation formula. Note that we chose S′ to be the frame in which the two events occur at the same place, so that $x_1' = x_2'$ and the terms containing $x_1'$ and $x_2'$ cancel out.

## Relativistic Addition of Velocities

The relativistically correct velocity equations are obtained by differentiating Eqs. 36–6 with respect to time. For example (using $\gamma = 1/\sqrt{1 - v^2/c^2}$ and the chain rule for derivatives):

$$u_x = \frac{dx}{dt} = \frac{d}{dt}\left[\gamma(x' + vt')\right]$$
$$= \frac{d}{dt'}\left[\gamma(x' + vt')\right]\frac{dt'}{dt} = \gamma\left[\frac{dx'}{dt'} + v\right]\frac{dt'}{dt}.$$

But $dx'/dt' = u'_x$ and we differentiate the last of Eqs. 36–6 with respect to time to get

$$\frac{dt'}{dt} = \frac{1}{(dt/dt')} = \frac{1}{\gamma(1 + vu'_x/c^2)}.$$

Then

$$u_x = \frac{[\gamma(u'_x + v)]}{[\gamma(1 + vu'_x/c^2)]} = \frac{u'_x + v}{1 + vu'_x/c^2}.$$

The others are obtained in the same way and we collect them here:

*LORENTZ VELOCITY TRANSFORMATIONS*

$$u_x = \frac{u'_x + v}{1 + vu'_x/c^2} \qquad \textbf{(36–7a)}$$

$$u_y = \frac{u'_y\sqrt{1 - v^2/c^2}}{1 + vu'_x/c^2} \qquad \textbf{(36–7b)}$$

$$u_z = \frac{u'_z\sqrt{1 - v^2/c^2}}{1 + vu'_x/c^2}. \qquad \textbf{(36–7c)}$$

**⚠ CAUTION**
*Velocity components "mix"*

Note that even though the relative velocity $\vec{\mathbf{v}}$ is in the $x$ direction, if the object has $y$ or $z$ components of velocity, they too are affected by $v$ and the $x'$ component of the object's velocity. This was not true for the Galilean transformation, Eqs. 36–5.

**EXAMPLE 36–8** **Adding velocities.** Calculate the speed of rocket 2 in Fig. 36–13 with respect to Earth.

**APPROACH** Consider Earth as reference frame S, and rocket 1 as reference frame S′. Rocket 2 moves with speed $u' = 0.60c$ with respect to rocket 1. Rocket 1 has speed $v = 0.60c$ with respect to Earth. The velocities are along the same straight line which we take to be the $x$ (and $x'$) axis. We need use only the first of Eqs. 36–7, and drop the subscripts $x$ and $x'$.

**SOLUTION** The speed of rocket 2 with respect to Earth is

$$u = \frac{u' + v}{1 + \dfrac{vu'}{c^2}} = \frac{0.60c + 0.60c}{1 + \dfrac{(0.60c)(0.60c)}{c^2}} = \frac{1.20c}{1.36} = 0.88c.$$

**NOTE** The Galilean transformation would have given $u = 1.20c$.

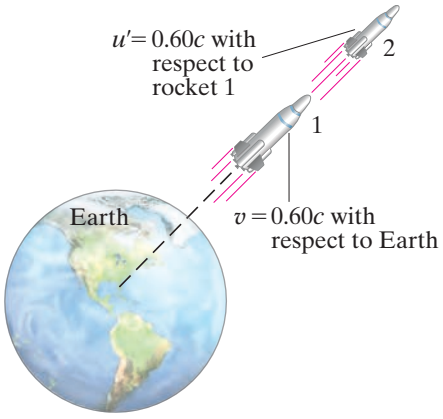

**FIGURE 36–13** Rocket 1 moves away from Earth at speed $v = 0.60c$. Rocket 2 is fired from rocket 1 with speed $u' = 0.60c$. What is the speed of rocket 2 with respect to Earth?

For one-dimensional motion, we can rewrite Eq. 36–7a as we did in Example 36–8:

$$u = \frac{u' + v}{1 + vu'/c^2}. \qquad \text{[1–D]} \qquad \textbf{(36–7d)}$$

**EXERCISE E** Calculate the speed of rocket 2 in Fig. 36–13 relative to Earth if it was shot from rocket 1 at a speed $u' = 3000\ \text{km/s} = 0.010c$. Assume rocket 1 had a speed $v = 6000\ \text{km/s} = 0.020c$.

**EXERCISE F** Return to the Chapter-Opening Question, page 1055, and answer it again now. Try to explain why you may have answered differently the first time.

We can see that Eqs. 36–7 reduce to the classical (Galilean) forms for velocities small compared to the speed of light, since $1 + vu'/c^2 \approx 1$ for $v$ and $u' \ll c$. Thus, $u \approx v + u'$, as in classical physics (Chapter 3).

At the other extreme, let rocket 1 in Fig. 36–13 send out a beam of light, so that $u' = c$. Then Eq. 36–7a tells us the speed of light relative to Earth is

$$u = \frac{0.60c + c}{1 + \dfrac{(0.60c)(c)}{c^2}} = c,$$

which is fully consistent with the second postulate of relativity.

# 36–9 Relativistic Momentum

So far in this Chapter, we have seen that two basic mechanical quantities, length and time intervals, need modification because they are relative—their value depends on the reference frame from which they are measured. We might expect that other physical quantities might need some modification according to the theory of relativity, such as momentum and energy.

The analysis of collisions between two particles shows that if we want to preserve the law of conservation of momentum in relativity, we must redefine momentum as

$$p = \frac{mv}{\sqrt{1 - v^2/c^2}} = \gamma mv. \qquad \textbf{(36–8)}$$

Here $\gamma$ is shorthand for $1/\sqrt{1 - v^2/c^2}$ as before (Eq. 36–2). For speeds much less than the speed of light, Eq. 36–8 gives the classical momentum, $p = mv$.

Relativistic momentum has been tested many times on tiny elementary particles (such as muons), and it has been found to behave in accord with Eq. 36–8. We derive Eq. 36–8 in the optional Subsection starting below.

**EXAMPLE 36–9** **Momentum of moving electron.** Compare the momentum of an electron to its classical value when it has a speed of (*a*) $4.00 \times 10^7$ m/s in the CRT of an old TV set, and (*b*) $0.98c$ in an accelerator used for cancer therapy.

**APPROACH** We use Eq. 36–8 for the momentum of a moving electron.

**SOLUTION** (*a*) At $v = 4.00 \times 10^7$ m/s, the electron's momentum is

$$p = \frac{mv}{\sqrt{1 - \dfrac{v^2}{c^2}}} = \frac{mv}{\sqrt{1 - \dfrac{(4.00 \times 10^7\ \text{m/s})^2}{(3.00 \times 10^8\ \text{m/s})^2}}} = 1.01mv.$$

The factor $\gamma = 1/\sqrt{1 - v^2/c^2} \approx 1.01$, so the momentum is only about 1% greater than the classical value.

(*b*) With $v = 0.98c$, the momentum is

$$p = \frac{mv}{\sqrt{1 - \dfrac{v^2}{c^2}}} = \frac{mv}{\sqrt{1 - \dfrac{(0.98c)^2}{c^2}}} = \frac{mv}{\sqrt{1 - (0.98)^2}} = 5.0mv.$$

An electron traveling at 98% the speed of light has $\gamma = 5.0$ and a momentum 5.0 times its classical value.

Newton's second law, stated in its most general form, is

$$\vec{\mathbf{F}} = \frac{d\vec{\mathbf{p}}}{dt} = \frac{d}{dt}(\gamma m\vec{\mathbf{v}}) = \frac{d}{dt}\left(\frac{m\vec{\mathbf{v}}}{\sqrt{1 - v^2/c^2}}\right) \qquad \textbf{(36–9)}$$

and is valid relativistically.

## *Derivation of Relativistic Momentum

Classically, momentum is a conserved quantity. We hope to find a formula for momentum that will also be valid relativistically. To do so, let us assume it has the general form given by $p = fmv$ where $f$ is some function of $v$: $f(v)$. We consider a hypothetical collision between two objects—a thought experiment—and see what form $f(v)$ must take if momentum is to be conserved.

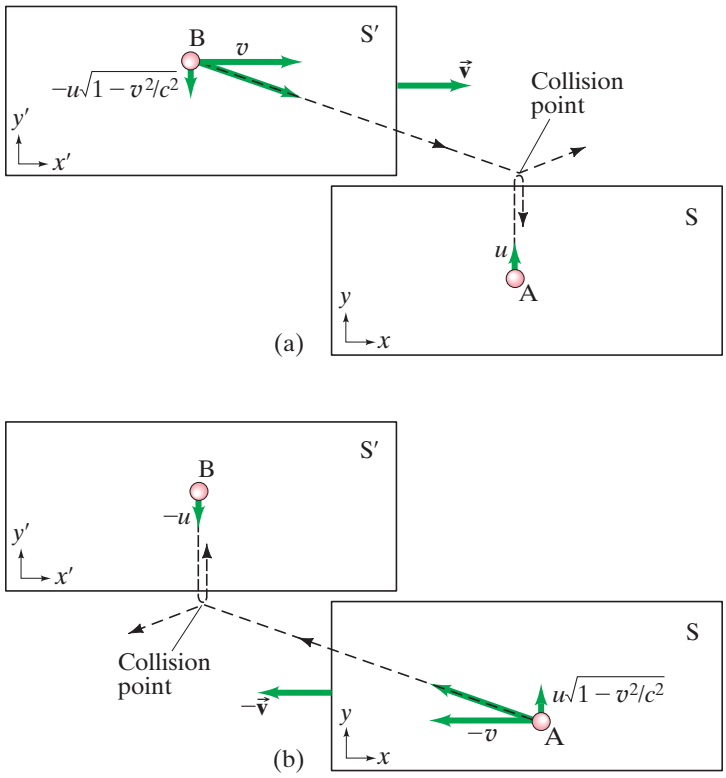

**FIGURE 36–14** Deriving the momentum formula. Collision as seen by observers (a) in reference frame S, (b) in reference frame S′.

Our thought experiment involves the elastic collision of two identical balls, A and B. We consider two inertial reference frames, S and S′, moving along the $x$ axis with a speed $v$ with respect to each other, Fig. 36–14. That is, frame S′ moves to the right with velocity $\vec{\mathbf{v}}$ as seen by observers in frame S (Fig. 36–14a); and frame S moves to the left with $-\vec{\mathbf{v}}$ as seen by observers in S′ (Fig. 36–14b). In reference frame S, ball A is thrown with speed $u$ in the $+y$ direction. In reference frame S′, ball B is thrown with speed $u$ in the negative $y'$ direction. The two balls are thrown at just the right time so that they collide. We assume that they rebound elastically and that each moves with the same speed $u$ back in the opposite direction in its thrower's reference frame. In reference frame S, Fig. 36–14a, ball A has $u_x = 0$ both before and after the collision; it has $u_y = +u$ before the collision and $u_y = -u$ after the collision. In frame S′, Fig. 36–14b, ball A has $x$ component of velocity $u'_x = -v$ both before and after the collision, and a $y'$ component (solving Eq. 36–7b for $u'_y$ and putting $u'_x = -v$) of magnitude

$$u'_y = \frac{u_y(1 + vu'_x/c^2)}{\sqrt{1 - v^2/c^2}} = \frac{u(1 + v(-v)/c^2)}{\sqrt{1 - v^2/c^2}}$$

or

$$u'_y = u\sqrt{1 - v^2/c^2}.$$

The same holds true for ball B, except in reverse: $u'_y = -u\sqrt{1 - v^2/c^2}$. These velocity components are indicated in Fig. 36–14.

We now apply the law of conservation of momentum, which we hope remains valid in relativity, even if momentum has to be redefined. That is, we assume that the total momentum before the collision is equal to the total momentum after the collision. We apply conservation of momentum to the $y$ component of momentum in reference frame S (Fig. 36–14a). To make our task easier, let us assume $u \ll v$ so that the speed of ball B as seen in reference frame S is essentially $v$. Then B's $y$ component of momentum in S before collision is $-f(v)mu\sqrt{1 - v^2/c^2}$ and after the collision B's momentum in S is $+f(v)mu\sqrt{1 - v^2/c^2}$. Ball A in S has $y$ component $f(u)mu$ before and $-f(u)mu$ after the collision. (We use $f(u)$ for A because its speed in S is only $u$.)

Conservation of momentum in S for the $y$ component is

$$(p_{Ay} + p_{By})_{before} = (p_{Ay} + p_{By})_{after}$$

$$f(u)mu - f(v)mu\sqrt{1 - v^2/c^2} = -f(u)mu + f(v)mu\sqrt{1 - v^2/c^2}.$$

We solve this for $f(v)$ and obtain

$$f(v) = \frac{f(u)}{\sqrt{1 - v^2/c^2}}.$$

To simplify this relation so we can solve for $f$, let us allow $u$ to become very small so that it approaches zero (this corresponds to a glancing collision with one of the balls essentially at rest and the other moving with speed $v$). Then the momentum terms $f(u)mu$ are in the nonrelativistic realm and take on the classical form, simply $mu$, meaning that $f(u) = 1$. So the previous equation becomes

$$f(v) = \frac{1}{\sqrt{1 - v^2/c^2}}.$$

We see that $f(v)$ comes out to be the factor we used before and called $\gamma$, and here has been shown to be valid for ball A. Using Fig. 36–14b we can derive the same relation for ball B. Thus we can conclude that we need to define the relativistic momentum of a particle moving with velocity $\vec{\mathbf{v}}$ as

$$\vec{\mathbf{p}} = \frac{m\vec{\mathbf{v}}}{\sqrt{1 - v^2/c^2}} = \gamma m\vec{\mathbf{v}}. \qquad \textbf{(36–8, again)}$$

With this definition the law of conservation of momentum will remain valid even in the relativistic realm. This relativistic momentum formula (Eq. 36–8) has been tested countless times on tiny elementary particles and been found valid.

### *Rest Mass and Relativistic Mass

**CAUTION**
*Most physicists prefer to consider the mass of a particle as fixed*

The relativistic definition of momentum, Eq. 36–8, has sometimes been interpreted as an increase in the mass of an object. In this interpretation, a particle can have a **relativistic mass**, $m_{rel}$, which increases with speed according to

$$m_{rel} = \frac{m}{\sqrt{1 - v^2/c^2}}.$$

In this "mass-increase" formula, $m$ is referred to as the **rest mass** of the object. With this interpretation, *the mass of an object appears to increase as its speed increases*. But there are problems with relativistic mass. If we plug it into formulas like $F = ma$ or $K = \frac{1}{2}mv^2$, we obtain formulas that do not agree with experiment. If we write Newton's second law in its more general form, $\vec{\mathbf{F}} = d\vec{\mathbf{p}}/dt$, we do get a correct result, Eq. 36–9.

Also, be careful *not* to think a mass acquires more particles or more molecules as its speed becomes very large. It doesn't. Today, most physicists prefer not to use relativistic mass, so an object has only one mass, its rest mass, and it is only the momentum that increases with speed.

Whenever we talk about the mass of an object, we will always mean its rest mass (a fixed value). [But see Problem 103.]

## 36–10 The Ultimate Speed

A basic result of the special theory of relativity is that the speed of an object cannot equal or exceed the speed of light. That the speed of light is a natural speed limit in the universe can be seen from any of Eqs. 36–1, 36–3, 36–8, or the addition of velocities formula. It is perhaps easiest to see from Eq. 36–8. As an object is accelerated to greater and greater speeds, its momentum becomes larger and larger. Indeed, if $v$ were to equal $c$, the denominator in this equation would be zero, and the momentum would be infinite. To accelerate an object up to $v = c$ would thus require infinite energy, and so is not possible.

# 36–11 $E = mc^2$; Mass and Energy

If momentum needs to be modified to fit with relativity as we just saw in Eq. 36–8, then we might expect that energy would also need to be rethought. Indeed, Einstein not only developed a new formula for kinetic energy to replace $K = \frac{1}{2}mv^2$, but also found a new relation between mass and energy, and the startling idea that mass is a form of energy.

## Deriving Relativistic Energy

We start with the work-energy principle (Chapter 7), hoping it is still valid in relativity and will give verifiable results. That is, we assume the net work done on a particle is equal to its change in kinetic energy ($K$), and we take the motion of the particle to be along the $x$ axis. The work done to increase a particle's speed from zero to $v$ is

$$W = \int_i^f F\,dx = \int_i^f \frac{dp}{dt}\,dx = \int_i^f \frac{dp}{dt}\,v\,dt = \int_i^f v\,dp$$

where $i$ and $f$ refer to the initial $(v = 0)$ and final $(v = v)$ states. Since $d(pv) = p\,dv + v\,dp$ we can write

$$v\,dp = d(pv) - p\,dv$$

so

$$W = \int_i^f d(pv) - \int_i^f p\,dv.$$

The first term on the right of the equal sign is

$$\int_i^f d(pv) = pv\Big|_i^f = (\gamma mv)v = \frac{mv^2}{\sqrt{1 - v^2/c^2}}.$$

The second term in our equation for $W$ above is integrated using

$$\frac{d}{dv}\left(\sqrt{1 - v^2/c^2}\right) = -(v/c^2)/\sqrt{1 - v^2/c^2},$$

and so the second term in the formula for $W$ becomes

$$-\int_i^f p\,dv = -\int_0^v \frac{mv}{\sqrt{1 - v^2/c^2}}\,dv = mc^2\sqrt{1 - v^2/c^2}\Big|_0^v$$

$$= mc^2\sqrt{1 - v^2/c^2} - mc^2.$$

Combining these results, we have for $W$:

$$W = \frac{mv^2}{\sqrt{1 - v^2/c^2}} + mc^2\sqrt{1 - v^2/c^2} - mc^2.$$

We multiply the second term on the right by $\sqrt{1 - v^2/c^2}/\sqrt{1 - v^2/c^2} = 1$, and obtain

$$W = \frac{mv^2 + mc^2 - mv^2}{\sqrt{1 - v^2/c^2}} - mc^2$$

or

$$W = \frac{mc^2}{\sqrt{1 - v^2/c^2}} - mc^2.$$

By the work-energy theorem, the work $W$ done on the particle must equal its final kinetic energy $K$ since the particle started from rest. Therefore

$$K = \frac{mc^2}{\sqrt{1 - v^2/c^2}} - mc^2 \qquad \textbf{(36–10a)}$$

$$= \gamma mc^2 - mc^2 = (\gamma - 1)mc^2. \qquad \textbf{(36–10b)}$$

These Eqs. 36–10 replace the nonrelativistic form, $K = \frac{1}{2}mv^2$.

## Using Relativistic Energy

Equations 36–10 require some interpretation. The first term increases with the speed $v$ of the particle. The second term, $mc^2$, is constant; it is called the **rest energy** of the particle, and represents a form of energy that a particle has even when at rest. Note that if a particle is at rest $(v = 0)$ the first term in Eq. 36–10a becomes $mc^2$, so $K = 0$ as it should.

We can rearrange Eq. 36–10b to get

$$\gamma mc^2 = mc^2 + K.$$

We call $\gamma mc^2$ the *total energy* $E$ of the particle (assuming no potential energy), because it equals the rest energy plus the kinetic energy:

$$E = K + mc^2. \qquad \textbf{(36–11a)}$$

The total energy[†] can also be written, using Eqs. 36–10, as

$$E = \gamma mc^2 = \frac{mc^2}{\sqrt{1 - v^2/c^2}}. \qquad \textbf{(36–11b)}$$

For a particle at rest in a given reference frame, $K$ is zero in Eq. 36–11a, so the total energy is its rest energy:

$$E = mc^2. \qquad \textbf{(36–12)}$$

*MASS RELATED TO ENERGY*

Here we have Einstein's famous formula, $E = mc^2$. This formula mathematically relates the concepts of energy and mass. But if this idea is to have any physical meaning, then mass ought to be convertible to other forms of energy and vice versa. Einstein suggested that this might be possible, and indeed changes of mass to other forms of energy, and vice versa, have been experimentally confirmed countless times in nuclear and elementary particle physics. For example, an electron and a positron (= a positive electron, see Section 37–5) have often been observed to collide and disappear, producing pure electromagnetic radiation. The amount of electromagnetic energy produced is found to be exactly equal to that predicted by Einstein's formula, $E = mc^2$. The reverse process is also observed in the laboratory: electromagnetic radiation under certain conditions can be converted into material particles such as electrons (see Section 37–5 on pair production). On a larger scale, the energy produced in nuclear power plants is a result of the loss in mass of the uranium fuel as it undergoes the process called fission (Chapter 42). Even the radiant energy we receive from the Sun is an example of $E = mc^2$; the Sun's mass is continually decreasing as it radiates electromagnetic energy outward.

The relation $E = mc^2$ is now believed to apply to all processes, although the changes are often too small to measure. That is, when the energy of a system changes by an amount $\Delta E$, the mass of the system changes by an amount $\Delta m$ given by

$$\Delta E = (\Delta m)(c^2). \qquad \textbf{(36–13)}$$

In a nuclear reaction where an energy $E$ is required or released, the masses of the reactants and the products will be different by $\Delta m = \Delta E/c^2$.

[†]This is for a "free particle," without forces and potential energy. Potential energy terms can be added.

**EXAMPLE 36–10** **Pion's kinetic energy.** A $\pi^0$ meson $(m = 2.4 \times 10^{-28}\,\text{kg})$ travels at a speed $v = 0.84c = 2.5 \times 10^8\,\text{m/s}$. What is its kinetic energy? Compare to a classical calculation.

**APPROACH** We use Eq. 36–10 and compare to $\frac{1}{2}mv^2$.

**SOLUTION** We substitute values into Eq. 36–10a or b.

$$K = (\gamma - 1)mc^2$$

where

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}} = \frac{1}{\sqrt{1 - (0.84)^2}} = 1.84.$$

Then

$$K = (1.84 - 1)(2.4 \times 10^{-28}\,\text{kg})(3.0 \times 10^8\,\text{m/s})^2$$
$$= 1.8 \times 10^{-11}\,\text{J}.$$

Notice that the units of $mc^2$ are $\text{kg} \cdot \text{m}^2/\text{s}^2$, which is the joule.

**NOTE** Classically, $K = \frac{1}{2}mv^2 = \frac{1}{2}(2.4 \times 10^{-28}\,\text{kg})(2.5 \times 10^8\,\text{m/s})^2 = 7.5 \times 10^{-12}\,\text{J}$, less than half as much, but this is not a correct result. Note that $\frac{1}{2}\gamma mv^2$ also does not work.

**EXERCISE G** A proton is traveling in an accelerator with a speed of $1.0 \times 10^8\,\text{m/s}$. By what factor does the proton's kinetic energy increase if its speed is doubled? (*a*) 1.3, (*b*) 2.0, (*c*) 4.0, (*d*) 5.6.

**EXAMPLE 36–11** **Energy from nuclear decay.** The energy required or released in nuclear reactions and decays comes from a change in mass between the initial and final particles. In one type of radioactive decay (Chapter 41), an atom of uranium $(m = 232.03716\,\text{u})$ decays to an atom of thorium $(m = 228.02874\,\text{u})$ plus an atom of helium $(m = 4.00260\,\text{u})$ where the masses given are in atomic mass units $(1\,\text{u} = 1.6605 \times 10^{-27}\,\text{kg})$. Calculate the energy released in this decay.

**APPROACH** The initial mass minus the total final mass gives the mass loss in atomic mass units (u); we convert that to kg, and multiply by $c^2$ to find the energy released, $\Delta E = \Delta mc^2$.

**SOLUTION** The initial mass is 232.03716 u, and after the decay the mass is 228.02874 u + 4.00260 u = 232.03134 u, so there is a loss of mass of 0.00582 u. This mass, which equals $(0.00582\,\text{u})(1.66 \times 10^{-27}\,\text{kg/u}) = 9.66 \times 10^{-30}\,\text{kg}$, is changed into energy. By $\Delta E = \Delta mc^2$, we have

$$\Delta E = (9.66 \times 10^{-30}\,\text{kg})(3.0 \times 10^8\,\text{m/s})^2$$
$$= 8.70 \times 10^{-13}\,\text{J}.$$

Since $1\,\text{MeV} = 1.60 \times 10^{-13}\,\text{J}$ (Section 23–8), the energy released is 5.4 MeV.

In the tiny world of atoms and nuclei, it is common to quote energies in eV (electron volts) or multiples such as MeV $(10^6\,\text{eV})$. Momentum (see Eq. 36–8) can be quoted in units of eV/$c$ (or MeV/$c$). And mass can be quoted (from $E = mc^2$) in units of eV/$c^2$ (or MeV/$c^2$).

Note the use of $c$ to keep the units correct. The masses of the electron and the proton are $0.511\,\text{MeV}/c^2$ and $938\,\text{MeV}/c^2$, respectively. For example, for the electron, $mc^2 = (9.11\times10^{-31}\,\text{kg})(2.998\times10^8\,\text{m/s})^2/(1.602\times10^{-13}\,\text{J/MeV}) = 0.511\,\text{MeV}$. See also the Table inside the front cover.

**EXAMPLE 36–12** **A 7.0-TeV proton.** If a proton in the LHC accelerator in Switzerland is accelerated to 7.0 TeV, what is its speed?

**APPROACH** We solve the kinetic energy formula, Eq. 36–10a, for $v$.

**SOLUTION** The rest energy of a proton is $mc^2 = 938\,\text{MeV}$ or $9.38\times10^8\,\text{eV}$. Compared to the given kinetic energy of $7.0\times10^{12}\,\text{eV}$, the rest energy can be neglected, so we simplify Eq. 36–10a to

$$K \approx \frac{mc^2}{\sqrt{1 - v^2/c^2}}.$$

We solve this for $v$ in the following steps:

$$\sqrt{1 - \frac{v^2}{c^2}} = \frac{mc^2}{K};$$

$$1 - \frac{v^2}{c^2} = \left(\frac{mc^2}{K}\right)^2;$$

$$\frac{v^2}{c^2} = 1 - \left(\frac{mc^2}{K}\right)^2 = 1 - \left(\frac{9.38\times10^8\,\text{eV}}{7.0\times10^{12}\,\text{eV}}\right)^2;$$

$$v = \sqrt{1 - (1.34\times10^{-4})^2}\,c = 0.99999998c.$$

So the proton is traveling at a speed very nearly equal to $c$.

At low speeds, $v \ll c$, the relativistic formula for kinetic energy reduces to the classical one, as we now show by using the binomial expansion (Appendix A–2): $(1 \pm x)^n = 1 \pm nx + n(n-1)x^2/2! + \cdots$. We keep only the first two terms, because when $x = v/c$ is very much less than 1, each term in the sequence is very much smaller than the previous one. With $n = -\frac{1}{2}$ we expand the square root in Eq. 36–10a

$$K = mc^2\left(\frac{1}{\sqrt{1 - v^2/c^2}} - 1\right)$$

so that

$$K \approx mc^2\left(1 + \frac{1}{2}\frac{v^2}{c^2} + \cdots - 1\right) \approx \tfrac{1}{2}mv^2.$$

The dots represent very small terms in the expansion which we neglect since we assumed that $v \ll c$. Thus at low speeds, the relativistic form for kinetic energy reduces to the classical form, $K = \frac{1}{2}mv^2$. This makes relativity a viable theory in that it can predict accurate results at low speed as well as at high. Indeed, the other equations of special relativity also reduce to their classical equivalents at ordinary speeds: length contraction, time dilation, and modifications to momentum as well as kinetic energy, all become negligibly small for $v \ll c$ since $\sqrt{1 - v^2/c^2} \approx 1$.

A useful relation between the total energy $E$ of a particle and its momentum $p$ can also be derived. The momentum of a particle of mass $m$ and speed $v$ is given by Eq. 36–8

$$p = \gamma mv = \frac{mv}{\sqrt{1 - v^2/c^2}}.$$

The total energy is (Eqs. 36–11)

$$E = K + mc^2$$

or

$$E = \gamma mc^2 = \frac{mc^2}{\sqrt{1 - v^2/c^2}}.$$

We square this equation (and we insert "$v^2 - v^2$" which is zero, but will help us):

$$E^2 = \frac{m^2c^2c^2}{1 - v^2/c^2} = \frac{m^2c^2(c^2 - v^2 + v^2)}{1 - v^2/c^2} = \frac{m^2c^2v^2}{1 - v^2/c^2} + \frac{m^2c^2(c^2 - v^2)}{1 - v^2/c^2}$$

$$= p^2c^2 + \frac{m^2c^4(1 - v^2/c^2)}{1 - v^2/c^2}$$

or

$$E^2 = p^2c^2 + m^2c^4. \qquad \textbf{(36–14)}$$

Thus, the total energy can be written in terms of the momentum $p$, or in terms of the kinetic energy (Eq. 36–11a), where we have assumed there is no potential energy.

## Invariant Energy–Momentum

We can rewrite Eq. 36–14 as $E^2 - p^2c^2 = m^2c^4$. Since the mass $m$ of a given particle is the same in any reference frame, we see that the quantity $E^2 - p^2c^2$ must also be the same in any reference frame. Thus, at any given moment the total energy $E$ and momentum $p$ of a particle will be different in different reference frames, but the quantity $E^2 - p^2c^2$ will have the same value in all inertial reference frames. We say that the quantity $E^2 - p^2c^2$ is **invariant** under a Lorentz transformation.

## When Do We Use Relativistic Formulas?

From a practical point of view, we do not have much opportunity in our daily lives to use the mathematics of relativity. For example, the $\gamma$ factor, $\gamma = 1/\sqrt{1 - v^2/c^2}$ has a value of 1.005 when $v = 0.10c$. Thus, for speeds even as high as $0.10c = 3.0 \times 10^7$ m/s, the factor $\sqrt{1 - v^2/c^2}$ in relativistic formulas gives a numerical correction of less than 1%. For speeds less than $0.10c$, or unless mass and energy are interchanged, we don't usually need the more complicated relativistic formulas, and can use the simpler classical formulas.

If you are given a particle's mass $m$ and its kinetic energy $K$, you can do a quick calculation to determine if you need to use relativistic formulas or if classical ones are good enough. You simply compute the ratio $K/mc^2$ because (Eq. 36–10b)

$$\frac{K}{mc^2} = \gamma - 1 = \frac{1}{\sqrt{1 - v^2/c^2}} - 1.$$

If this ratio comes out to be less than, say, 0.01, then $\gamma \leq 1.01$ and relativistic equations will correct the classical ones by about 1%. If your expected precision is no better than 1%, classical formulas are good enough. But if your precision is 1 part in 1000 (0.1%) then you would want to use relativistic formulas. If your expected precision is only 10%, you need relativity if $(K/mc^2) \gtrsim 0.1$.

**EXERCISE H** For 1% accuracy, does an electron with $K = 100$ eV need to be treated relativistically? [*Hint*: The mass of an electron is 0.511 MeV.]

**EXERCISE I** For what value of $v$ will $K/mc^2 = 0.10$?

# 36–12 Doppler Shift for Light

In Section 16–7 we discussed how the frequency and wavelength of sound are altered if the source of the sound and the observer are moving toward or away from each other. When a source is moving toward us, the frequency is higher than when the source is at rest. If the source moves away from us, the frequency is lower. We obtained four different equations for the Doppler shift (Eqs. 16–9a and b, Eqs. 16–10a and b), depending on the direction of the relative motion and whether the source or the observer is moving. The Doppler effect occurs also for light; but the shifted frequency or wavelength is given by slightly different equations, and there are only two of them, because for light—according to special relativity—we can make no distinction between motion of the source and motion of the observer. (Recall that sound must travel in a medium such as air, whereas light does not need a medium—there is no evidence for an ether.)

To derive the Doppler shift for light, let us consider a light source and an observer that move toward each other, and let their relative velocity be $v$ as measured in the reference frame of either the source or the observer. Figure 36–15a shows a source at rest emitting light waves of frequency $f_0$ and wavelength $\lambda_0 = c/f_0$. Two wavecrests are shown, a distance $\lambda_0$ apart, the second crest just having been emitted. In Fig. 36–15b, the source is shown moving at speed $v$ toward a stationary observer who will see the wavelength $\lambda$ being somewhat less than $\lambda_0$. (This is much like Fig. 16–19 for sound.) Let $\Delta t$ represent the time between crests as detected by the observer, whose reference frame is shown in Fig. 36–15b. From Fig. 36–15b we see that

$$\lambda = c\,\Delta t - v\,\Delta t,$$

where $c\,\Delta t$ is the distance crest 1 has moved in the time $\Delta t$ after it was emitted, and $v\,\Delta t$ is the distance the source has moved in time $\Delta t$. So far our derivation has not differed from that for sound (Section 16–7). Now we invoke the theory of relativity. The time between emission of wavecrests has undergone time dilation:

$$\Delta t = \Delta t_0/\sqrt{1 - v^2/c^2}$$

where $\Delta t_0$ is the time between emissions of wavecrests in the reference frame where the source is at rest (the "proper" time). In the source's reference frame (Fig. 36–15a), the time between emissions of the two crests is

$$\Delta t_0 = \frac{1}{f_0} = \frac{\lambda_0}{c}$$

(Eqs. 5–2 and 31–14). Thus

$$\lambda = (c - v)\,\Delta t = (c - v)\,\frac{\Delta t_0}{\sqrt{1 - v^2/c^2}} = \frac{(c - v)}{\sqrt{c^2 - v^2}}\,\lambda_0$$

or

$$\lambda = \lambda_0\sqrt{\frac{c - v}{c + v}}. \qquad \left[\begin{array}{c}\text{source and observer}\\ \text{moving toward}\\ \text{each other}\end{array}\right] \qquad \textbf{(36–15a)}$$

The frequency $f$ is (recall $\lambda_0 = c/f_0$)

$$f = \frac{c}{\lambda} = f_0\sqrt{\frac{c + v}{c - v}}. \qquad \left[\begin{array}{c}\text{source and observer}\\ \text{moving toward}\\ \text{each other}\end{array}\right] \qquad \textbf{(36–15b)}$$

Here $f_0$ is the frequency of the light as seen in the source's reference frame, and $f$ is the frequency as measured by an observer moving toward the source or toward whom the source is moving. Equations 36–15 depend only on the relative velocity $v$.

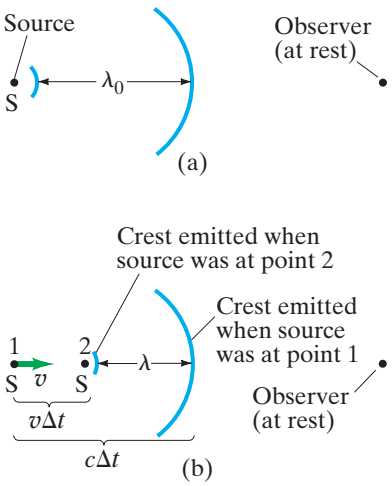

**FIGURE 36–15** Doppler shift for light. (a) Source and observer at rest. (b) Source moving toward stationary observer.

For relative motion *away* from each other we set $v < 0$ in Eqs. 36–15, and obtain

$$\lambda = \lambda_0 \sqrt{\frac{c + v}{c - v}} \qquad \text{(36–16a)}$$

$$f = f_0 \sqrt{\frac{c - v}{c + v}}. \qquad \text{(36–16b)}$$

[source and observer moving away from each other]

From Eqs. 36–15 and 36–16 we see that light from a source moving *toward* us will have a higher frequency and shorter wavelength, whereas if a light source moves *away* from us, we will see a lower frequency and a longer wavelength. In the latter case, visible light will have its wavelength lengthened toward the red end of the visible spectrum (Fig. 32–26), an effect called a **redshift**. As we will see in the next Chapter, all atoms have their own distinctive signature in terms of the frequencies of the light they emit. More than a century ago it was observed that radiation from atoms in distant galaxies is redshifted. That is, the frequencies of light observed are lower than those emitted by stationary atoms on Earth, suggesting that the galaxies are receding from us. This is the origin of the idea that the universe is expanding, first proposed by the Belgian physics professor and Catholic priest George Lemaître (1894–1966) in 1927.

**EXAMPLE 36–13** **Speeding through a red light.** A driver claims that he did not go through a red light because the light was Doppler shifted and appeared green. Calculate the speed of a driver in order for a red light to appear green.

**APPROACH** We apply the Doppler shift equation for red light ($\lambda_0 \approx 650\,\text{nm}$) and green light ($\lambda \approx 500\,\text{nm}$).

**SOLUTION** Equation 36–15a holds for the source and the object moving toward each other:

$$\lambda = \lambda_0 \sqrt{\frac{c - v}{c + v}}.$$

We square this equation:

$$\frac{c - v}{c + v} = \left(\frac{\lambda}{\lambda_0}\right)^2$$

where $(\lambda/\lambda_0)^2 = (500\,\text{nm}/650\,\text{nm})^2 = 0.59$. We solve for $v$:

$$v = c\left[\frac{1 - (\lambda/\lambda_0)^2}{1 + (\lambda/\lambda_0)^2}\right] = 0.26c.$$

With this defense, the driver might not be guilty of running a red light, but he would clearly be guilty of speeding.

## 36–13 The Impact of Special Relativity

A great many experiments have been performed to test the predictions of the special theory of relativity. Within experimental error, no contradictions have been found. Scientists have therefore accepted relativity as an accurate description of nature.

At speeds much less than the speed of light, the relativistic formulas reduce to the old classical ones, as we have discussed. We would, of course, hope—or rather, insist—that this be true since Newtonian mechanics works so well for objects moving with speeds $v \ll c$. This insistence that a more general theory (such as relativity) give the same results as a more restricted theory (such as classical mechanics which works for $v \ll c$) is called the **correspondence principle**. The two theories must correspond where their realms of validity overlap. Relativity thus does not contradict classical mechanics. Rather, it is a more general theory, of which classical mechanics is now considered to be a limiting case.

The importance of relativity is not simply that it gives more accurate results, especially at very high speeds. Much more than that, it has changed the way we view the world. The concepts of space and time are now seen to be relative, and intertwined with one another, whereas before they were considered absolute and separate. Even our concepts of matter and energy have changed: either can be converted to the other. The impact of relativity extends far beyond physics. It has influenced the other sciences, and even the world of art and literature; it has, indeed, entered the general culture.

From a practical point of view, we do not have much opportunity in our daily lives to use the mathematics of relativity. For example, the $\gamma$ factor $1/\sqrt{1 - v^2/c^2}$, which appears in relativistic formulas, has a value of only 1.005 even for a speed as high as $0.10c = 3.0 \times 10^7$ m/s, giving a correction of less than 1%. For speeds less than $0.10c$, or unless mass and energy are interchanged, we don't usually need to use the more complicated relativistic formulas, and can use the simpler classical formulas.

The special theory of relativity we have studied in this Chapter deals with inertial (nonaccelerating) reference frames. In Chapter 44 we will briefly discuss the more complicated "general theory of relativity" which deals with noninertial reference frames.

# Summary

An **inertial reference frame** is one in which Newton's law of inertia holds. Inertial reference frames move at constant velocity relative to one another. Accelerating reference frames are **noninertial**.

The **special theory of relativity** is based on two principles: the **relativity principle**, which states that the laws of physics are the same in all inertial reference frames, and the principle of the **constancy of the speed of light**, which states that the speed of light in empty space has the same value in all inertial reference frames.

One consequence of relativity theory is that two events that are simultaneous in one reference frame may not be simultaneous in another. Other effects are **time dilation**: moving clocks are measured to run slow; and **length contraction**: the length of a moving object is measured to be shorter (in its direction of motion) than when it is at rest. Quantitatively,

$$\Delta t = \frac{\Delta t_0}{\sqrt{1 - v^2/c^2}} = \gamma \, \Delta t_0 \qquad \textbf{(36–1)}$$

$$\ell = \ell_0 \sqrt{1 - v^2/c^2} = \frac{\ell_0}{\gamma} \qquad \textbf{(36–3)}$$

where $\ell$ and $\Delta t$ are the length and time interval of objects (or events) observed as they move by at the speed $v$. The quantities $\ell_0$ and $\Delta t_0$ are the **proper length** and **proper time**—that is, the same quantities as measured in the rest frame of the objects or events. The quantity $\gamma$ is shorthand for

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}}. \qquad \textbf{(36–2)}$$

The theory of relativity has changed our notions of space and time, and of momentum, energy, and mass. Space and time are seen to be intimately connected, with time being the fourth dimension in addition to the three dimensions of space.

The **Lorentz transformations** relate the positions and times $(x, t)$ of events in one inertial reference frame to their positions and times $(x', t')$ in a second inertial reference frame which moves at constant speed $v$ in the positive $x$ direction:

$$\begin{aligned} x &= \gamma(x' + vt') \\ y &= y' \\ z &= z' \\ t &= \gamma\left(t' + \frac{vx'}{c^2}\right) \end{aligned} \qquad \textbf{(36–6)}$$

where $\gamma = 1/\sqrt{1 - v^2/c^2}$.

Velocity addition also must be done in a special way. All these relativistic effects are significant only at high speeds, close to the speed of light, which itself is the ultimate speed in the universe.

The **momentum** of an object is given by

$$p = \gamma m v = \frac{mv}{\sqrt{1 - v^2/c^2}}. \qquad \textbf{(36–8)}$$

Mass and energy are interconvertible. The equation

$$E = mc^2 \qquad \textbf{(36–12)}$$

tells how much energy $E$ is needed to create a mass $m$, or vice versa. Said another way, $E = mc^2$ is the amount of energy an object has because of its mass $m$. The law of conservation of energy must include mass as a form of energy.

The **kinetic energy** $K$ of an object moving at speed $v$ is given by

$$K = (\gamma - 1)mc^2 = \frac{mc^2}{\sqrt{1 - v^2/c^2}} - mc^2 \qquad \textbf{(36–10)}$$

where $m$ is the mass of the object. The total energy $E$, if there is no potential energy, is

$$\begin{aligned} E &= K + mc^2 \\ &= \gamma mc^2. \end{aligned} \qquad \textbf{(36–11)}$$

The momentum $p$ of an object is related to its total energy $E$ (assuming no potential energy) by

$$E^2 = p^2c^2 + m^2c^4. \qquad \textbf{(36–14)}$$

Because $m^2c^4$ is constant, independent of reference frame, $E^2 - p^2c^2$ is **invariant** under a Lorentz transformation.

# Questions

1. You are in a windowless car in an exceptionally smooth train moving at constant velocity. Is there any physical experiment you can do in the train car to determine whether you are moving? Explain.
2. You might have had the experience of being in a car at a red light when, out of the corner of your eye, you see the car beside you creep forward. Instinctively you stomp on the brake pedal, thinking that you are rolling backward. What does this say about absolute and relative motion?
3. A worker stands on top of a railroad car moving at constant velocity and throws a heavy ball straight up (from his point of view). Ignoring air resistance, explain whether the ball will land back in his hand or behind him.
4. Does the Earth really go around the Sun? Or is it also valid to say that the Sun goes around the Earth? Discuss in view of the relativity principle (that there is no best reference frame). Explain. See Section 6–5.
5. If you were on a spaceship traveling at $0.6c$ away from a star, at what speed would the starlight pass you?
6. The time dilation effect is sometimes expressed as "moving clocks run slowly." Actually, this effect has nothing to do with motion affecting the functioning of clocks. What then does it deal with?
7. Does time dilation mean that time actually passes more slowly in moving reference frames or that it only *seems* to pass more slowly?
8. A young-looking woman astronaut has just arrived home from a long trip. She rushes up to an old gray-haired man and in the ensuing conversation refers to him as her son. How might this be possible?
9. If you were traveling away from Earth at speed $0.6c$, would you notice a change in your heartbeat? Would your mass, height, or waistline change? What would observers on Earth using telescopes say about you?
10. Do time dilation and length contraction occur at ordinary speeds, say 90 km/h?
11. What if the speed of light was infinite. What would happen to the relativistic predictions of length contraction and time dilation?
12. Explain how the length contraction and time dilation formulas might be used to indicate that $c$ is the limiting speed in the universe.
13. Discuss how our everyday lives would be different if the speed of light was only 25 m/s.
14. An electron is limited to travel at speeds less than $c$. Does this put an upper limit on the momentum of an electron? If so, what is this upper limit? If not, explain.
15. Can a particle of nonzero mass attain the speed of light? Explain.
16. Does the equation $E = mc^2$ conflict with the conservation of energy principle? Explain.
17. You are traveling in a spaceship at a speed of $0.70c$ away from Earth. You send a laser beam toward the Earth traveling at velocity $c$ relative to you. What do observers on the Earth measure for the speed of the laser beam?
18. If mass is a form of energy, does this mean that a spring has more mass when compressed than when relaxed? Explain.
19. It is not correct to say that "matter can neither be created nor destroyed." What must we say instead?
20. Is our intuitive notion that velocities simply add, as in Section 3–9, completely wrong?
21. The drawing at the start of this Chapter (repeated here) shows the street and my girlfriend as I saw them, with the speed of light pretended to be $c = 100$ km/h. (a) Describe what I and the streetscape look like to my girlfriend as she speeds by at 70 km/h. (b) Also, make a drawing showing the shops from her reference frame. Include both of us.

**FIGURE 36–16** Question 21. Chapter-Opening Figure on page 1055, part b, repeated here.

# MisConceptual Questions

1. Which statement is true concerning the speed of light relative to its source?
   (*a*) Light moves more slowly if emitted by a source moving in the direction of emission.
   (*b*) Light moves faster if emitted by a source moving in the direction of emission.
   (*c*) Light moves more slowly if emitted by a source moving in the direction opposite the emission.
   (*d*) Light moves faster if emitted by a source moving in the direction opposite the emission.
   (*e*) Light moves at the same speed independent of the motion of the source.
2. Which of the following are noninertial frames of reference?
   (*a*) A reference frame that is not moving relative to another inertial frame.
   (*b*) A reference frame that is moving at constant velocity relative to another inertial frame.
   (*c*) A reference frame that is moving at constant acceleration relative to another inertial frame.
   (*d*) A reference frame that is rotating at constant angular velocity relative to another inertial frame.

**3.** The fictional rocket ship *Endurance* is measured to be 50 m long by the ship's captain inside the rocket. When the rocket moves past a space dock at 0.5*c*, space-dock personnel measure the rocket ship to be 43.3 m long. What is its proper length?
(*a*) 50 m.
(*b*) 43.3 m.
(*c*) 93.3 m.
(*d*) 13.3 m.

**4.** As rocket ship *Endurance* (MisConceptual Question 3) passes by the space dock, the ship's captain flashes a flashlight at 1.00-s intervals as measured by space-dock personnel. How far apart in time are the flashes relative to the captain?
(*a*) More than 1.00 s.
(*b*) 1.00 s.
(*c*) Less than 1.00 s.
(*d*) We need to know the distance between the ship and the space dock.

**5.** The rocket ship of MisConceptual Question 3 travels to a star many light-years away, then turns around and returns at the same speed. When it returns to the space dock, who would have aged less: the space-dock personnel or the ship's crew?
(*a*) The space-dock personnel.
(*b*) The ship's crew.
(*c*) Both the same amount, because both sets of people were moving relative to each other.
(*d*) We need to know how far away the star is.

**6.** Relativistic formulas for time dilation, length contraction, and momentum are valid
(*a*) only for speeds less than 0.10*c*.
(*b*) only for speeds greater than 0.10*c*.
(*c*) only for speeds very close to *c*.
(*d*) for all speeds.

**7.** Reference frames A and B are in relative motion. A mass *m* is at rest in B. Observers in both reference frames calculate the particle's momentum and energy, getting different values. This is an example of
(*a*) a situation where momentum is not conserved.
(*b*) a situation where energy is not conserved.
(*c*) Both (*a*) and (*b*) are true.
(*d*) Neither (*a*) nor (*b*) is true.

**8.** In the theory of special relativity, which of the following are not relative?
(*a*) The speed of light in a vacuum.
(*b*) The time interval between two events.
(*c*) The length of an object in its direction of motion.
(*d*) The length of an object perpendicular to its direction of motion.
(*e*) The laws of physics.
(*f*) The simultaneity of events.

**9.** Spaceships A and B are traveling directly toward each other at a speed 0.5*c* relative to the Earth, and each has a headlight aimed toward the other ship. What value do technicians on ship B get by measuring the speed of the light emitted by ship A's headlight?
(*a*) 0.5*c*.
(*b*) 0.80*c*.
(*c*) 1.0*c*.
(*d*) 1.5*c*.

**10.** An Earth observer notes that clocks on a passing spacecraft run slowly. The person on the spacecraft
(*a*) agrees her clocks move slower than those on Earth.
(*b*) feels normal, and her heartbeat and eating habits are normal.
(*c*) observes that Earth clocks are moving slowly.
(*d*) The real time is in between the times measured by the two observers.
(*e*) Both (*a*) and (*b*).
(*f*) Both (*b*) and (*c*).

**11.** Which of the following will two observers in inertial reference frames that move relative to each other always agree on?
(*a*) The time an event occurred.
(*b*) The distance between two events.
(*c*) The time interval between the occurence of two events.
(*d*) The speed of light.
(*e*) The validity of the laws of physics.
(*f*) The simultaneity of two events.

**12.** Two observers in different inertial reference frames moving relative to each other at nearly the speed of light see the same two events but, using precise equipment, record different time intervals between the two events. Which of the following is true of their measurements?
(*a*) One observer is incorrect, but it is impossible to tell which one.
(*b*) One observer is incorrect, and it is possible to tell which one.
(*c*) Both observers are incorrect.
(*d*) Both observers can be correct.

**13.** You are in a spaceship with no windows, radios, or other means to check outside. How could you determine whether your spaceship is at rest or moving at constant velocity?
(*a*) By determining the apparent velocity of light in the spaceship.
(*b*) By checking your precision watch. If it's running slow, then the ship is moving.
(*c*) By measuring the lengths of objects in the spaceship. If they are shortened, then the ship is moving.
(*d*) Give up, because you can't tell.

**14.** The period of a pendulum swinging in a spaceship is 2 s while the spaceship is parked on Earth. What is the period to an observer on Earth when the spaceship moves at 0.6*c* with respect to the Earth?
(*a*) Less than 2 s.
(*b*) More than 2 s.
(*c*) 2 s.

**15.** Two spaceships, each moving at a speed 0.75*c* relative to the Earth, are headed directly toward each other. What do occupants of one ship measure the speed of the other ship to be?
(*a*) 0.96*c*.
(*b*) 1.0*c*.
(*c*) 1.5*c*.
(*d*) 1.75*c*.
(*e*) 0.75*c*.

# Problems

## 36–5 and 36–6 Time Dilation, Length Contraction

1. (I) A certain type of elementary particle travels at a speed of $2.70 \times 10^8$ m/s. At this speed, the average lifetime is measured to be $5.16 \times 10^{-6}$ s. What is the particle's lifetime at rest?
2. (I) A spaceship passes you at a speed of $0.750c$. You measure its length to be 112 m. How long would it be when at rest?
3. (II) You travel to a star 115 light-years from Earth at a speed of $2.90 \times 10^8$ m/s. What do you measure this distance to be?
4. (II) What is the speed of a pion if its average lifetime is measured to be $4.80 \times 10^{-8}$ s? At rest, its average lifetime is $2.60 \times 10^{-8}$ s.
5. (II) In an Earth reference frame, a star is 49 light-years away. How fast would you have to travel so that to you the distance would be only 32 light-years?
6. (II) At what speed $v$ will the length of a 1.00-m stick look 10.0% shorter (90.0 cm)?
7. (II) At what speed do the relativistic formulas for (*a*) length and (*b*) time intervals differ from classical values by 1.00%? (This is a reasonable way to estimate when to use relativistic calculations rather than classical.)
8. (II) You decide to travel to a star 68 light-years from Earth at a speed that tells you the distance is only 25 light-years. How many years would it take you to make the trip?
9. (II) A friend speeds by you in her spacecraft at a speed of $0.670c$. It is measured in your frame to be 4.80 m long and 1.35 m high. (*a*) What will be its length and height at rest? (*b*) How many seconds elapsed on your friend's watch when 20.0 s passed on yours? (*c*) How fast did you appear to be traveling according to your friend? (*d*) How many seconds elapsed on your watch when she saw 20.0 s pass on hers?
10. (II) A star is 23.5 light-years from Earth. How long would it take a spacecraft traveling $0.950c$ to reach that star as measured by observers: (*a*) on Earth, (*b*) on the spacecraft? (*c*) What is the distance traveled according to observers on the spacecraft? (*d*) What will the spacecraft occupants compute their speed to be from the results of (*b*) and (*c*)?
11. (II) A fictional news report stated that starship *Enterprise* had just returned from a 5-year voyage while traveling at $0.80c$. (*a*) If the report meant 5.0 years of *Earth time*, how much time elapsed on the ship? (*b*) If the report meant 5.0 years of *ship time*, how much time passed on Earth?
12. (II) A box at rest has the shape of a cube 2.4 m on a side. This box is loaded onto the flat floor of a spaceship and the spaceship then flies past us with a horizontal speed of $0.80c$. What is the volume of the box as we observe it?
13. (II) Escape velocity from the Earth is 11.2 km/s. What would be the percent decrease in length of a 73.6-m-long spacecraft traveling at that speed as seen from Earth?
14. (II) An unstable particle produced in an accelerator experiment travels at constant velocity, covering 1.00 m in 3.80 ns in the lab frame before changing ("decaying") into other particles. In the rest frame of the particle, determine (*a*) how long it lived before decaying, (*b*) how far it moved before decaying.
15. (II) How fast must a pion be moving on average to travel 28 m before it decays? The average lifetime, at rest, is $2.6 \times 10^{-8}$ s.
16. (III) When at rest, a spaceship has the form of an isosceles triangle whose two equal sides have length $\ell$ and whose base has length $1.5\ell$. At what speed is this spaceship traveling past you (parallel to its base) if it appears to be an equilateral triangle?
17. (III) When it is stationary, the half-life of a certain subatomic particle is $T_0$. That is, if $N$ of these particles are present at a certain time, then a time $T_0$ later only $N/2$ particles will be present, assuming the particles are at rest. A beam carrying $N$ such particles per second is created at position $x = 0$ in a high-energy physics laboratory. This beam travels along the $x$ axis at speed $v$ in the laboratory reference frame and it is found that only $N/2$ particles per second travel in the beam at $x = 2cT_0$, where $c$ is the speed of light. Find the speed $v$ of the particles within the beam.

## 36–8 Lorentz Transformations

18. (I) An observer on Earth sees an alien vessel approach at a speed of $0.70c$. The fictional starship *Enterprise* comes to the rescue (Fig. 36–17), overtaking the aliens while moving directly toward Earth at a speed of $0.90c$ relative to Earth. What is the relative speed of one vessel as seen by the other?

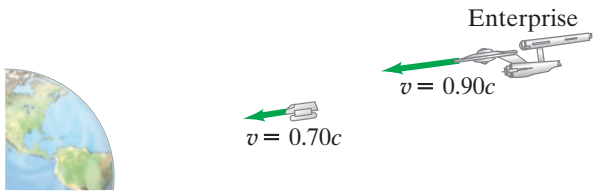

**FIGURE 36–17** Problem 18.

19. (I) Suppose in Fig. 36–12 that the origins of S and S′ overlap at $t = t' = 0$ and that S′ moves at speed $v = 30$ m/s with respect to S. In S′, a person is resting at a point whose coordinates are $x' = 25$ m, $y' = 20$ m, and $z' = 0$. Calculate this person's coordinates in S $(x, y, z)$ at (*a*) $t = 3.5$ s, (*b*) $t = 10.0$ s. Use the Galilean transformation.
20. (I) Repeat Problem 19 using the Lorentz transformation and a relative speed $v = 1.60 \times 10^8$ m/s, but choose the time $t$ to be (*a*) 3.5 $\mu$s and (*b*) 10.0 $\mu$s.
21. (II) In Problem 20, suppose that the person moves with a velocity whose components are $u'_x = u'_y = 1.30 \times 10^8$ m/s. What will be her velocity with respect to S? (Give magnitude and direction.)
22. (II) Two spaceships leave Earth in opposite directions, each with a speed of $0.50c$ with respect to Earth. (*a*) What is the velocity of spaceship 1 relative to spaceship 2? (*b*) What is the velocity of spaceship 2 relative to spaceship 1?
23. (II) A spaceship leaves Earth traveling at $0.66c$. A second spaceship leaves the first at a speed of $0.87c$ with respect to the first. Calculate the speed of the second ship with respect to Earth if it is fired (*a*) in the same direction the first spaceship is already moving, (*b*) directly backward toward Earth.

24. (II) Reference frame S′ moves at speed $v = 0.88c$ in the $+x$ direction with respect to reference frame S. The origins of S and S′ overlap at $t = t' = 0$. An object is stationary in S′ at position $x' = 100\,\text{m}$. What is the position of the object in S when the clock in S reads $1.00\,\mu\text{s}$ according to the (*a*) Galilean and (*b*) Lorentz transformation equations?

25. (II) A spaceship traveling at $0.76c$ away from Earth fires a module with a speed of $0.85c$ at right angles to its own direction of travel (as seen by the spaceship). What is the speed of the module, and its direction of travel (relative to the spaceship's direction), seen by an observer on Earth?

26. (II) Your spaceship, traveling at $0.85c$, needs to launch a probe out the forward hatch so that its speed relative to the planet that you are approaching is $0.95c$. With what speed must it leave your ship?

27. (II) A stick of length $\ell_0$, at rest in reference frame S, makes an angle $\theta$ with the $x$ axis. In reference frame S′, which moves to the right with velocity $\vec{\mathbf{v}} = v\hat{\mathbf{i}}$ with respect to S, determine (*a*) the length $\ell$ of the stick, and (*b*) the angle $\theta'$ it makes with the $x'$ axis.

28. (III) An observer in reference frame S notes that two events are separated in space by 180 m and in time by $0.80\,\mu\text{s}$. How fast must reference frame S′ be moving relative to S in order for an observer in S′ to detect the two events as occurring at the same location in space?

29. (III) In the old West, a marshal riding on a train traveling 35.0 m/s sees a duel between two men standing on the Earth 55.0 m apart parallel to the train. The marshal's instruments indicate that in his reference frame the two men fired simultaneously. (*a*) Which of the two men, the first one the train passes (A) or the second one (B) should be arrested for firing the first shot? That is, in the gunfighter's frame of reference, who fired first? (*b*) How much earlier did he fire? (*c*) Who was struck first?

30. (III) If a particle moves in the $xy$ plane of system S (Fig. 36–12) with speed $u$ in a direction that makes an angle $\theta$ with the $x$ axis, show that it makes an angle $\theta'$ in S′ given by $\tan\theta' = (\sin\theta)\sqrt{1 - v^2/c^2}/(\cos\theta - v/u)$.

31. (III) Two lightbulbs, A and B, are placed at rest on the $x$ axis at positions $x_\text{A} = 0$ and $x_\text{B} = +\ell$. In this reference frame, the bulbs are turned on simultaneously. Use the Lorentz transformations to find an expression for the time interval between when the bulbs are turned on as measured by an observer moving at velocity $v$ in the $+x$ direction. According to this observer, which bulb is turned on first?

32. (III) A farm boy studying physics believes that he can fit a 13.0-m-long pole into a 10.0-m-long barn if he runs fast enough, carrying the pole. Can he do it? Explain in detail. How does this fit with the idea that when he is running the barn looks even shorter than 10.0 m?

## 36–9 Relativistic Momentum

33. (I) What is the momentum of a proton traveling at $v = 0.72c$?

34. (II) (*a*) A particle travels at $v = 0.10c$. By what percentage will a calculation of its momentum be wrong if you use the classical formula? (*b*) Repeat for $v = 0.50c$.

35. (II) A particle of mass $m$ travels at a speed $v = 0.32c$. At what speed will its momentum be doubled?

36. (II) An unstable particle is at rest and suddenly decays into two fragments. No external forces act on the particle or its fragments. One of the fragments has a speed of $0.53c$ and a mass of $6.68 \times 10^{-27}\,\text{kg}$, while the other has a mass of $1.67 \times 10^{-27}\,\text{kg}$. What is the speed of the less massive fragment?

37. (II) What is the percent change in momentum of a proton that accelerates (*a*) from $0.45c$ to $0.80c$, (*b*) from $0.80c$ to $0.98c$?

## 36–11 $E = mc^2$; Mass and Energy

38. (I) Calculate the rest energy of an electron $(m = 9.11 \times 10^{-31}\,\text{kg})$ in joules and in MeV $(1\,\text{MeV} = 1.60 \times 10^{-13}\,\text{J})$.

39. (I) When a uranium nucleus at rest breaks apart in the process known as fission in a nuclear reactor, the resulting fragments have a total kinetic energy of about 200 MeV. How much mass (kg) was lost in the process?

40. (I) The total annual energy consumption in the United States is about $1 \times 10^{20}\,\text{J}$. How much mass would have to be converted to energy to fuel this need?

41. (II) Suppose there was a process by which two photons, each with momentum $0.75\,\text{MeV}/c$, could collide and make a single particle. (Photons are particles of light with mass $m = 0$; see next Chapter.) What is the maximum mass (kg) that the particle could possess?

42. (II) (*a*) How much work is required to accelerate a proton from rest up to a speed of $0.995c$? (*b*) What would be the momentum of this proton?

43. (II) A proton is traveling in an accelerator with a speed of $1.0 \times 10^8\,\text{m/s}$. By what factor does the proton's kinetic energy increase if its speed is doubled?

44. (II) What is the speed of an electron after being accelerated from rest by 28,000 V?

45. (II) To accelerate a particle of mass $m$ from rest to speed $0.90c$ requires work $W_1$. To accelerate the particle from speed $0.90c$ to $0.99c$, requires work $W_2$. Determine the ratio $W_2/W_1$.

46. (II) How much energy can be obtained from conversion of 1.0 gram of mass? How much mass could this energy raise to a height of 1.0 km above the Earth's surface?

47. (II) What is the momentum of a 950-MeV proton (that is, its kinetic energy is 950 MeV)?

48. (II) What is the speed of a particle when its kinetic energy equals its rest energy? Does the mass of the particle affect the result?

49. (II) What is the speed of an electron whose kinetic energy is 1.45 MeV?

50. (II) Two identical particles of mass $m$ approach each other at equal and opposite speeds, $v$. The collision is completely inelastic and results in a single particle at rest. What is the mass of the new particle? How much energy was lost in the collision? How much kinetic energy was lost in this collision?

51. (II) The kinetic energy of a particle is 45 MeV. If its momentum is $121\,\text{MeV}/c$, what is the particle's mass?

52. (II) Calculate the speed of a proton $(m = 1.67 \times 10^{-27}\,\text{kg})$ whose kinetic energy is exactly half (*a*) its total energy, (*b*) its rest energy.

**53.** (II) Calculate the kinetic energy and momentum of a proton $(m = 1.67 \times 10^{-27}\,\text{kg})$ traveling $7.85 \times 10^7\,\text{m/s}$. By what percentages would your calculations have been in error if you had used classical formulas?

**54.** (II) Suppose a spacecraft of mass 17,000 kg was accelerated to $0.22c$. (*a*) How much kinetic energy would it have? (*b*) If you used the classical formula for kinetic energy, by what percentage would you be in error?

**55.** (II) The americium nucleus, $^{241}_{95}\text{Am}$, decays to a neptunium nucleus, $^{237}_{93}\text{Np}$, by emitting an alpha particle of mass 4.00260 u and kinetic energy 5.5 MeV. Estimate the mass of the neptunium nucleus, ignoring its recoil, given that the americium mass is 241.05682 u.

**56.** (II) Make a graph of the kinetic energy versus momentum for (*a*) a particle of nonzero mass, and (*b*) a particle with zero mass.

**57.** (II) A negative muon traveling at 38% the speed of light collides head on with a positive muon traveling at 55% the speed of light. The two muons (each of mass $105.7\,\text{MeV}/c^2$) annihilate, and produce how much electromagnetic energy?

**58.** (II) Show that the kinetic energy $K$ of a particle of mass $m$ is related to its momentum $p$ by the equation

$$p = \sqrt{K^2 + 2Kmc^2}/c.$$

**59.** (II) The fictional starship *Enterprise* obtains its power by combining matter and antimatter, achieving complete conversion of mass into energy. If the mass of the *Enterprise* is approximately $4 \times 10^9\,\text{kg}$, how much mass must be converted into kinetic energy to accelerate it from rest to one-tenth the speed of light?

**60.** (III) (*a*) In reference frame S, a particle has momentum $\vec{\mathbf{p}} = p_x\,\hat{\mathbf{i}}$ along the positive $x$ axis. Show that in frame S′, which moves with speed $v$ as in Fig. 36–12, the momentum has components

$$p'_x = \frac{p_x - vE/c^2}{\sqrt{1 - v^2/c^2}}$$
$$p'_y = p_y$$
$$p'_z = p_z$$
$$E' = \frac{E - p_x v}{\sqrt{1 - v^2/c^2}}.$$

(These transformation equations hold, actually, for any direction of $\vec{\mathbf{p}}$, as long as the motion of S′ is along the $x$ axis.) (*b*) Show that $p_x, p_y, p_z, E/c$ transform according to the Lorentz transformation in the same way as $x, y, z, ct$.

### 36–12 Doppler Shift for Light

**61.** (II) A certain galaxy has a Doppler shift given by $f_0 - f = 0.1015 f_0$. Estimate how fast it is moving away from us.

**62.** (II) A spaceship moving toward Earth at $0.65c$ transmits radio signals at 95.0 MHz. At what frequency should Earth receivers be tuned?

**63.** (II) Starting from Eq. 36–16a, show that the Doppler shift in wavelength is, if $v \ll c$,

$$\frac{\Delta\lambda}{\lambda} = \frac{v}{c}.$$

**64.** (III) A radar "speed gun" emits microwaves of frequency $f_0 = 36.0\,\text{GHz}$. When the gun is pointed at an object moving toward it at speed $v$, the object senses the microwaves at the Doppler-shifted frequency $f$. The moving object reflects these microwaves at this same frequency $f$. The stationary radar apparatus detects these reflected waves at a (double) Doppler-shifted frequency $f'$. The gun combines its emitted wave at $f_0$ and its detected wave at $f'$. These waves interfere, creating a beat pattern whose beat frequency is $f_{\text{beat}} = f' - f_0$. (*a*) Show that

$$v \approx \frac{c f_{\text{beat}}}{2 f_0},$$

if $f_{\text{beat}} \ll f_0$. If $f_{\text{beat}} = 6670\,\text{Hz}$, what is $v$ (km/h)? (*b*) If the object's speed is different by $\Delta v$, show that the difference in beat frequency $\Delta f_{\text{beat}}$ is given by

$$\Delta f_{\text{beat}} = \frac{2 f_0\,\Delta v}{c}.$$

If the accuracy of the speed gun is to be 1 km/h, to what accuracy must the beat frequency be measured?

**65.** (III) A certain atom emits light of frequency $f_0$ when at rest. A monatomic gas composed of these atoms is at temperature $T$. Some of the gas atoms move toward, and others away from, an observer due to their random thermal motion. Using the rms speed of thermal motion, (*a*) show that the fractional difference between the Doppler-shifted frequencies for atoms moving directly toward the observer and directly away from the observer is $\Delta f/f_0 \approx 2\sqrt{3kT/mc^2}$. Assume $mc^2 \gg 3kT$. (*b*) Evaluate $\Delta f/f_0$ for a gas of hydrogen atoms at 650 K. [This "Doppler-broadening" effect is commonly used to measure gas temperature, such as in astronomy.]

## General Problems

**66.** An atomic clock is taken to the North Pole, while another stays at the Equator. How far will they be out of synchronization after 1.5 years has elapsed? [*Hint*: Use the binomial expansion, Appendix A–2.]

**67.** An airplane travels 1500 km/h around the Earth in a circle of radius essentially equal to that of the Earth, returning to the same place. Using special relativity, estimate the difference in time to make the trip as seen by Earth and airplane observers. [*Hint*: Use the binomial expansion, Appendix A–2.]

**68.** The nearest star to Earth is Proxima Centauri, 4.3 light-years away. (*a*) At what constant velocity must a spacecraft travel from Earth if it is to reach the star in 5.5 years, as measured by travelers on the spacecraft? (*b*) How long does the trip take according to Earth observers?

**69.** An electron $(m = 9.11 \times 10^{-31}\,\text{kg})$ is accelerated from rest to speed $v$ by a conservative force. In this process, its potential energy decreases by $7.20 \times 10^{-14}\,\text{J}$. Determine the electron's speed, $v$.

70. A healthy astronaut's heart rate is 60 beats/min. Flight doctors on Earth can monitor an astronaut's vital signs remotely while in flight. How fast would an astronaut be flying away from Earth if the doctor measured her heart rate as 52 beats/min?

71. A spacecraft (reference frame S′) moves past Earth (reference frame S) at velocity $\vec{\mathbf{v}}$, which points along the $x$ and $x'$ axes. The spacecraft emits a light beam (speed $c$) along its $y'$ axis as shown in Fig. 36–18. (*a*) What angle $\theta$ does this light beam make with the $x$ axis in the Earth's reference frame? (*b*) Use velocity transformations to show that the light moves with speed $c$ also in the Earth's reference frame. (*c*) Compare these relativistic results to what you would have obtained classically (Galilean transformations).

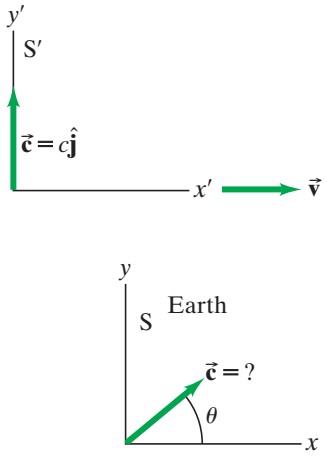

**FIGURE 36–18** Problem 71.

72. Rocket A passes Earth at a speed of $0.65c$. At the same time, rocket B passes Earth moving $0.90c$ relative to Earth in the same direction. How fast is B moving relative to A when it passes A?

73. (*a*) What is the speed $v$ of an electron whose kinetic energy is 14,000 times its rest energy? You can state the answer as the difference $c - v$. Such speeds have been reached in the Stanford Linear Accelerator, SLAC. (*b*) If the electrons travel in the lab through a tube 3.0 km long (as at SLAC), how long is this tube in the electrons' reference frame? [*Hint*: Use the binomial expansion.]

74. As a rough rule, anything traveling faster than about $0.1c$ is called *relativistic*—that is, special relativity is a significant effect. Determine the speed of an electron in a hydrogen atom (radius $0.53 \times 10^{-10}$ m) and state whether or not it is relativistic. (Treat the electron as though it were in a circular orbit around the proton.)

75. What minimum amount of electromagnetic energy is needed to produce an electron and a positron together? A positron is a particle with the same mass as an electron, but has the opposite charge. (Note that electric charge is conserved in this process. See Section 37–5.)

76. How many grams of matter would have to be totally destroyed to run a 15-W lightbulb for 1.0 year?

77. If $E$ is the total energy of a particle with zero potential energy, show that $dE/dp = v$, where $p$ and $v$ are the momentum and velocity of the particle, respectively.

78. A free neutron can decay into a proton, an electron, and a neutrino. Assume the neutrino's mass is zero; the other masses can be found in the Table inside the front cover. Determine the total kinetic energy shared among the three particles when a neutron decays at rest.

79. The Sun radiates energy at a rate of about $4 \times 10^{26}$ W. (*a*) At what rate is the Sun's mass decreasing? (*b*) How long does it take for the Sun to lose a mass equal to that of Earth? (*c*) Estimate how long the Sun could last if it radiated constantly at this rate.

80. An unknown particle is measured to have a negative charge and a speed of $2.24 \times 10^8$ m/s. Its momentum is determined to be $3.07 \times 10^{-22}$ kg · m/s. Identify the particle by finding its mass. See inside the front cover.

81. How much energy would be required to break a helium nucleus into its constituents, two protons and two neutrons? The rest masses of a proton (including an electron), a neutron, and neutral helium are, respectively, 1.00783 u, 1.00867 u, and 4.00260 u. (This energy difference is called the *total binding energy* of the ${}^4_2\text{He}$ nucleus.)

82. Show analytically that a particle with momentum $p$ and energy $E$ has a speed given by

$$v = \frac{pc^2}{E} = \frac{pc}{\sqrt{m^2c^2 + p^2}}.$$

83. Two protons, each having a speed of $0.945c$ in the laboratory, are moving toward each other. Determine (*a*) the momentum of each proton in the laboratory, (*b*) the total momentum of the two protons in the laboratory, and (*c*) the momentum of one proton as seen by the other proton.

84. Suppose a 14,500-kg spaceship left Earth at a speed of $0.80c$. What is the spaceship's kinetic energy? Compare with the total U.S. annual energy consumption (about $10^{20}$ J).

85. A pi meson of mass $m_\pi$ decays at rest into a muon (mass $m_\mu$) and a neutrino of negligible or zero mass. Show that the kinetic energy of the muon is $K_\mu = (m_\pi - m_\mu)^2c^2/(2m_\pi)$.

86. When two moles of hydrogen molecules ($H_2$) and one mole of oxygen molecules ($O_2$) react to form two moles of water ($H_2O$), the energy released is 484 kJ. How much does the mass decrease in this reaction? What % of the total original mass is this?

87. A quasar emits familiar hydrogen lines whose wavelengths are 8.5% longer than what we measure in the laboratory. (*a*) Using the Doppler formula for light, estimate the speed of this quasar. (*b*) What result would you obtain if you used the "classical" Doppler shift discussed in Chapter 16?

88. A spaceship and its occupants have a total mass of 160,000 kg. The occupants would like to travel to a star that is 32 light-years away at a speed of $0.70c$. To accelerate, the engine of the spaceship changes mass directly to energy. (*a*) Estimate how much mass will be converted to energy to accelerate the spaceship to this speed. (*b*) Assuming the acceleration is rapid, so the speed for the entire trip can be taken to be $0.70c$, determine how long the trip will take according to the astronauts on board.

89. A 42,000-kg spaceship is to travel to the vicinity of a star 6.6 light-years from Earth. Passengers on the ship want the (one-way) trip to take no more than 1.0 year. How much work must be done on the spaceship to bring it to the speed necessary for this trip?

**90.** For a 1.0-kg mass, make a plot of the kinetic energy as a function of speed for speeds from 0 to $0.9c$, using both the classical formula $\left(K = \frac{1}{2}mv^2\right)$ and the correct relativistic formula $\left(K = (\gamma - 1)mc^2\right)$.

**91.** Examine the experiment of Fig. 36–6 from $O_1$'s reference frame. In this case, $O_1$ will be at rest and will see the lightning bolt at $B_1$ and $B_2$ before the lightning bolt at $A_1$ and $A_2$. Will $O_1$ recognize that $O_2$, who is moving with speed $v$ to the left, will see the two events as simultaneous? Explain in detail, drawing diagrams equivalent to Fig. 36–6. [*Hint*: Include length contraction.]

**92.** Using Example 36–2 as a guide, show that for objects that move slowly in comparison to $c$, the length contraction formula is roughly $\ell \approx \ell_0\left(1 - \frac{1}{2}v^2/c^2\right)$. Use this approximation to find the "length shortening" $\Delta\ell = \ell_0 - \ell$ of the train in Example 36–6 if the train travels at 100 km/h (rather than $0.92c$).

**93.** In Example 36–5, the spaceship is moving at $0.90c$ in the horizontal direction relative to an observer on the Earth. If instead the spaceship moved at $0.90c$ directed at 35° above the horizontal, what would be the painting's dimensions as seen by the observer on Earth?

**94.** Protons from outer space crash into the Earth's atmosphere at a high rate and create particles that eventually decay into other particles called *muons*. These "cosmic rays" travel through the atmosphere. Every second, dozens of muons pass through your body. If a muon is created 30 km above the Earth's surface, what minimum speed and kinetic energy must the muon have in order to hit Earth's surface? A muon's mean lifetime (at rest) is 2.20 $\mu$s and its mass is 105.7 MeV/$c^2$.

**95.** An astronaut on a spaceship traveling at $0.75c$ relative to Earth measures his ship to be 35 m long. On the ship, he eats his lunch in 25 min. (*a*) What length is the spaceship according to observers on Earth? (*b*) How long does the astronaut's lunch take to eat according to observers on Earth?

**96.** At what rate is the Sun losing mass? Energy reaches Earth $1.5 \times 10^{11}$ m from the Sun at the rate of 1300 W/m$^2$.

**97.** A 0.30-kg meter stick moving parallel to its length passes you at high speed. You measure its length to be 48.0 cm. What is its kinetic energy?

**98.** Astronomers measure the distance to a particular star to be 6.0 light-years (1 ly = distance light travels in 1 year). A spaceship travels from Earth to the vicinity of this star at steady speed, arriving in 3.25 years as measured by clocks on the spaceship. (*a*) How long does the trip take as measured by clocks in Earth's reference frame? (*b*) What distance does the spaceship travel as measured in its own reference frame?

**99.** An electron is accelerated so that its kinetic energy is greater than its rest energy $mc^2$ by a factor of (*a*) 5.00, (*b*) 999. What is the speed of the electron in each case?

**100.** A 2.42-kg mass oscillates on the end of a spring whose spring stiffness constant is $k = 84.2$ N/m. If this system is in a spaceship moving past Earth at $0.900c$, what is its period of oscillation according to (*a*) observers on the ship, and (*b*) observers on Earth?

**101.** Show that the space-time interval, $(c\,\Delta t)^2 - (\Delta x)^2$, is invariant, meaning that all observers in all inertial reference frames calculate the same number for this quantity for any pair of events.

**102.** A slab of glass with index of refraction $n$ moves to the right with speed $v$. A flash of light is emitted at point A (Fig. 36–19) and passes through the glass arriving at point B a distance $\ell$ away. The glass has thickness $d$ in the reference frame where it is at rest, and the speed of light in the glass is $c/n$. How long does it take the light to go from point A to point B according to an observer at rest with respect to points A and B? Check your answer for the cases $v = c$, $v = 0$, and $n = 1$.

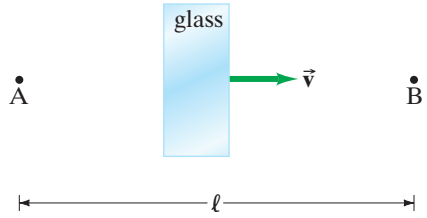

**FIGURE 36–19** Problem 102.

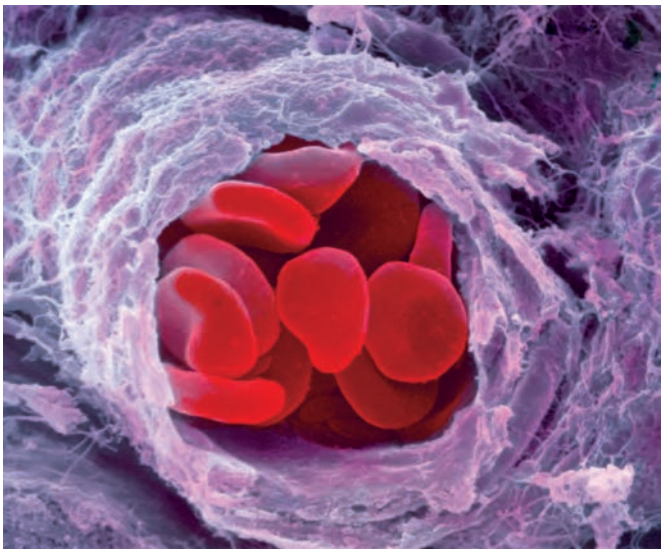
***103.** What magnetic field $B$ is needed to keep 998-GeV protons revolving in a circle of radius 1.0 km? Use the relativistic mass. The proton's "rest mass" is 0.938 GeV/$c^2$. (1 GeV = $10^9$ eV.) [*Hint*: In relativity, $m_{\text{rel}}v^2/r = qvB$ is still valid in a magnetic field, where $m_{\text{rel}} = \gamma m$.]



## ANSWERS TO EXERCISES

**A:** Yes.
**B:** (*c*).
**C:** (*a*) No; (*b*) yes.
**D:** 80 m.
**E:** $0.030c$, same as classical, to an accuracy of better than 0.1%.
**F:** (*d*).
**G:** (*d*).
**H:** No.
**I:** $0.41c$.

Electron microscopes (EM) produce images using electrons which have wave properties just as light does. Because the wavelength of electrons can be much smaller than that of visible light, much greater resolution and magnification can be obtained. A scanning electron microscope (SEM) can produce images with a three-dimensional quality.

All EM images are monochromatic (black and white). Artistic coloring has been added here, as is common. On the left is an SEM image of a blood clot forming (yellow-color web) due to a wound. White blood cells are colored green here for visibility. On the right, red blood cells in a small artery. A red blood cell travels about 15 km a day inside our bodies and lives roughly four months before damage or rupture. Humans contain 4 to 6 liters of blood, and 2 to $3 \times 10^{13}$ red blood cells.

CHAPTER 37

# Early Quantum Theory and Models of the Atom

**CHAPTER-OPENING QUESTION—Guess now!**

It has been found experimentally that

**(a)** light behaves as a wave.
**(b)** light behaves as a particle.
**(c)** electrons behave as particles.
**(d)** electrons behave as waves.
**(e)** all of the above are true.
**(f)** only (a) and (b) are true.
**(g)** only (a) and (c) are true.
**(h)** none of the above are true.

The second aspect of the revolution that shook the world of physics in the early part of the twentieth century was the quantum theory (the other was Einstein's theory of relativity). Unlike the special theory of relativity, the revolution of quantum theory required almost three decades to unfold, and many scientists contributed to its development. It began in 1900 with Planck's quantum hypothesis, used to explain the radiation emitted by hot objects; it culminated in the mid-1920s with the theory of quantum mechanics of Schrödinger and Heisenberg which has been so effective in explaining the structure of matter.

# 37–1 Blackbody Radiation; Planck's Quantum Hypothesis

One of the observations that was unexplained at the end of the nineteenth century was the spectrum of light emitted by hot objects. We saw in Section 19–10 that all objects emit radiation whose total intensity is proportional to the fourth power of the Kelvin (absolute) temperature $(T^4)$. At normal temperatures $(\approx 300\,\text{K})$, we are not aware of this electromagnetic radiation because of its low intensity. At higher temperatures, there is sufficient infrared radiation that we can feel heat if we are close to the object. At still higher temperatures (on the order of 1000 K), objects actually glow, such as a red-hot electric stove burner or the heating element in a toaster. At temperatures above 2000 K, objects glow with a yellow or whitish color, such as white-hot iron and the filament of a lightbulb. The light emitted contains a continuous range of wavelengths or frequencies, and the *spectrum* is a plot of intensity vs. wavelength or frequency. As the temperature increases, the electromagnetic radiation emitted by objects not only increases in total intensity but has its peak intensity at higher and higher frequencies.

The spectrum of light emitted by a hot dense object is shown in Fig. 37–1 for an idealized **blackbody**. A blackbody is a body that would absorb all the radiation falling on it (and so, when cool, would appear black under reflection when illuminated by other sources). The radiation such an idealized blackbody would emit when hot and luminous, called **blackbody radiation** (though not necessarily black in color), approximates that from many real objects. The 6000-K curve in Fig. 37–1, corresponding to the temperature of the surface of the Sun, peaks in the visible part of the spectrum. At lower temperatures, the total intensity drops considerably and the peak occurs at longer wavelengths (or lower frequencies). (This is why objects glow with a red color at around 1000 K.) It is found experimentally that the wavelength at the peak of the spectrum, $\lambda_P$, is related to the Kelvin temperature $T$ by

$$\lambda_P T = 2.90 \times 10^{-3}\,\text{m}\cdot\text{K}. \qquad \textbf{(37–1)}$$

This is known as **Wien's law**.

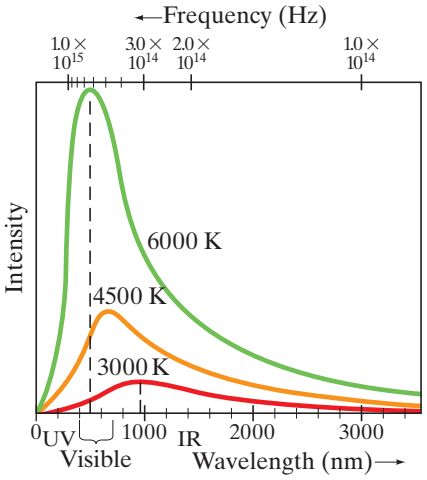

**FIGURE 37–1** Measured spectra of wavelengths and frequencies emitted by a blackbody at three different temperatures.

**EXAMPLE 37–1** **The Sun's surface temperature.** Estimate the temperature of the surface of our Sun, given that the Sun emits light whose peak intensity occurs in the visible spectrum at around 500 nm.

**APPROACH** We assume the Sun acts as a blackbody, and use $\lambda_P = 500\,\text{nm}$ in Wien's law (Eq. 37–1).

**SOLUTION** Wien's law gives

$$T = \frac{2.90 \times 10^{-3}\,\text{m}\cdot\text{K}}{\lambda_P} = \frac{2.90 \times 10^{-3}\,\text{m}\cdot\text{K}}{500 \times 10^{-9}\,\text{m}} \approx 6000\,\text{K}.$$

**EXAMPLE 37–2** **Star color.** Suppose a star has a surface temperature of 32,500 K. What color would this star appear?

**APPROACH** We assume the star emits radiation as a blackbody, and solve for $\lambda_P$ in Wien's law, Eq. 37–1.

**SOLUTION** From Wien's law we have

$$\lambda_P = \frac{2.90 \times 10^{-3}\,\text{m}\cdot\text{K}}{T} = \frac{2.90 \times 10^{-3}\,\text{m}\cdot\text{K}}{3.25 \times 10^{4}\,\text{K}} = 89.2\,\text{nm}.$$

The peak is in the UV range of the spectrum, and will be way to the left in Fig. 37–1. In the visible region, the curve will be descending, so the shortest visible wavelengths will be strongest. Hence the star will appear bluish (or blue-white).

**NOTE** This example helps us to understand why stars have different colors (reddish for the coolest stars, orangish, yellow, white, bluish for "hotter" stars.)

**EXERCISE A** What is the color of an object at 4000 K?

A major problem facing scientists in the 1890s was to explain blackbody radiation. Maxwell's electromagnetic theory had predicted that oscillating electric charges produce electromagnetic waves, and the radiation emitted by a hot object could be due to the oscillations of electric charges in the molecules of the material. Although this would explain where the radiation came from, it did not correctly predict the observed spectrum of emitted light. Two important theoretical curves based on classical ideas were those proposed by W. Wien (in 1896) and by Lord Rayleigh (in 1900). The latter was modified later by J. Jeans and since then has been known as the Rayleigh–Jeans theory. As experimental data came in, it became clear that neither Wien's nor the Rayleigh–Jeans formulations were in accord with experiment (see Fig. 37–2).

In the year 1900 Max Planck (1858–1947) proposed an empirical formula that nicely fit the data (now often called *Planck's radiation formula*):

$$I(\lambda, T) = \frac{2\pi hc^2\lambda^{-5}}{e^{hc/\lambda kT} - 1}.$$

$I(\lambda, T)$ is the radiation intensity as a function of wavelength $\lambda$ at the temperature $T$; $k$ is Boltzman's constant, $c$ is the speed of light, and $h$ is a new constant, now called **Planck's constant**. The value of $h$ was estimated by Planck by fitting his formula for the blackbody radiation curve to experiment (and the fit was excellent). The value accepted today is

$$h = 6.626 \times 10^{-34}\,\text{J}\cdot\text{s}.$$

To provide a theoretical basis for his formula, Planck made a new and radical assumption: that the energy of the oscillations of atoms within molecules cannot have just any value; instead each has energy which is a multiple of a minimum value related to the frequency of oscillation by

$$E = hf.$$

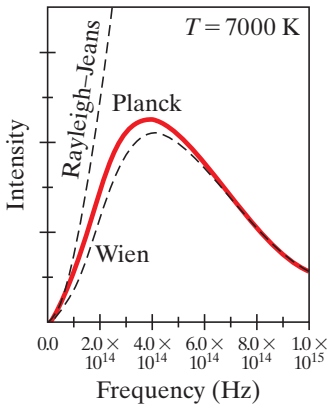
Planck's assumption suggests that the energy of any molecular vibration could be only a whole number multiple of $hf$:

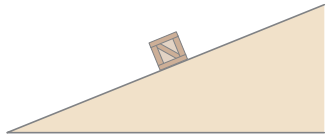
$$E = nhf, \qquad n = 1, 2, 3, \cdots, \tag{37–2}$$

where $n$ is called a **quantum number** ("quantum" means "discrete amount" as opposed to "continuous"). This idea is often called **Planck's quantum hypothesis**, although little attention was brought to this point at the time. In fact, it appears that Planck considered it more as a mathematical device to get the "right answer" rather than as an important discovery. Planck himself continued to seek a classical explanation for the introduction of $h$. The recognition that this was an important and radical innovation did not come until later, after about 1905 when others, particularly Einstein, entered the field.

The quantum hypothesis, Eq. 37–2, states that the energy of an oscillator can be $E = hf$, or $2hf$, or $3hf$, and so on, but there cannot be vibrations with energies between these values. That is, energy would not be a continuous quantity as had been believed for centuries; rather it is **quantized**—it exists only in discrete amounts. The smallest amount of energy possible $(hf)$ is called the **quantum of energy**. Recall from Chapter 14 that the energy of an oscillation is proportional to the amplitude squared. Another way of expressing the quantum hypothesis is that not just any amplitude of vibration is possible. The possible values for the amplitude are related to the frequency $f$.

A simple analogy may help. Compare a ramp, on which a box can be placed at any height, to a flight of stairs on which the box can have only certain discrete amounts of potential energy, as shown in Fig. 37–3. The stairs are "quantized", but the ramp is continuous.





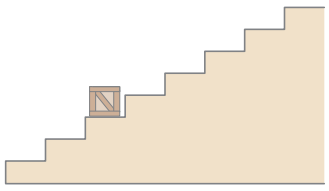


**FIGURE 37–2** Comparison of the Wien and the Rayleigh–Jeans theories to that of Planck, which closely follows experiment. The dashed lines show lack of agreement of older theories.

**CAUTION**
*Quantum vs. continuous*

**FIGURE 37–3** Ramp versus stair analogy. (a) On a ramp, a box can have continuous values of potential energy. (b) But on stairs, the box can have only discrete (quantized) values of energy.

## 37–2 Photon Theory of Light and the Photoelectric Effect

In 1905, the same year that he introduced the special theory of relativity, Einstein made a bold extension of the quantum idea by proposing a new theory of light. Planck's work had suggested that the vibrational energy of molecules in a radiating object is quantized with energy $E = nhf$, where $n$ is an integer and $f$ is the frequency of molecular vibration. Einstein argued that when light is emitted by a molecular oscillator, the molecule's vibrational energy of $nhf$ must decrease by an amount $hf$ (or by $2hf$, etc.) to another integer times $hf$, such as $(n-1)hf$. Then to conserve energy, the light ought to be emitted in packets, or *quanta*, each with an energy

*Photon energy*

$$E = hf, \tag{37–3}$$

where $f$ is here the frequency of the emitted light.

Again $h$ is Planck's constant. Because all light ultimately comes from a radiating source, this idea suggests that *light is transmitted as tiny particles*, or **photons** as they are now called, as well as via the waves predicted by Maxwell's electromagnetic theory. The photon theory of light was a radical departure from classical ideas. Einstein proposed a test of the quantum theory of light: quantitative measurements on the photoelectric effect.

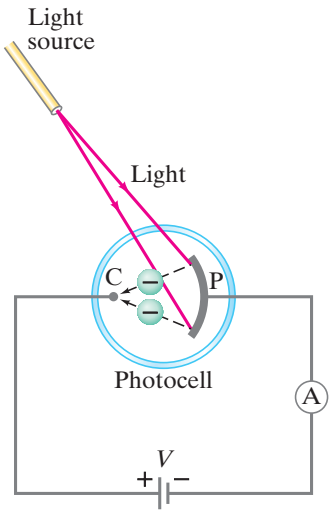

**FIGURE 37–4** The photoelectric effect.

When light shines on a metal surface, electrons are found to be emitted from the surface. This effect is called the **photoelectric effect** and it occurs in many materials, but is most easily observed with metals. It can be observed using the apparatus shown in Fig. 37–4. A metal plate P and a smaller electrode C are placed inside an evacuated glass tube, called a **photocell**. The two electrodes are connected to an ammeter and a source of emf, as shown. When the photocell is in the dark, the ammeter reads zero. But when light of sufficiently high frequency illuminates the plate P, the ammeter indicates a current flowing in the circuit. We explain completion of the circuit by imagining that electrons, ejected from the plate by the impinging radiation, flow across the tube from the plate to the "collector" C as indicated in Fig. 37–4.

That electrons should be emitted when light shines on a metal is consistent with the electromagnetic (EM) wave theory of light: the electric field of an EM wave could exert a force on electrons in the metal and eject some of them. Einstein pointed out, however, that the wave theory and the photon theory of light give very different predictions on the details of the photoelectric effect. For example, one thing that can be measured with the apparatus of Fig. 37–4 is the maximum kinetic energy $(K_{\max})$ of the emitted electrons. This can be done by using a variable voltage source $V$ in Fig. 37–4, and reversing the terminals so that electrode C is negative and P is positive. The electrons emitted from P will be repelled by the negative electrode, but if this reverse voltage is small enough, the fastest electrons will still reach C and there will be a current in the circuit. If the reversed voltage is increased, a point is reached where the current reaches zero—no electrons have sufficient kinetic energy to reach C. This is called the *stopping potential*, or **stopping voltage**, $V_0$, and from its measurement, $K_{\max}$ can be determined using conservation of energy (loss of kinetic energy = gain in potential energy):

$$K_{\max} = eV_0.$$

Now let us examine the details of the photoelectric effect from the point of view of the wave theory versus Einstein's particle theory.

First the wave theory, assuming monochromatic light. The two important properties of a light wave are its intensity and its frequency (or wavelength). When these two quantities are varied, the wave theory makes the following predictions:

*Wave theory predictions*

1. If the light intensity is increased, the number of electrons ejected and their maximum kinetic energy should be increased because the higher intensity means a greater electric field amplitude, and the greater electric field should eject electrons with higher speed.
2. The frequency of the light should not affect the kinetic energy of the ejected electrons. Only the intensity of the incoming light should affect $K_{max}$.

The photon theory makes completely different predictions. First we note that in a monochromatic beam, all photons have the same energy $(= hf)$. Increasing the intensity of the light beam means increasing the number of photons in the beam, but does not affect the energy of each photon as long as the frequency is not changed. According to Einstein's theory, an electron is ejected from the metal by a collision with a single photon. In the process, all the photon energy is transferred to the electron and the photon ceases to exist. Since electrons are held in the metal by attractive forces, some minimum energy $W_0$ is required just to get an electron out through the surface. $W_0$ is called the **work function**, and is a few electron volts $(1\,\text{eV} = 1.6 \times 10^{-19}\,\text{J})$ for most metals. If the frequency $f$ of the incoming light is so low that $hf$ is less than $W_0$, then the photons will not have enough energy to eject any electrons at all. If $hf > W_0$, then electrons will be ejected and energy will be conserved in the process. That is, the input energy (of the photon), $hf$, will equal the outgoing kinetic energy $K$ of the electron plus the energy required to get it out of the metal, $W$:

$$hf = K + W. \qquad \textbf{(37–4a)}$$

The least tightly held electrons will be emitted with the most kinetic energy $(K_{max})$, in which case $W$ in this equation is the work function $W_0$, and $K$ becomes $K_{max}$:

$$hf = K_{max} + W_0. \qquad \text{[least bound electrons]} \quad \textbf{(37–4b)}$$

Many electrons will require more energy than the bare minimum $(W_0)$ to get out of the metal, and thus the kinetic energy of such electrons will be less than the maximum.

From these considerations, the photon theory makes the following predictions:

*Photon theory predictions*

1. An increase in intensity of the light beam means more photons are incident, so more electrons will be ejected; but since the energy of each photon is not changed, the maximum kinetic energy of electrons is not changed by an increase in intensity.
2. If the frequency of the light is increased, the maximum kinetic energy of the electrons increases linearly, according to Eq. 37–4b. That is,

$$K_{max} = hf - W_0.$$

This relationship is plotted in Fig. 37–5.

3. If the frequency $f$ is less than the "cutoff" frequency $f_0$, where $hf_0 = W_0$, no electrons will be ejected, no matter how great the intensity of the light.

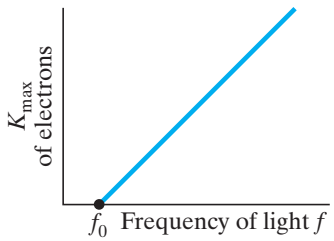

**FIGURE 37–5** Photoelectric effect: the maximum kinetic energy of ejected electrons increases linearly with the frequency of incident light. No electrons are emitted if $f < f_0$.

These predictions of the photon theory are very different from the predictions of the wave theory. In 1913–1914, careful experiments were carried out by R. A. Millikan. The results were fully in agreement with Einstein's photon theory.

One other aspect of the photoelectric effect also confirmed the photon theory. If extremely low light intensity is used, the wave theory predicts a time delay before electron emission so that an electron can absorb enough energy to exceed the work function. The photon theory predicts no such delay—it only takes one photon (if its frequency is high enough) to eject an electron—and experiments showed no delay. This too confirmed Einstein's photon theory.

**EXAMPLE 37–3** **Photon energy.** Calculate the energy of a photon of blue light, $\lambda = 450\,\text{nm}$ in air (or vacuum).

**APPROACH** The photon has energy $E = hf$ (Eq. 37–3) where $f = c/\lambda$ (Eq. 31–14).

**SOLUTION** Since $f = c/\lambda$, we have

$$E = hf = \frac{hc}{\lambda} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^{8}\,\text{m/s})}{(4.5 \times 10^{-7}\,\text{m})} = 4.4 \times 10^{-19}\,\text{J},$$

or $(4.4 \times 10^{-19}\,\text{J})/(1.60 \times 10^{-19}\,\text{J/eV}) = 2.8\,\text{eV}$. (See definition of eV in Section 23–8, $1\,\text{eV} = 1.60 \times 10^{-19}\,\text{J}$.)

**EXAMPLE 37–4** **ESTIMATE** **Photons from a lightbulb.** Estimate how many visible light photons a 100-W incandescent lightbulb emits per second. Assume the bulb has a typical efficiency of about 3% (that is, 97% of the energy goes to heat).

**APPROACH** Let's assume an average wavelength in the middle of the visible spectrum, $\lambda \approx 500\,\text{nm}$. The energy of each photon is $E = hf = hc/\lambda$. Only 3% of the 100-W power is emitted as visible light, or $3\,\text{W} = 3\,\text{J/s}$. The number of photons emitted per second equals the light output of 3 J/s divided by the energy of each photon.

**SOLUTION** The energy emitted in one second $(= 3\,\text{J})$ is $E = Nhf$ where $N$ is the number of photons emitted per second and $f = c/\lambda$. Hence

$$N = \frac{E}{hf} = \frac{E\lambda}{hc} = \frac{(3\,\text{J})(500 \times 10^{-9}\,\text{m})}{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^{8}\,\text{m/s})} \approx 8 \times 10^{18}$$

per second, or almost $10^{19}$ photons emitted per second, an enormous number.

**EXERCISE B** A beam contains infrared light of a single wavelength, 1000 nm, and monochromatic UV at 100 nm, both of the same intensity. Are there more 100-nm photons or more 1000-nm photons?

**EXAMPLE 37–5** **Photoelectron speed and energy.** What is the kinetic energy and speed of an electron ejected from a sodium surface whose work function is $W_0 = 2.28\,\text{eV}$ when illuminated by light of wavelength (*a*) 410 nm, (*b*) 550 nm?

**APPROACH** We first find the energy of the photons $(E = hf = hc/\lambda)$. If the energy is greater than $W_0$, then electrons will be ejected with varying amounts of kinetic energy, with a maximum of $K_{\text{max}} = hf - W_0$.

**SOLUTION** (*a*) For $\lambda = 410\,\text{nm}$,

$$hf = \frac{hc}{\lambda} = 4.85 \times 10^{-19}\,\text{J} \quad \text{or} \quad 3.03\,\text{eV}.$$

The maximum kinetic energy an electron can have is given by Eq. 37–4b, $K_{\text{max}} = 3.03\,\text{eV} - 2.28\,\text{eV} = 0.75\,\text{eV}$, or $(0.75\,\text{eV})(1.60 \times 10^{-19}\,\text{J/eV}) = 1.2 \times 10^{-19}\,\text{J}$. Since $K = \frac{1}{2}mv^2$ where $m = 9.11 \times 10^{-31}\,\text{kg}$,

$$v_{\text{max}} = \sqrt{\frac{2K}{m}} = 5.1 \times 10^{5}\,\text{m/s}.$$

Most ejected electrons will have less kinetic energy and less speed than these maximum values.

(*b*) For $\lambda = 550\,\text{nm}$, $hf = hc/\lambda = 3.61 \times 10^{-19}\,\text{J} = 2.26\,\text{eV}$. Since this photon energy is less than the work function, no electrons are ejected.

**NOTE** In (*a*) we used the nonrelativistic equation for kinetic energy. If $v$ had turned out to be more than about $0.1c$, our calculation would have been inaccurate by more than a percent or so, and we would probably prefer to redo it using the relativistic form (Eq. 36–10).

**EXERCISE C** Determine the lowest frequency and the longest wavelength needed to emit electrons from sodium.

By converting units, we can show that the energy of a photon in electron volts, when given the wavelength $\lambda$ in nm, is

$$E\,(\text{eV}) = \frac{1.240 \times 10^3\,\text{eV}\cdot\text{nm}}{\lambda\,(\text{nm})}. \qquad \text{[photon energy in eV]}$$

### Applications of the Photoelectric Effect

The photoelectric effect, besides playing an important historical role in confirming the photon theory of light, also has many practical applications. Burglar alarms and automatic doors often make use of the photocell circuit of Fig. 37–4. When a person interrupts the beam of light, the sudden drop in current in the circuit activates a switch—often a solenoid—which operates a bell or opens the door. UV or IR light is sometimes used in burglar alarms because of its invisibility. Many smoke detectors use the photoelectric effect to detect tiny amounts of smoke that interrupt the flow of light and so alter the electric current. Photographic light meters use this circuit as well. Photocells are used in many other devices, such as absorption spectrophotometers, to measure light intensity. One type of film sound track is a variably shaded narrow section at the side of the film, Fig. 37–6. Light passing through the film is thus "modulated," and the output electrical signal of the photocell detector follows the frequencies on the sound track. For many applications today, the vacuum-tube photocell of Fig. 37–4 has been replaced by a semiconductor device known as a **photodiode** (Section 40–9). In these semiconductors, the absorption of a photon liberates a bound electron so it can move freely, which changes the conductivity of the material and the current through a photodiode is altered.

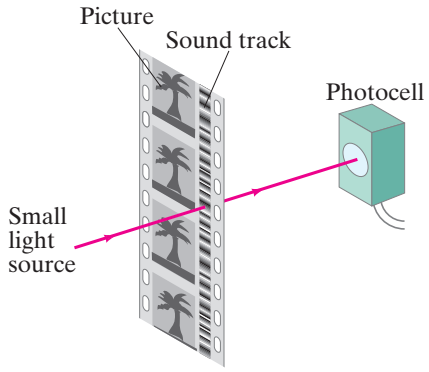

**FIGURE 37–6** Optical sound track on movie film. In the projector, light from a small source (different from that for the picture) passes through the sound track on the moving film. The light and dark areas on the sound track vary the intensity of the transmitted light which reaches the photocell, whose output current is then a replica of the original sound. This output is amplified and sent to the loudspeakers. High-quality projectors can show movies containing several parallel sound tracks to go to different speakers around the theater.

## 37–3 Energy, Mass, and Momentum of a Photon

We have seen that the total energy of a single photon is given by $E = hf$ (Eq. 37–3). But because a photon always travels at the speed of light, it is truly a relativistic particle. Thus we must use relativistic formulas for dealing with its energy and momentum. The momentum of any particle of mass $m$ is given by $p = mv/\sqrt{1 - v^2/c^2}$. Since $v = c$ for a photon, the denominator is zero. To avoid having an infinite momentum, we conclude that the photon's mass must be zero: $m = 0$. This makes sense too because a photon can never be at rest (it always moves at the speed of light). A photon's kinetic energy is its total energy (rest energy $= 0$):

$$K = E = hf. \qquad \text{[photon]}$$

The momentum of a photon can be obtained from the relativistic formula (Eq. 36–14) $E^2 = p^2c^2 + m^2c^4$ where we set $m = 0$, so $E^2 = p^2c^2$ or

$$p = \frac{E}{c}. \qquad \text{[photon]}$$

**CAUTION**
*Momentum of photon is* not *mv*

Since $E = hf$ for a photon, its momentum is related to its wavelength by

$$p = \frac{E}{c} = \frac{hf}{c} = \frac{h}{\lambda}. \qquad \textbf{(37–5)}$$

**EXAMPLE 37–6** **Photosynthesis.** In *photosynthesis*, pigments such as chlorophyll in plants capture the energy of sunlight to change $CO_2$ to useful carbohydrate. About nine photons are needed to transform one molecule of $CO_2$ to carbohydrate and $O_2$. Assuming light of wavelength $\lambda = 670\,\text{nm}$ (chlorophyll absorbs most strongly in the range 650 nm to 700 nm), how efficient is the photosynthetic process? The reverse chemical reaction releases an energy of 4.9 eV/molecule of $CO_2$, so 4.9 eV is needed to transform one molecule of $CO_2$ to carbohydrate.

**PHYSICS APPLIED**
*Photosynthesis*

**APPROACH** The efficiency is the minimum energy required (4.9 eV) divided by the actual energy absorbed, nine times the energy $(hf)$ of one photon.

**SOLUTION** The energy of nine photons, each of energy $hf = hc/\lambda$, is $(9)(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^8\,\text{m/s})/(6.7 \times 10^{-7}\,\text{m}) = 2.7 \times 10^{-18}\,\text{J}$ or 17 eV. Thus the process is about $(4.9\,\text{eV}/17\,\text{eV}) = 29\%$ efficient.

**EXAMPLE 37–7** **ESTIMATE** **Photon momentum and force.** Suppose the $10^{19}$ photons emitted per second from the 100-W lightbulb in Example 37–4 were all focused onto a piece of black paper and absorbed. (*a*) Calculate the momentum of one photon and (*b*) estimate the force all these photons could exert on the paper.

**APPROACH** Each photon's momentum is obtained from Eq. 37–5, $p = h/\lambda$. Next, each absorbed photon's momentum changes from $p = h/\lambda$ to zero. We use Newton's second law, $F = \Delta p/\Delta t$, to get the force. Let $\lambda = 500\,\text{nm}$.

**SOLUTION** (*a*) Each photon has a momentum

$$p = \frac{h}{\lambda} = \frac{6.63 \times 10^{-34}\,\text{J}\cdot\text{s}}{500 \times 10^{-9}\,\text{m}} = 1.3 \times 10^{-27}\,\text{kg}\cdot\text{m/s}.$$

(*b*) Using Newton's second law for $N = 10^{19}$ photons (Example 37–4) whose momentum changes from $h/\lambda$ to 0, we obtain

$$F = \frac{\Delta p}{\Delta t} = \frac{Nh/\lambda - 0}{1\,\text{s}} = N\frac{h}{\lambda} \approx (10^{19}\,\text{s}^{-1})(10^{-27}\,\text{kg}\cdot\text{m/s}) \approx 10^{-8}\,\text{N}.$$

**NOTE** This is a tiny force, but we can see that a much stronger light source could exert a measurable force, and near the Sun or a star the force due to photons in electromagnetic radiation could be considerable. See Section 31–9.

# 37–4 Compton Effect

Besides the photoelectric effect, a number of other experiments were carried out in the early twentieth century which also supported the photon theory. One of these was the **Compton effect** (1923) named after its discoverer, A. H. Compton (1892–1962). Compton aimed short-wavelength light (actually X-rays) at various materials, and detected light scattered at various angles. He found that the scattered light had a slightly longer wavelength than did the incident light, and therefore a slightly lower frequency indicating a loss of energy. He explained this result on the basis of the photon theory as incident photons colliding with electrons of the material, Fig. 37–7.

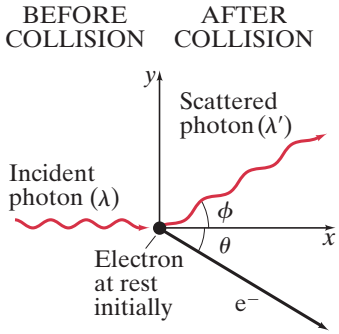

**FIGURE 37–7** The Compton effect. A single photon of wavelength $\lambda$ strikes an electron in some material, knocking it out of its atom. The scattered photon has less energy (some energy is given to the electron) and hence has a longer wavelength $\lambda'$ (shown exaggerated). Experiments found scattered X-rays of just the wavelengths predicted by conservation of energy and momentum using the photon model.

Using Eq. 37–5 for momentum of a photon, Compton applied the laws of conservation of momentum and energy to the collision of Fig. 37–7 and derived the following equation for the wavelength of the scattered photons:

$$\lambda' = \lambda + \frac{h}{m_e c}(1 - \cos\phi), \qquad \textbf{(37–6a)}$$

where $m_e$ is the mass of the electron. For $\phi = 0$, the wavelength is unchanged (there is no collision for this case of the photon passing straight through).

At any other angle, $\lambda'$ is longer than $\lambda$. The difference in wavelength,

$$\Delta\lambda = \lambda' - \lambda = \frac{h}{m_e c}(1 - \cos\phi), \qquad \textbf{(37–6b)}$$

is called the **Compton shift**. The quantity $h/m_e c$, which has the dimensions of length, is called the **Compton wavelength** $\lambda_C$ of a free electron,

$$\lambda_C = \frac{h}{m_e c} = 2.43 \times 10^{-3}\,\text{nm} = 2.43\,\text{pm}. \qquad \text{[electron]}$$

Equations 37–6 predict that $\lambda'$ depends on the angle $\phi$ at which the photons are detected. Compton's measurements of 1923 were consistent with this formula, confirming the value of $\lambda_C$ and the dependence of $\lambda'$ on $\phi$. See Fig. 37–8.

In contrast, the wave theory of light predicts no wavelength shift: an incoming electromagnetic wave of frequency $f$ should set electrons into oscillation at the same frequency $f$, and such oscillating electrons should reemit EM waves of this same frequency $f$ (Chapter 31), which would not change with the angle $\phi$. Hence the Compton effect adds to the firm experimental foundation for the photon theory of light.

**EXERCISE D** When a photon scatters off an electron by the Compton effect, which of the following increases: its energy, frequency, or wavelength?

**EXAMPLE 37–8** **X-ray scattering.** X-rays of wavelength 0.140 nm are scattered from a very thin slice of carbon. What will be the wavelengths of X-rays scattered at (*a*) 0°, (*b*) 90°, (*c*) 180°?

**APPROACH** This is an example of the Compton effect, and we use Eq. 37–6a to find the wavelengths.

**SOLUTION** (*a*) For $\phi = 0°$, $\cos\phi = 1$ and $1 - \cos\phi = 0$. Then Eq. 37–6a gives $\lambda' = \lambda = 0.140\,\text{nm}$. This makes sense since for $\phi = 0°$, there really isn't any collision as the photon goes straight through without interacting.

(*b*) For $\phi = 90°$, $\cos\phi = 0$, and $1 - \cos\phi = 1$. So

$$\lambda' = \lambda + \frac{h}{m_e c} = 0.140\,\text{nm} + \frac{6.63 \times 10^{-34}\,\text{J}\cdot\text{s}}{(9.11 \times 10^{-31}\,\text{kg})(3.00 \times 10^{8}\,\text{m/s})}$$

$$= 0.140\,\text{nm} + 2.4 \times 10^{-12}\,\text{m} = 0.142\,\text{nm};$$

that is, the wavelength is longer by one Compton wavelength ($= h/m_e c^2 = 0.0024\,\text{nm}$ for an electron).

(*c*) For $\phi = 180°$, which means the photon is scattered backward, returning in the direction from which it came (a direct "head-on" collision), $\cos\phi = -1$, and $1 - \cos\phi = 2$. So

$$\lambda' = \lambda + 2\frac{h}{m_e c} = 0.140\,\text{nm} + 2(0.0024\,\text{nm}) = 0.145\,\text{nm}.$$

**NOTE** The maximum shift in wavelength occurs for backward scattering, and it is twice the Compton wavelength.

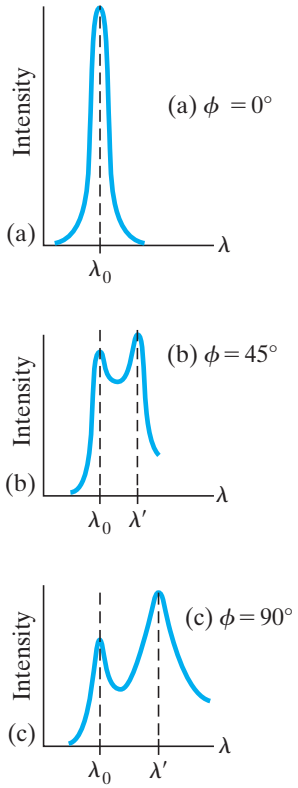

**FIGURE 37–8** Plots of intensity of radiation scattered from a target such as graphite (carbon), for three different angles. The values for $\lambda'$ match Eq. 37–6. For (a) $\phi = 0°$, $\lambda' = \lambda_0$. In (b) and (c) a peak is found at 45° or 90° at $\lambda'$ (Eq. 37–6a) due to photons scattered from free electrons (or very nearly free). But there is also a peak at just slightly more than $\lambda_0$, which is due to scattering from electrons very tightly bound to their atoms so the mass in Eqs. 37–6 becomes very large (mass of the atom) and $\Delta\lambda$ becomes very small.

**PHYSICS APPLIED**
*Measuring bone density*

The Compton effect has been used to diagnose bone disease such as osteoporosis. Gamma rays ($\gamma$), which are photons of even shorter wavelength than X-rays, coming from a radioactive source are scattered off bone material. The total intensity of the scattered radiation is proportional to the density of electrons, which is in turn proportional to the bone density. A low bone density may indicate osteoporosis.

**PHYSICS APPLIED**
*How visible light comes from the Sun: Compton scattering*

The energy output of the Sun comes from nuclear reactions (Chapters 41 and 42) that release high-energy $\gamma$ rays. Created near the center of the Sun, they may take tens of thousands of years to escape the Sun, undergoing repeated Compton scattering at small angles, slowly losing energy and increasing their wavelengths to be visible light, UV, or IR.

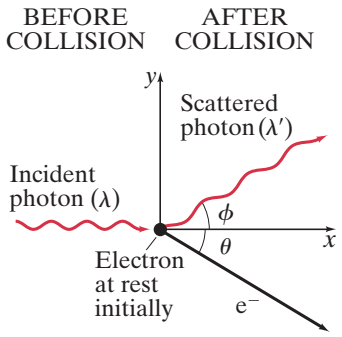

**FIGURE 37–7** (Repeated.) The Compton effect. A single photon of wavelength $\lambda$ strikes an electron in some material, knocking it out of its atom. The scattered photon has less energy (some energy is given to the electron) and hence has a longer wavelength $\lambda'$ (shown exaggerated). Experiments found scattered X-rays of just the wavelengths predicted by conservation of energy and momentum using the photon model.

### *Derivation of Compton Shift

If the incoming photon in Fig. 37–7 has wavelength $\lambda$, then its total energy and momentum are

$$E = hf = \frac{hc}{\lambda} \quad \text{and} \quad p = \frac{h}{\lambda}.$$

After the collision of Fig. 37–7, the photon scattered at the angle $\phi$ has a wavelength which we call $\lambda'$. Its energy and momentum are

$$E' = \frac{hc}{\lambda'} \quad \text{and} \quad p' = \frac{h}{\lambda'}.$$

The electron, assumed at rest before the collision but free to move when struck, is scattered at an angle $\theta$. The electron's kinetic energy after the photon collides with it is (see Eq. 36–10):

$$K_e = \left(\frac{1}{\sqrt{1 - v^2/c^2}} - 1\right) m_e c^2$$

where $m_e$ is the mass of the electron and $v$ is its speed. The electron's momentum is

$$p_e = \frac{1}{\sqrt{1 - v^2/c^2}} m_e v.$$

We apply conservation of energy, before and after the collision of photon and electron (Fig. 37–7):

$$\text{incoming photon} \longrightarrow \text{scattered photon} + \text{electron}$$

$$\frac{hc}{\lambda} = \frac{hc}{\lambda'} + \left(\frac{1}{\sqrt{1 - v^2/c^2}} - 1\right) m_e c^2.$$

We apply conservation of momentum, before and after collision, to the $x$ and $y$ components of momentum:

$$(x) \qquad \frac{h}{\lambda} = \frac{h}{\lambda'} \cos\phi + \frac{m_e v \cos\theta}{\sqrt{1 - v^2/c^2}}$$

$$(y) \qquad 0 = \frac{h}{\lambda'} \sin\phi - \frac{m_e v \sin\theta}{\sqrt{1 - v^2/c^2}}.$$

We can combine the last three equations to eliminate $v$ and $\theta$, and we obtain, as Compton did, an equation for the wavelength of the scattered photon in terms of its scattering angle $\phi$:

$$\lambda' = \lambda + \frac{h}{m_e c}(1 - \cos\phi),$$

which is Eq. 37–6a, and gives us the Compton shift (previous page).

## 37–5 Photon Interactions; Pair Production

When a photon passes through matter, it interacts with the atoms and electrons. There are four important types of interactions that a photon can undergo:

1. The *photoelectric effect*: A photon may knock an electron out of an atom and in the process the photon disappears.
2. The photon may knock an atomic electron to a higher energy state in the atom if its energy is not sufficient to knock the electron out altogether. In this process the photon also disappears, and all its energy is given to the atom. Such an atom is then said to be in an *excited state*, and we shall discuss it more later.
3. The photon can be scattered from an electron (or a nucleus) and in the process lose some energy; this is the *Compton effect* (Fig. 37–7). But notice that the photon is not slowed down. It still travels with speed $c$, but its frequency will be lower because its energy is less.
4. *Pair production*: A photon can actually create matter, such as the production of an electron and a positron, Fig. 37–9. (A positron has the same mass as an electron, but the opposite charge, $+e$, and is called its *antiparticle*.)

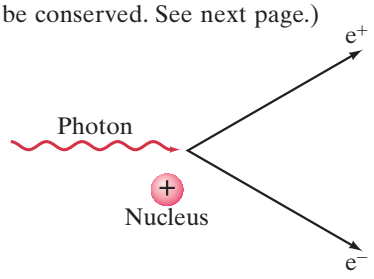

**FIGURE 37–9** Pair production: a photon disappears and produces an electron and a positron. (This process requires an additional massive object, often an atomic nucleus, so that energy and momentum can be conserved. See next page.)

In process 4, **pair production**, the photon disappears in the process of creating the electron–positron pair. This is an example of mass being created from pure energy, and it occurs in accord with Einstein's equation $E = mc^2$. Notice that a photon cannot create an electron alone since electric charge would not then be conserved. The inverse of pair production also occurs: if a positron comes close to an electron, the two quickly **annihilate** each other and their energy, including their mass, appears as electromagnetic energy of photons. Positrons are not nearly as plentiful in nature as electrons, and they usually do not last long before annihilating with an electron.

Electron–positron annihilation is the basis for the type of medical imaging known as PET, as discussed in Section 42–9.

**EXAMPLE 37–9** **Pair production.** (*a*) What is the minimum energy of a photon that can produce an electron–positron pair? (*b*) What is this photon's wavelength?

**APPROACH** The minimum photon energy $E$ equals the rest energy $(mc^2)$ of the two particles created, via Einstein's famous equation $E = mc^2$ (Eq. 36–12). There is no energy left over, so the particles produced will have zero kinetic energy. The wavelength is $\lambda = c/f$ where $E = hf$ for the original photon.

**SOLUTION** (*a*) Because $E = mc^2$, and the mass created is equal to two electron masses, the photon must have energy of at least

$$E = 2(9.11 \times 10^{-31}\,\text{kg})(3.0 \times 10^8\,\text{m/s})^2 = 1.64 \times 10^{-13}\,\text{J} = 1.02\,\text{MeV}$$

$(1\,\text{MeV} = 10^6\,\text{eV} = 1.60 \times 10^{-13}\,\text{J})$. A photon with less energy cannot undergo pair production.

(*b*) Since $E = hf = hc/\lambda$, the wavelength of a 1.02-MeV photon is

$$\lambda = \frac{hc}{E} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^8\,\text{m/s})}{(1.64 \times 10^{-13}\,\text{J})} = 1.2 \times 10^{-12}\,\text{m},$$

which is 0.0012 nm. Such photons are in the gamma-ray (or very short X-ray) region of the electromagnetic spectrum (Fig. 31–12).

**NOTE** Photons of higher energy (shorter wavelength) can also create an electron–positron pair, with the excess energy becoming kinetic energy of the particles.

Pair production cannot occur in empty space, for momentum could not be conserved. In Example 37–9, for instance, energy is conserved, but only enough energy was provided to create the electron–positron pair at rest, and thus with zero momentum, which could not equal the initial momentum of the photon. Indeed, it is necessary that an additional massive object, such as an atomic nucleus, must take part in the interaction to carry off some of the momentum (Fig. 37–9).

## 37–6 Wave–Particle Duality; the Principle of Complementarity

The photoelectric effect, the Compton effect, and other experiments have placed the particle theory of light on a firm experimental basis. But what about the classic experiments of Young and others (Chapters 34 and 35) on interference and diffraction which showed that the *wave theory* of light also rests on a firm experimental basis?

We seem to be in a dilemma. Some experiments indicate that light behaves like a wave; others indicate that it behaves like a stream of particles. These two theories seem to be incompatible, but both have been shown to have validity. Physicists finally came to the conclusion that this duality of light must be accepted as a fact of life. It is referred to as the **wave–particle duality**. Apparently, light is a more complex phenomenon than just a simple wave or a simple beam of particles.

**FIGURE 37–10** Niels Bohr (right), walking with Enrico Fermi along the Appian Way outside Rome. This photo shows one important way physics is done.

**CAUTION**

*Not correct to say light is a wave and/or a particle. Light can* **act** *like a wave or like a particle.*

To clarify the situation, the great Danish physicist Niels Bohr (1885–1962, Fig. 37–10) proposed his famous **principle of complementarity**. It states that to understand an experiment, sometimes we find an explanation using wave theory and sometimes using particle theory. Yet we must be aware of both the wave and particle aspects of light if we are to have a full understanding of light. Therefore these two aspects of light complement one another.

It is not easy to "visualize" this duality. We cannot readily picture a combination of wave and particle. Instead, we must recognize that the two aspects of light are different "faces" that light shows to experimenters.

Part of the difficulty stems from how we think. Visual pictures (or models) in our minds are based on what we see in the everyday world. We apply the concepts of waves and particles to light because in the macroscopic world we see that energy is transferred from place to place by these two methods. We cannot see directly whether light is a wave or particle, so we do indirect experiments. To explain the experiments, we apply the models of waves or of particles to the nature of light. But these are abstractions of the human mind. When we try to conceive of what light really "is," we insist on a visual picture. Yet there is no reason why light should conform to these models (or visual images) taken from the macroscopic world. The "true" nature of light—if that means anything—is not possible to visualize. The best we can do is recognize that our knowledge is limited to the indirect experiments, and that in terms of everyday language and images, light reveals both wave and particle properties.

It is worth noting that Einstein's equation $E = hf$ itself links the particle and wave properties of a light beam. In this equation, $E$ refers to the energy of a particle; and on the other side of the equals sign we have the frequency $f$ of the corresponding wave.

## 37–7 Wave Nature of Matter

In 1923, Louis de Broglie (1892–1987) extended the idea of the wave–particle duality. He appreciated the *symmetry* in nature, and argued that if light sometimes behaves like a wave and sometimes like a particle, then perhaps those things in nature thought to be particles—such as electrons and other material objects—might also have wave properties. De Broglie proposed that the wavelength of a material particle would be related to its momentum in the same way as for a photon, Eq. 37–5, $p = h/\lambda$. That is, for a particle having linear momentum $p = mv$, the wavelength $\lambda$ is given by

$$\lambda = \frac{h}{p}, \tag{37–7}$$

and is valid classically ($p = mv$ for $v \ll c$) and relativistically ($p = \gamma mv = mv/\sqrt{1 - v^2/c^2}$). This is sometimes called the **de Broglie wavelength** of a particle.

**EXAMPLE 37–10** **Wavelength of a ball.** Calculate the de Broglie wavelength of a 0.20-kg ball moving with a speed of 15 m/s.

**APPROACH** We use Eq. 37–7.

**SOLUTION** $\lambda = \dfrac{h}{p} = \dfrac{h}{mv} = \dfrac{(6.6 \times 10^{-34}\,\text{J}\cdot\text{s})}{(0.20\,\text{kg})\,(15\,\text{m/s})} = 2.2 \times 10^{-34}\,\text{m}.$

Ordinary size objects, such as the ball of Example 37–10, have unimaginably small wavelengths. Even if the speed is extremely small, say $10^{-4}$ m/s, the wavelength would be about $10^{-29}$ m. Indeed, the wavelength of any ordinary object is much too small to be measured and detected. The problem is that the properties of waves, such as interference and diffraction, are significant only when the size of objects or slits is not much larger than the wavelength. And there are no known objects or slits to diffract waves only $10^{-30}$ m long, so the wave properties of ordinary objects go undetected.

But tiny elementary particles, such as electrons, are another matter. Since the mass $m$ appears in the denominator of Eq. 37–7, a very small mass should have a much larger wavelength.

**EXAMPLE 37–11** **Wavelength of an electron.** Determine the wavelength of an electron that has been accelerated through a potential difference of 100 V.

**APPROACH** If the kinetic energy is much less than the rest energy, we can use the classical formula, $K = \frac{1}{2}mv^2$ (see Section 36–11). For an electron, $mc^2 = 0.511\,\text{MeV}$. We then apply conservation of energy: the kinetic energy acquired by the electron equals its loss in potential energy. After solving for $v$, we use Eq. 37–7 to find the de Broglie wavelength.

**SOLUTION** The gain in kinetic energy equals the loss in potential energy: $\Delta U = eV - 0$. Thus $K = eV$, so $K = 100\,\text{eV}$. The ratio $K/mc^2 = 100\,\text{eV}/(0.511 \times 10^6\,\text{eV}) \approx 10^{-4}$, so relativity is not needed. Thus

$$\frac{1}{2}mv^2 = eV$$

and

$$v = \sqrt{\frac{2eV}{m}} = \sqrt{\frac{(2)(1.6 \times 10^{-19}\,\text{C})(100\,\text{V})}{(9.1 \times 10^{-31}\,\text{kg})}} = 5.9 \times 10^6\,\text{m/s}.$$

Then

$$\lambda = \frac{h}{mv} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})}{(9.1 \times 10^{-31}\,\text{kg})(5.9 \times 10^6\,\text{m/s})} = 1.2 \times 10^{-10}\,\text{m},$$

or 0.12 nm.

**EXERCISE E** As a particle travels faster, does its de Broglie wavelength decrease, increase, or remain the same?

**EXERCISE F** Return to the Chapter-Opening Question, page 1095, and answer it again now. Try to explain why you may have answered differently the first time.

## Electron Diffraction; Wave–Particle Duality of Matter

From Example 37–11, we see that electrons can have wavelengths on the order of $10^{-10}\,\text{m}$, and even smaller. Although small, this wavelength can be detected: the spacing of atoms in a crystal is on the order of $10^{-10}\,\text{m}$ and the orderly array of atoms in a crystal could be used as a type of diffraction grating, as was done earlier for X-rays (Section 35–11, especially Fig. 35–28, and Fig. 37–12 on next page.) C. J. Davisson and L. H. Germer performed the crucial experiment; they scattered electrons from the surface of a metal crystal and, in early 1927, observed that the electrons were scattered into a pattern of regular peaks. When they interpreted these peaks as a diffraction pattern, the wavelength of the diffracted electron wave was found to be just that predicted by de Broglie, Eq. 37–7. In the same year, G. P. Thomson (son of J. J. Thomson) used different materials and also detected diffraction of electrons. See Fig. 37–11 and further discussion on next page, Example 37–12 and Fig. 37–12. Compare it to X-ray diffraction, Section 35–11.

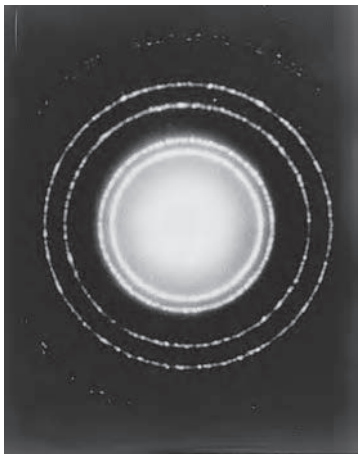

**FIGURE 37–11** Diffraction pattern of electrons scattered from aluminum foil, as recorded on film.

Later experiments showed that protons, neutrons, and other particles also have wave properties.

Thus the wave–particle duality applies to material objects as well as to light. The principle of complementarity applies to matter as well. That is, we must be aware of both the particle and wave aspects in order to have an understanding of matter, including electrons. But again we must recognize that a visual picture of a "wave–particle" is not possible. The principle of complementarity (Section 37–6) applies also to matter.

PHYSICS APPLIED
*Electron diffraction*

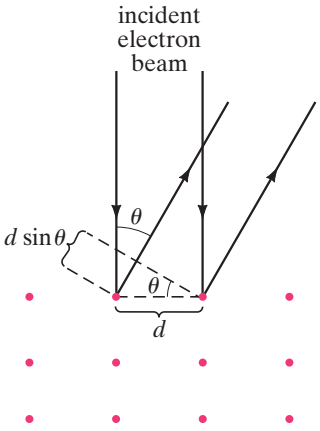

**FIGURE 37–12** Example 37–12. The red dots represent atoms in an orderly array in a solid.

**EXAMPLE 37–12** **Electron diffraction.** The wave nature of electrons is manifested in experiments where an electron beam interacts with the atoms on the surface of a solid, especially crystals. By studying the angular distribution of the diffracted electrons, one can indirectly measure the geometrical arrangement of atoms. Assume that the electrons strike perpendicular to the surface of a solid (see Fig. 37–12), and that their energy is low, $K = 100\,\text{eV}$, so that they interact only with the surface layer of atoms. If the smallest angle at which a diffraction maximum occurs is at 24°, what is the separation $d$ between the atoms on the surface?

**SOLUTION** Treating the electrons as waves, we need to determine the condition where the difference in path traveled by the wave diffracted from adjacent atoms is an integer multiple of the de Broglie wavelength, so that constructive interference occurs. The path length difference is $d\sin\theta$; so for the smallest value of $\theta$ we must have

$$d\sin\theta = \lambda.$$

However, $\lambda$ is related to the (non-relativistic) kinetic energy $K$ by

$$K = \frac{p^2}{2m_e} = \frac{h^2}{2m_e\lambda^2}.$$

Thus

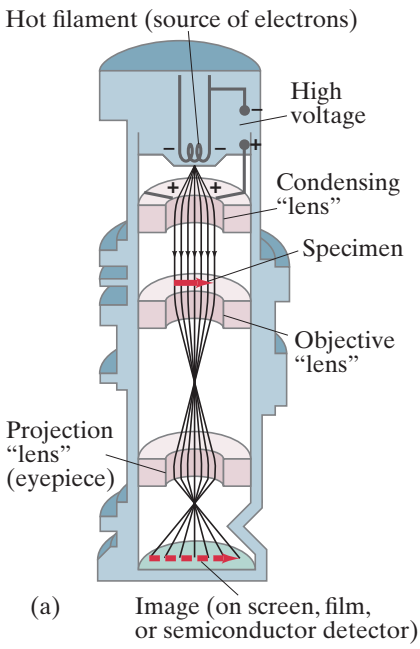
$$\lambda = \frac{h}{\sqrt{2m_eK}}$$

$$= \frac{(6.63\times10^{-34}\,\text{J}\cdot\text{s})}{\sqrt{2(9.11\times10^{-31}\,\text{kg})(100\,\text{eV})(1.6\times10^{-19}\,\text{J/eV})}} = 0.123\,\text{nm}.$$

The surface inter-atomic spacing is

$$d = \frac{\lambda}{\sin\theta} = \frac{0.123\,\text{nm}}{\sin 24^\circ} = 0.30\,\text{nm}.$$

**NOTE** Experiments of this type verify both the wave nature of electrons and the orderly array of atoms in crystalline solids.



### What Is an Electron?

We might ask ourselves: "What is an electron?" The early experiments of J. J. Thomson (Section 27–7) indicated a glow in a tube, and that glow moved when a magnetic field was applied. The results of these and other experiments were best interpreted as being caused by tiny negatively charged particles which we now call electrons. No one, however, has actually seen an electron directly. The drawings we sometimes make of electrons as tiny spheres with a negative charge on them are merely convenient pictures (now recognized to be inaccurate). Again we must rely on experimental results, some of which are best interpreted using the particle model and others using the wave model. These models are mere pictures that we use to extrapolate from the macroscopic world to the tiny microscopic world of the atom. And there is no reason to expect that these models somehow reflect the reality of an electron. We thus use a wave or a particle model (whichever works best in a situation) so that we can talk about what is happening. But we should not be led to believe that an electron *is* a wave or a particle. Instead we could say that an electron is the set of its properties that we can measure. Bertrand Russell said it well when he wrote that an electron is "a logical construction."

## 37–8 Electron Microscopes

PHYSICS APPLIED
*Electron microscope*

The idea that electrons have wave properties led to the development of the **electron microscope** (EM), which can produce images of much greater magnification than a light microscope because electron wavelengths can be much shorter (Section 35–6). Figures 37–13 (a) and (b) are diagrams of two types, developed around the middle of the twentieth century: the **transmission electron microscope** (TEM), which produces a two-dimensional image, and the **scanning electron microscope** (SEM), which produces images with a three-dimensional quality.

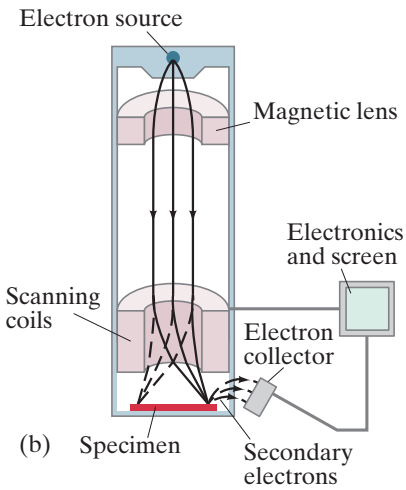


**FIGURE 37–13** (a) Transmission electron microscope. The magnetic field coils are designed to be "magnetic lenses," which bend the electron paths and bring them to a focus, as shown. The sensors of the image measure electron intensity only, not color. (b) Scanning electron microscope. Scanning coils move an electron beam back and forth across the specimen. Secondary electrons produced when the beam strikes the specimen are collected and their intensity affects the brightness of pixels in a monitor to produce a picture.

In both types, the objective and eyepiece lenses are actually magnetic fields that exert forces on the electrons to bring them to a focus. The fields are produced by carefully designed current-carrying coils of wire. Photographs using each type are shown in Fig. 37–14. EMs measure the intensity of electrons, producing monochromatic photos. Color is often added artificially to highlight.

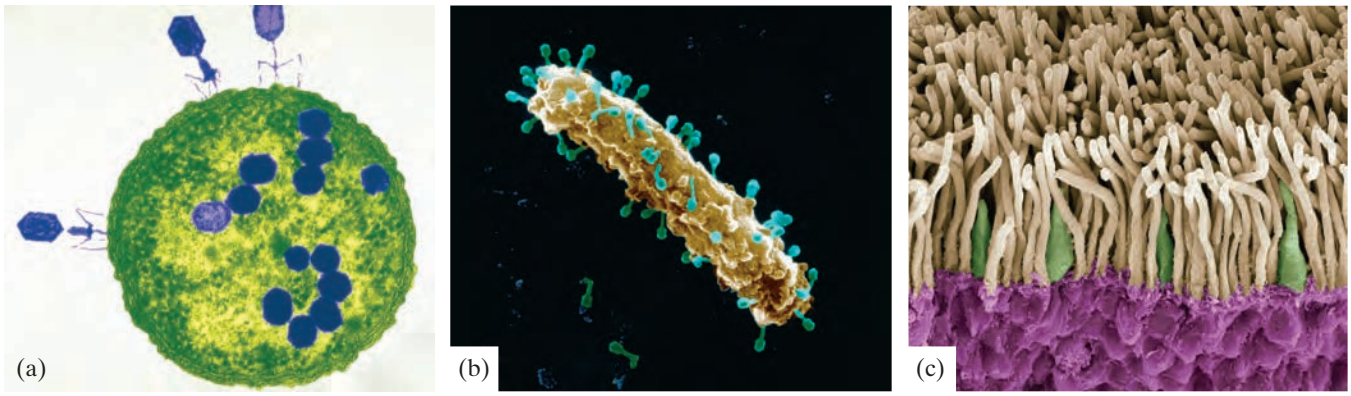

**FIGURE 37–14** Electron micrographs, in false color, of (a) viruses attacking a bacterium (TEM, ≈ 50,000×). (b) Same subject by an SEM (≈ 35,000×). (c) SEM image of an eye's retina (Section 33–6); rods and cones colored beige and green, respectively.

As discussed in Section 35–6, the maximum resolution of details on an object is about the size of the wavelength of the radiation used to view it. Electrons accelerated by voltages on the order of $10^5$ V have wavelengths of about 0.004 nm. The maximum resolution obtainable would be on this order, but in practice, aberrations in the magnetic lenses limit the resolution in transmission electron microscopes to about 0.1 to 0.5 nm. This is still 1000 times better than a visible-light microscope, and corresponds to a useful magnification of about a million. Such magnifications are difficult to achieve, and more common magnifications are $10^4$ to $10^5$. The maximum resolution of a scanning electron microscope is less, typically 5 to 10 nm, although new high-resolution SEMs approach 1 nm.

The **scanning tunneling electron microscope** (STM), developed in the 1980s, contains a tiny probe, whose tip may be only one (or a few) atoms wide, that is moved across the specimen to be examined in a series of linear passes. The tip, as it scans, remains very close to the surface of the specimen, about 1 nm above it, Fig. 37–15. A small voltage applied between the probe and the surface causes electrons to leave the surface and pass through the vacuum to the probe, by a quantum process known as *tunneling* (discussed in Section 38–10). This "tunneling" current is very sensitive to the gap width, so a feedback mechanism can be used to raise and lower the probe to maintain a constant electron current.

**PHYSICS APPLIED**
*STM and AFM*

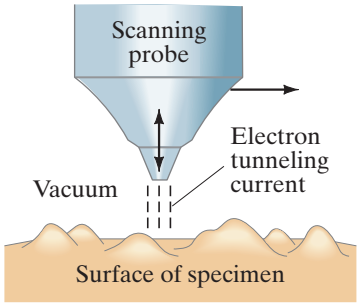

**FIGURE 37–15** The probe tip of a scanning tunneling electron microscope, as it is moved horizontally, automatically moves up and down to maintain a constant tunneling current, and this motion is translated into an image of the surface.

The probe's vertical motion, following the surface of the specimen, is then plotted as a function of position, scan after scan, producing a three-dimensional image of the surface. Surface features as fine as the size of an atom can be resolved: a resolution better than 50 pm (0.05 nm) laterally and 0.01 to 0.001 nm vertically. This resolution allows the study of the surface structure of materials. The "topographic" image of a surface represents the distribution of electron charge.

The **atomic force microscope** (AFM) is similar to an STM, but can be used on a wider range of materials. An AFM measures the force between a cantilevered tip and the sample, a force which depends strongly on the tip-sample separation at each point.

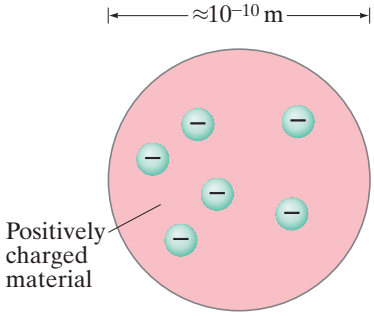

**FIGURE 37–16** Plum-pudding model of the atom.

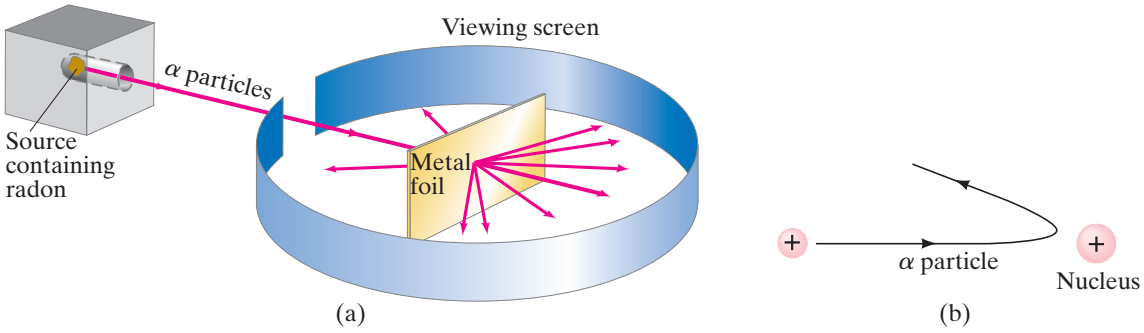
## 37–9 Early Models of the Atom

The idea that matter is made up of atoms was accepted by most scientists by 1900. With the discovery of the electron in the 1890s, scientists began to think of the atom itself as having a structure with electrons as part of that structure. We now discuss how our modern view of the atom developed, and the quantum theory with which it is intertwined.†

A typical model of the atom in the 1890s visualized the atom as a homogeneous sphere of positive charge inside of which there were tiny negatively charged electrons, a little like plums in a pudding, Fig. 37–16.

Around 1911, Ernest Rutherford (1871–1937) and his colleagues performed experiments whose results contradicted the plum-pudding model of the atom. In these experiments a beam of positively charged alpha ($\alpha$) particles was directed at a thin sheet of metal foil such as gold, Fig. 37–17a. (These newly discovered $\alpha$ particles were emitted by certain radioactive materials and were soon shown to be doubly ionized helium atoms—that is, having a charge of $+2e$.) It was expected from the plum-pudding model that the alpha particles would not be deflected significantly because electrons are so much lighter than alpha particles, and the alpha particles should not have encountered any massive concentration of positive charge to strongly repel them. The experimental results completely contradicted these predictions. It was found that most of the alpha particles passed through the foil unaffected, as if the foil was mostly empty space.

**FIGURE 37–17** (a) Experimental setup for Rutherford's experiment: $\alpha$ particles emitted by radon are deflected by the atoms of a thin metal foil and a few rebound backward. (b) Backward rebound of $\alpha$ particles explained as the repulsion from a heavy positively charged nucleus.



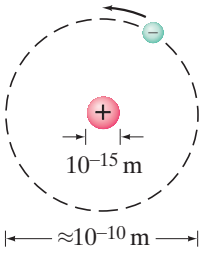


**FIGURE 37–18** Rutherford's model of the atom: electrons orbit a tiny positive nucleus (not to scale). The atom is visualized as mostly empty space.

And of those deflected, a few were deflected at very large angles—some even backward, nearly in the direction from which they had come. This could happen, Rutherford reasoned, only if the positively charged alpha particles were being repelled by a massive positive charge concentrated in a very small region of space (see Fig. 37–17b). He hypothesized that the atom must consist of a tiny but massive positively charged nucleus, containing over 99.9% of the mass of the atom, surrounded by much lighter electrons some distance away. The electrons would be moving in orbits about the nucleus—much as the planets move around the Sun—because if they were at rest, they would fall into the nucleus due to electrical attraction. See Fig. 37–18.

†Some readers may say: "Tell us the facts as we know them today, and don't bother us with the historical background and its outmoded theories." Such an approach would ignore the creative aspect of science and give a false impression of how science develops. Moreover, it is not really possible to understand today's view of the atom without insight into the concepts that led to it.

Rutherford's experiments suggested that the nucleus must have a radius of about $10^{-15}$ to $10^{-14}$ m. From kinetic theory, and especially Einstein's analysis of Brownian motion (see Section 17–1), the radius of atoms was estimated to be about $10^{-10}$ m. Thus the electrons would seem to be at a distance from the nucleus of about 10,000 to 100,000 times the radius of the nucleus itself. (If the nucleus were the size of a baseball, the atom would have the diameter of a big city several kilometers across.) So an atom would be mostly empty space.

*Atom diameters* $\approx 10^{-10}$ m
*Nucleus diameters* $\approx 10^{-15}$ m

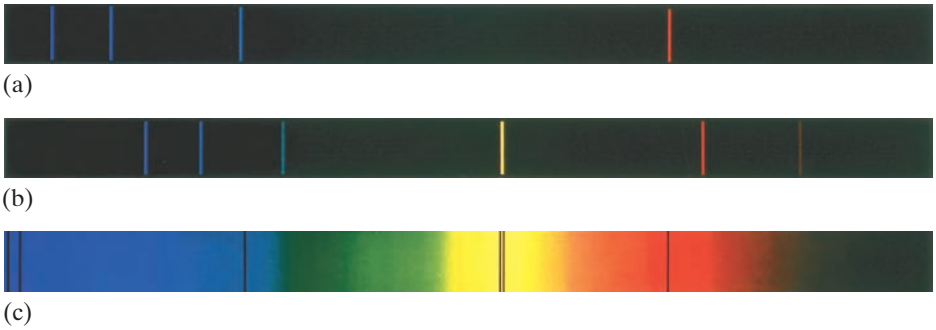
Rutherford's **planetary model** of the atom (also called the **nuclear model** of the atom) was a major step toward how we view the atom today. It was not, however, a complete model and presented some major problems, as we shall see.

## 37–10 Atomic Spectra: Key to the Structure of the Atom

Earlier in this Chapter we saw that heated solids (as well as liquids and dense gases) emit light with a continuous spectrum of wavelengths. This radiation is assumed to be due to oscillations of atoms and molecules, which are largely governed by the interaction of each atom or molecule with its neighbors.

Rarefied gases can also be excited to emit light. This is done by intense heating, or more commonly by applying a high voltage to a "discharge tube" containing the gas at low pressure, Fig. 37–19. The radiation from excited gases had been observed early in the nineteenth century, and it was found that the spectrum was not continuous. Rather, excited gases emit light of only certain wavelengths, and when this light is analyzed through the slit of a spectroscope or spectrometer (Section 35–9), a **line spectrum** is seen rather than a continuous spectrum. The line spectra emitted by a number of elements in the visible region are shown below in Fig. 37–20, and in Chapter 35, Fig. 35–22. The **emission spectrum** is characteristic of the material and can serve as a type of "fingerprint" for identification of the gas.

We also saw (Section 35–9 and Fig. 35–22) that if a continuous spectrum passes through a rarefied gas, dark lines are observed in the emerging spectrum, at wavelengths corresponding to lines normally emitted by the gas. This is called an **absorption spectrum** (Fig. 37–20c), and it became clear that gases can absorb light at the same frequencies at which they emit. Using film sensitive to ultraviolet and to infrared light, it was found that gases emit and absorb discrete frequencies in these regions as well as in the visible.



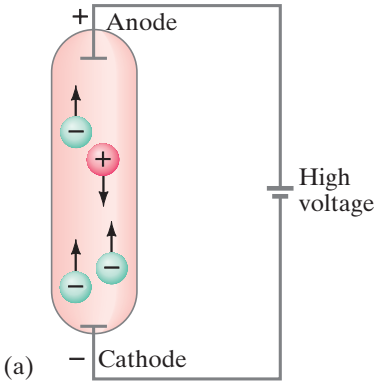


**FIGURE 37–20** Emission spectra of the gases (a) atomic hydrogen, (b) helium, and (c) the *solar absorption* spectrum.

In low-density gases, the atoms are far apart on the average and hence the light emitted or absorbed is assumed to be by *individual atoms* rather than through interactions between atoms, as in a solid, liquid, or dense gas. Thus the line spectra serve as a key to the structure of the atom: any theory of atomic structure must be able to explain why atoms emit light only of discrete wavelengths, and it should be able to predict what these wavelengths are.

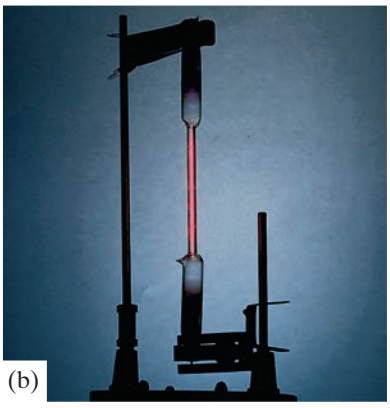

**FIGURE 37–19** Gas-discharge tube: (a) diagram; (b) photo of an actual discharge tube for hydrogen.

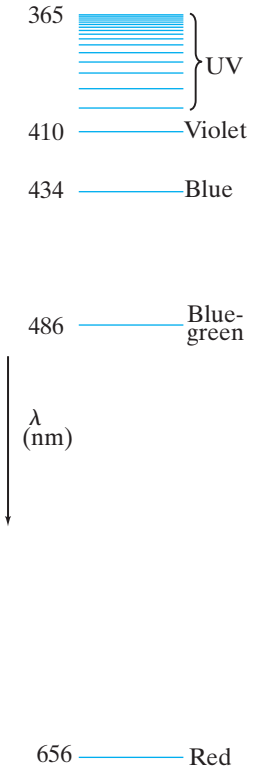

**FIGURE 37–21** Balmer series of lines for hydrogen.

Hydrogen is the simplest atom—it has only one electron orbiting its nucleus. It also has the simplest spectrum. The spectrum of most atoms shows little apparent regularity. But the spacing between lines in the hydrogen spectrum decreases in a regular way, Fig. 37–21. Indeed, in 1885, J. J. Balmer (1825–1898) showed that the four lines in the visible portion of the hydrogen spectrum (with measured wavelengths 656 nm, 486 nm, 434 nm, and 410 nm) have wavelengths that fit the formula

$$\frac{1}{\lambda} = R\left(\frac{1}{2^2} - \frac{1}{n^2}\right), \qquad n = 3, 4, \cdots. \tag{37–8}$$

Here $n$ takes on the values 3, 4, 5, 6 for the four visible lines, and $R$, called the **Rydberg constant**, has the value $R = 1.0974 \times 10^7\ \text{m}^{-1}$. Later it was found that this **Balmer series** of lines extended into the UV region, ending at $\lambda = 365$ nm, as shown in Fig. 37–21. Balmer's formula, Eq. 37–8, also worked for lines with higher integer values of $n$. The lines near 365 nm became too close together to distinguish, but the limit of the series at 365 nm corresponds to $n = \infty$ (so $1/n^2 = 0$ in Eq. 37–8).

Later experiments on hydrogen showed that there were similar series of lines in the UV and IR regions, and each series had a pattern just like the Balmer series, but at different wavelengths, Fig. 37–22. Each of these series was found to fit a formula with the same form as Eq. 37–8 but with the $1/2^2$ replaced by $1/1^2$, $1/3^2$, $1/4^2$, and so on. For example, the **Lyman series** contains lines with wavelengths from 91 nm to 122 nm (in the UV region) and fits the formula

$$\frac{1}{\lambda} = R\left(\frac{1}{1^2} - \frac{1}{n^2}\right), \qquad n = 2, 3, \cdots.$$

The wavelengths of the **Paschen series** (in the IR region) fit

$$\frac{1}{\lambda} = R\left(\frac{1}{3^2} - \frac{1}{n^2}\right), \qquad n = 4, 5, \cdots.$$

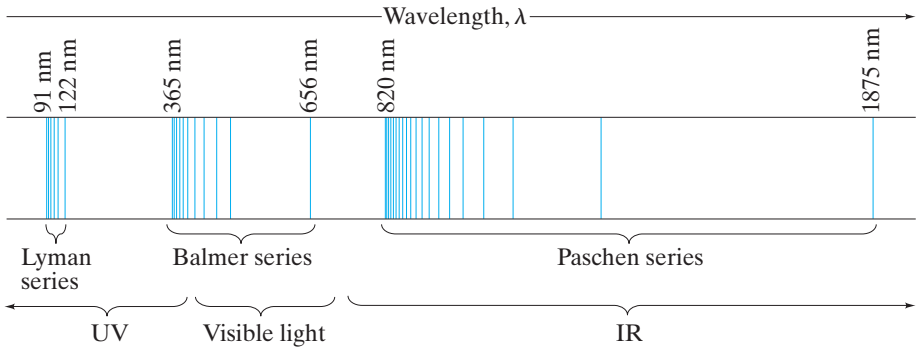

**FIGURE 37–22** Line spectrum of atomic hydrogen. Each series fits the formula $\frac{1}{\lambda} = R\left(\frac{1}{n'^2} - \frac{1}{n^2}\right)$ where $n' = 1$ for the Lyman series, $n' = 2$ for the Balmer series, $n' = 3$ for the Paschen series, and so on; $n$ can take on all integer values from $n = n' + 1$ up to infinity. The only lines in the visible region of the electromagnetic spectrum are part of the Balmer series.

The Rutherford model was unable to explain why atoms emit line spectra. It had other difficulties as well. According to the Rutherford model, electrons orbit the nucleus, and since their paths are curved the electrons are accelerating. Hence they should give off light like any other accelerating electric charge (Section 31–4). Since light carries off energy and energy is conserved, the electron's own energy must decrease to compensate. Hence electrons would be expected to spiral into the nucleus. As they spiraled inward, their frequency would increase in a short time and so too would the frequency of the light emitted. Thus the two main difficulties of the Rutherford model are these: (1) it predicts that light of a continuous range of frequencies would be emitted, whereas experiment shows line spectra; (2) it predicts that atoms are unstable—electrons would quickly spiral into the nucleus—but we know that atoms in general are stable, because there is stable matter all around us.

Clearly Rutherford's model was not sufficient. Some sort of modification was needed, and Niels Bohr provided it in a model that included the quantum hypothesis. Although the Bohr model has been superseded, it did provide a crucial stepping stone to our present understanding. And some aspects of the Bohr model are still useful today, so we examine it in detail in the next Section.

# 37–11 The Bohr Model

Bohr had studied in Rutherford's laboratory for several months in 1912 and was convinced that Rutherford's planetary model of the atom had validity. But in order to make it work, he felt that the newly developing quantum theory would somehow have to be incorporated in it. The work of Planck and Einstein had shown that in heated solids, the energy of oscillating electric charges must change discontinuously—from one discrete energy state to another, with the emission of a quantum of light. Perhaps, Bohr argued, the electrons in an atom also cannot lose energy continuously, but must do so in quantum "jumps." In working out his model during the next year, Bohr postulated that electrons move about the nucleus in circular orbits, but that only certain orbits are allowed. He further postulated that an electron in each orbit would have a definite energy and would move in the orbit *without radiating energy* (even though this violated classical ideas since accelerating electric charges are supposed to emit EM waves; see Section 31–4). He thus called the possible orbits **stationary states**. In this **Bohr model**, light is emitted only when an electron jumps from a higher (upper) stationary state to another of lower energy, Fig. 37–23. When such a transition occurs, a single photon of light is emitted whose energy, by energy conservation, is given by

$$hf = E_u - E_\ell, \tag{37–9}$$

where $E_u$ refers to the energy of the upper state and $E_\ell$ the energy of the lower state.

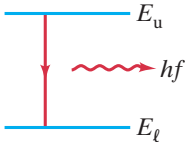

**FIGURE 37–23** An atom emits a photon (energy = $hf$) when its energy changes from $E_u$ to a lower energy $E_\ell$.

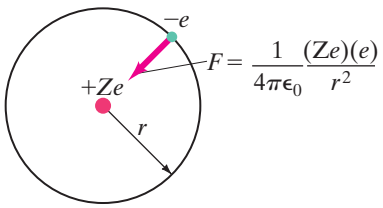
In 1912–13, Bohr set out to determine what energies these orbits would have in the simplest atom, hydrogen; the spectrum of light emitted could then be predicted from Eq. 37–9. In the Balmer formula he had the key he was looking for. Bohr quickly found that his theory would agree with the Balmer formula if he assumed that the electron's angular momentum $L$ is quantized and equal to an integer $n$ times $h/2\pi$. As we saw in Chapter 11 angular momentum is given by $L = I\omega$, where $I$ is the moment of inertia and $\omega$ is the angular velocity. For a single particle of mass $m$ moving in a circle of radius $r$ with speed $v$, $I = mr^2$ and $\omega = v/r$; hence, $L = I\omega = (mr^2)(v/r) = mvr$. Bohr's **quantum condition** is

$$L = mvr_n = n\frac{h}{2\pi}, \qquad n = 1, 2, 3, \cdots, \tag{37–10}$$

where $n$ is an integer and $r_n$ is the radius of the $n^{\text{th}}$ possible orbit. The allowed orbits are numbered $1, 2, 3, \cdots$, according to the value of $n$, which is called the **principal quantum number** of the orbit.



Equation 37–10 did not have a firm theoretical foundation. Bohr had searched for some "quantum condition," and such tries as $E = hf$ (where $E$ represents the energy of the electron in an orbit) did not give results in accord with experiment. Bohr's reason for using Eq. 37–10 was simply that it worked; and we now look at how. In particular, let us determine what the Bohr theory predicts for the measurable wavelengths of emitted light.

An electron in a circular orbit of radius $r$ (Fig. 37–24) would have a centripetal acceleration $v^2/r$ produced by the electrical force of attraction between the negative electron and the positive nucleus. This force is given by Coulomb's law,

$$F = k\frac{(Ze)(e)}{r^2} = \frac{1}{4\pi\epsilon_0}\frac{(Ze)(e)}{r^2}$$

where $k = 1/4\pi\epsilon_0 = 8.99 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2$. The charge on the electron is $q_1 = -e$, and the charge on the nucleus is $q_2 = +Ze$: $+e$ is the charge on a proton, $Z$ is the number of protons in the nucleus (called "atomic number,").[†] For the hydrogen atom, $Z = +1$.

**FIGURE 37–24** Electric force (Coulomb's law) keeps the negative electron in orbit around the positively charged nucleus.

[†]We include $Z$ in our derivation so that we can treat other single-electron ("hydrogenlike") atoms such as the ions $He^+$ $(Z = 2)$ and $Li^{2+}$ $(Z = 3)$. Helium in the neutral state has two electrons: if one electron is missing, the remaining $He^+$ ion consists of one electron revolving around a nucleus of charge $+2e$. Similarly, doubly ionized lithium, $Li^{2+}$, also has a single electron, and in this case $Z = 3$.

In Newton's second law, $F = ma$, we substitute Coulomb's law for $F$ and $a = v^2/r_n$ for a particular allowed orbit of radius $r_n$, and obtain

$$F = ma$$

$$\frac{1}{4\pi\epsilon_0}\frac{Ze^2}{r_n^2} = \frac{mv^2}{r_n}.$$

We solve this for $r_n$,

$$r_n = \frac{Ze^2}{4\pi\epsilon_0 mv^2},$$

and then substitute for $v$ from Eq. 37–10 (which says $v = nh/2\pi mr_n$):

$$r_n = \frac{Ze^2}{4\pi\epsilon_0 mv^2} = \frac{Ze^2 4\pi^2 mr_n^2}{4\pi\epsilon_0 n^2 h^2}.$$

We solve for $r_n$ (it appears on both sides, so we cancel one of them) and find

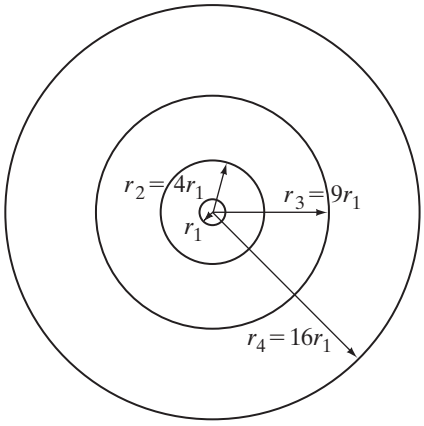
$$r_n = \frac{n^2h^2\epsilon_0}{\pi mZe^2} = \frac{n^2}{Z}r_1 \qquad \textbf{(37–11)}$$

where $n$ is an integer, the principal quantum number (Eq. 37–10), and

$$r_1 = \frac{h^2\epsilon_0}{\pi me^2}.$$

Equation 37–11 gives the radii of all possible orbits. The smallest orbit is for $n = 1$, and for hydrogen $(Z = 1)$ has the value

$$r_1 = \frac{(1)^2(6.626 \times 10^{-34}\,\text{J}\cdot\text{s})^2(8.85 \times 10^{-12}\,\text{C}^2/\text{N}\cdot\text{m}^2)}{(3.14)(9.11 \times 10^{-31}\,\text{kg})(1.602 \times 10^{-19}\,\text{C})^2}$$



or

$$r_1 = 0.529 \times 10^{-10}\,\text{m}. \qquad \textbf{(37–12)}$$

The radius of the smallest orbit in hydrogen, $r_1$, is often called the **Bohr radius**. From Eq. 37–11, we see that the radii of the larger orbits† increase as $n^2$, so

$$r_2 = 4r_1 = 2.12 \times 10^{-10}\,\text{m},$$
$$r_3 = 9r_1 = 4.76 \times 10^{-10}\,\text{m},$$
$$\vdots$$
$$r_n = n^2 r_1. \qquad n = 1, 2, 3, \cdots.$$

**FIGURE 37–25** The four smallest orbits in the Bohr model of hydrogen; $r_1 = 0.529 \times 10^{-10}\,\text{m}$.

The first four orbits are shown in Fig. 37–25. Notice that, according to Bohr's model, an electron can exist only in the orbits given by Eq. 37–11. There are no allowable orbits in between.

For an atom with $Z > 1$, we can write the orbital radii, $r_n$, using Eq. 37–11:

$$r_n = \frac{n^2}{Z}(0.529 \times 10^{-10}\,\text{m}), \qquad n = 1, 2, 3, \cdots. \qquad \textbf{(37–13)}$$

In each of its possible orbits, the electron in a Bohr model atom would have a definite energy, as the following calculation shows. The total energy equals the sum of the kinetic and potential energies. The potential energy of the electron is given by $U = qV = -eV$, where $V$ is the potential due to a point charge $+Ze$ as given by Eq. 23–5: $V = (1/4\pi\epsilon_0)(Q/r) = (1/4\pi\epsilon_0)(Ze/r)$. So

$$U = -eV = -\frac{1}{4\pi\epsilon_0}\frac{Ze^2}{r}.$$

†Be careful not to believe that these well-defined orbits actually exist. Today electrons are better thought of as forming "clouds," as discussed in Chapter 39.

The total energy $E_n$ for an electron in the $n^{\text{th}}$ orbit of radius $r_n$ is the sum of the kinetic and potential energies:

$$E_n = \tfrac{1}{2}mv^2 - \frac{1}{4\pi\epsilon_0}\frac{Ze^2}{r_n}.$$

When we substitute $v$ from Eq. 37–10 and $r_n$ from Eq. 37–11 into this equation, we obtain

$$E_n = -\left(\frac{Z^2e^4m}{8\epsilon_0^2h^2}\right)\left(\frac{1}{n^2}\right), \qquad n = 1, 2, 3, \cdots. \tag{37–14a}$$

We evaluate the constant term in Eq. 37–14a and convert it to electron volts, as is customary in atomic physics, recalling (Section 23–8) that $1\,\text{eV} = 1.60 \times 10^{-19}\,\text{J}$. Then we get

$$E_n = -(13.6\,\text{eV})\frac{Z^2}{n^2}, \qquad n = 1, 2, 3, \cdots. \tag{37–14b}$$

The lowest energy level $(n = 1)$ for hydrogen $(Z = 1)$ is

$$E_1 = -13.6\,\text{eV}.$$

Since $n^2$ appears in the denominator of Eq. 37–14b, the energies of the larger orbits in hydrogen $(Z = 1)$ are given by

$$E_n = \frac{-13.6\,\text{eV}}{n^2}.$$

For example,

$$E_2 = \frac{-13.6\,\text{eV}}{4} = -3.40\,\text{eV},$$

$$E_3 = \frac{-13.6\,\text{eV}}{9} = -1.51\,\text{eV}.$$

We see that not only are the orbit radii quantized, but from Eqs. 37–14 so is the energy. The quantum number $n$ that labels the orbit radii also labels the energy levels. The lowest **energy level** or **energy state** has energy $E_1$, and is called the **ground state**. The higher states, $E_2$, $E_3$, and so on, are called **excited states**. The fixed energy levels are also called **stationary states**.

Notice that although the energy for the larger orbits has a smaller numerical value, all the energies are less than zero. Thus, $-3.4\,\text{eV}$ is a higher energy than $-13.6\,\text{eV}$. Hence the orbit closest to the nucleus $(r_1)$ has the lowest energy (the most negative). The reason the energies have negative values has to do with the way we defined the zero for potential energy $(U)$. For two point charges, $U = (1/4\pi\epsilon_0)(q_1q_2/r)$ corresponds to zero potential energy when the two charges are infinitely far apart. Thus, an electron that can just barely be free from the atom by reaching $r = \infty$ (or, at least, far from the nucleus) with zero kinetic energy will have $E = K + U = 0 + 0 = 0$, corresponding to $n = \infty$ in Eqs. 37–14. If an electron is free and has kinetic energy, then $E > 0$. To remove an electron that is part of an atom requires an energy input (otherwise atoms would not be stable). Since $E \geq 0$ for a free electron, then an electron bound to an atom needs to have $E < 0$. That is, energy must be added to bring its energy up, from a negative value, to at least zero in order to free the electron.

The minimum energy required to remove an electron from an atom initially in the ground state is called the **binding energy** or **ionization energy**. The ionization energy for hydrogen has been measured to be 13.6 eV, and this corresponds precisely to removing an electron from the lowest state, $E_1 = -13.6\,\text{eV}$, up to $E = 0$ where it can be free.

At room temperature, nearly all atoms are in the ground state with $r_1 = 0.5 \times 10^{-10}\,\text{m}$. Thus we can expect that atoms typically have a diameter of about $10^{-10}\,\text{m}$, consistent with Brownian motion (Section 17–1).

*Atom diameter* $\approx 10^{-10}\,\text{m}$

## Spectra Lines Explained

It is useful to show the various possible energy values as horizontal lines on an energy-level diagram. This is shown for hydrogen in Fig. 37–26.[†] The electron in a hydrogen atom can be in any one of these levels according to Bohr's theory. But it could never be in between, say at $-9.0\,\text{eV}$. At room temperature, nearly all H atoms will be in the ground state $(n = 1)$. At higher temperatures, or during an electric discharge when there are many collisions between free electrons and atoms, many atoms can be in excited states $(n > 1)$. Once in an excited state, an atom's electron can jump down to a lower state, and give off a photon in the process. This is, according to the Bohr model, the origin of the emission spectra of excited gases.

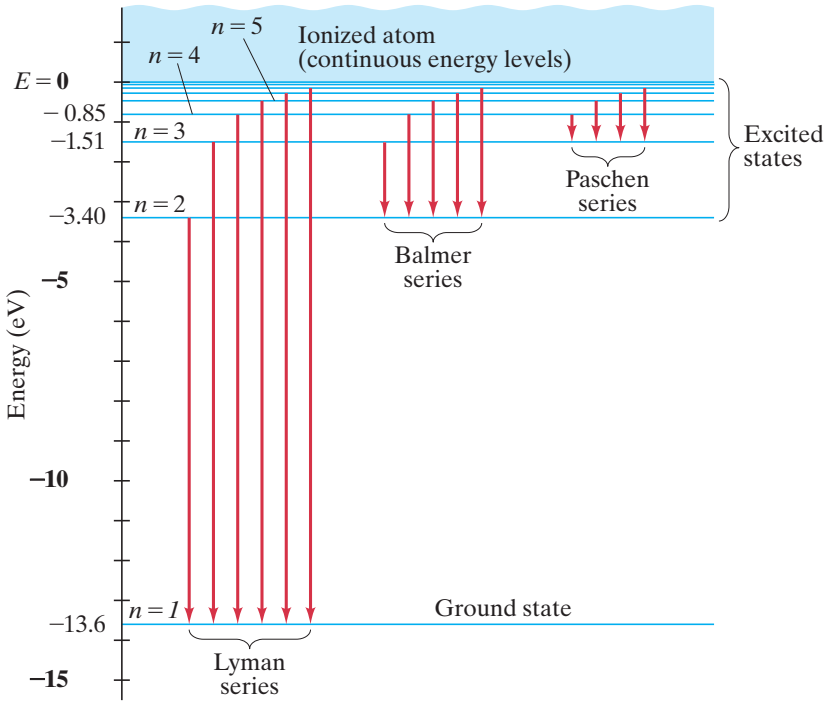


**FIGURE 37–26** Energy-level diagram for the hydrogen atom, showing the transitions for the spectral lines of the Lyman, Balmer, and Paschen series (Fig. 37–22). Each vertical arrow represents an atomic transition that gives rise to the photons of one spectral line (a single wavelength or frequency).

The vertical arrows in Fig. 37–26 represent the transitions or jumps that correspond to the various observed spectral lines. For example, an electron jumping from the level $n = 3$ to $n = 2$ would give rise to the 656-nm line in the Balmer series, and the jump from $n = 4$ to $n = 2$ would give rise to the 486-nm line (see Fig. 37–21). We can predict wavelengths of the spectral lines emitted according to Bohr by combining Eq. 37–9 $(hf = E_u - E_\ell)$ with Eq. 37–14a. Since $hf = hc/\lambda$, we have from Eq. 37–9

$$\frac{1}{\lambda} = \frac{hf}{hc} = \frac{1}{hc}(E_n - E_{n'}),$$

where $n$ refers to the upper state and $n'$ to the lower state. Then using Eq. 37–14a,

$$\frac{1}{\lambda} = \frac{Z^2e^4m}{8\epsilon_0^2h^3c}\left(\frac{1}{(n')^2} - \frac{1}{(n)^2}\right). \qquad \textbf{(37–15)}$$

This theoretical formula has the same form as the experimental Balmer formula, Eq. 37–8, with $n' = 2$. Thus we see that the Balmer series of lines corresponds to transitions or "jumps" that bring the electron down to the second energy level from higher energy levels. Similarly, $n' = 1$ corresponds to the Lyman series and $n' = 3$ to the Paschen series (see Fig. 37–26).

[†]Note that if $E \geq 0$, an electron is free and can have any energy ($E$ is not quantized). Thus there is a continuum of energy states above $E = 0$, as indicated as pale blue in the energy-level diagram of Fig. 37–26.

When the constant in Eq. 37–15 is evaluated with $Z = 1$, it is found to have the measured value of the Rydberg constant, $R = 1.0974 \times 10^7\,\text{m}^{-1}$, as in Eq. 37–8, in accord with experiment.

The great success of Bohr's model is that it gives an explanation for why atoms emit line spectra, and accurately predicts the wavelengths of emitted light for hydrogen. The Bohr model also explains absorption spectra: photons of just the right wavelength can knock an electron from one energy level to a higher one. To conserve energy, only photons that have just the right energy will be absorbed. This explains why a continuous spectrum of light entering a gas will emerge with dark (absorption) lines at frequencies that correspond to emission lines (Fig. 37–20c).

The Bohr theory also ensures the stability of atoms. It establishes stability by decree: the ground state is the lowest state for an electron and there is no lower energy level to which it can go and emit more energy. Finally, as we saw above, the Bohr theory accurately predicts the ionization energy of 13.6 eV for hydrogen. However, the Bohr model was not so successful for other atoms, and has been superseded as we shall discuss in the next Chapter. We discuss the Bohr model because it *was* an important start, and because we still use the concept of stationary states, the ground state, and transitions between states. Also, the terminology used in the Bohr model is still used by chemists and spectroscopists.

**EXAMPLE 37–13** **Wavelength of a Lyman line.** Use Fig. 37–26 to determine the wavelength of the first Lyman line, the transition from $n = 2$ to $n = 1$ in a hydrogen atom. In what region of the electromagnetic spectrum does this lie?

**APPROACH** We use Eq. 37–9, $hf = E_\text{u} - E_\ell$, with the energies obtained from Fig. 37–26 to find the energy and the wavelength of the transition. The region of the electromagnetic spectrum is found using the EM spectrum in Fig. 31–12.

**SOLUTION** For the transition from $n = 2$ to $n = 1$ in hydrogen, $hf = E_2 - E_1 = \{-3.4\,\text{eV} - (-13.6\,\text{eV})\} = 10.2\,\text{eV} = (10.2\,\text{eV})(1.60 \times 10^{-19}\,\text{J/eV}) = 1.63 \times 10^{-18}\,\text{J}$. Since $\lambda = c/f$, we have

$$\lambda = \frac{c}{f} = \frac{hc}{E_2 - E_1} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.00 \times 10^8\,\text{m/s})}{1.63 \times 10^{-18}\,\text{J}} = 1.22 \times 10^{-7}\,\text{m},$$

or 122 nm, which is in the UV region of the EM spectrum, Fig. 31–12. See also Fig. 37–22, where this value is confirmed experimentally.

**NOTE** An alternate approach: use Eq. 37–15 to find $\lambda$, and get the same result.

**EXAMPLE 37–14** **Wavelength of a Balmer line.** Use the Bohr model to calculate the wavelength of light emitted when a hydrogen atom makes a transition from the $n = 6$ to the $n = 2$ energy level.

**APPROACH** We can use Eq. 37–15 or its equivalent, Eq. 37–8, with $R = 1.097 \times 10^7\,\text{m}^{-1}$. (We could also use Fig. 37–26.)

**SOLUTION** We find

$$\frac{1}{\lambda} = (1.097 \times 10^7\,\text{m}^{-1})\left(\frac{1}{4} - \frac{1}{36}\right) = 2.44 \times 10^6\,\text{m}^{-1}.$$

So $\lambda = 1/(2.44 \times 10^6\,\text{m}^{-1}) = 4.10 \times 10^{-7}\,\text{m}$ or 410 nm. This is the fourth line in the Balmer series, Fig. 37–21, and is violet in color.

***Alternate Solution*** We can also use Fig. 37–26, but first we need Eq. 37–14b to give us $E_6 = 13.6\,\text{eV}/(6)^2 = 0.38\,\text{eV}$. So $hf = \Delta E = 3.40\,\text{eV} - 0.38\,\text{eV} = 3.02\,\text{eV}$. Then $\lambda = c/f = hc/hf = (6.626 \times 10^{-34}\,\text{J}\cdot\text{s})(3.00 \times 10^8\,\text{m/s})/(3.02\,\text{eV})(1.602 \times 10^{-19}\text{eV/J}) = 411\,\text{nm}$.

**EXERCISE G** The energy of the photon emitted when a hydrogen atom goes from the $n = 6$ state to the $n = 3$ state is (*a*) 0.378 eV; (*b*) 0.503 eV; (*c*) 1.13 eV; (*d*) 3.06 eV; (*e*) 13.6 eV.

**EXAMPLE 37–15 Absorption wavelength.** Use Fig. 37–26 to determine the maximum wavelength that hydrogen in its ground state can absorb. What would be the next smaller wavelength that would work?

**APPROACH** Maximum wavelength corresponds to minimum energy, and this would be the jump from the ground state up to the first excited state (Fig. 37–26). The next smaller wavelength occurs for the jump from the ground state to the second excited state. In each case, the energy difference can be used to find the wavelength.

**SOLUTION** The energy needed to jump from the ground state to the first excited state is $13.6\,\text{eV} - 3.4\,\text{eV} = 10.2\,\text{eV}$; the required wavelength, as we saw in Example 37–13, is 122 nm. The energy to jump from the ground state to the second excited state is $13.6\,\text{eV} - 1.5\,\text{eV} = 12.1\,\text{eV}$, which corresponds to a wavelength

$$\lambda = \frac{c}{f} = \frac{hc}{hf} = \frac{hc}{E_3 - E_1}$$
$$= \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.00 \times 10^{8}\,\text{m/s})}{(12.1\,\text{eV})(1.60 \times 10^{-19}\,\text{J/eV})} = 103\,\text{nm}.$$

**EXAMPLE 37–16 $He^+$ ionization energy.** (*a*) Use the Bohr model to determine the ionization energy of the $He^+$ ion, which has a single electron. (*b*) Also calculate the maximum wavelength a photon can have to cause ionization. The helium atom is the second atom, after hydrogen, in the Periodic Table (see inside rear cover).

**APPROACH** We want to determine the minimum energy required to lift the electron from its ground state and to barely reach the free state at $E = 0$. The ground state energy of $He^+$ is given by Eq. 37–14b with $n = 1$ and $Z = 2$.

**SOLUTION** (*a*) Since all the symbols in Eq. 37–14b are the same as for the calculation for hydrogen, except that $Z$ is 2 instead of 1, we see that $E_1$ will be $Z^2 = 2^2 = 4$ times the $E_1$ for hydrogen:

$$E_1 = 4(-13.6\,\text{eV}) = -54.4\,\text{eV}.$$

Thus, to ionize the $He^+$ ion should require 54.4 eV, and this value agrees with experiment.

(*b*) The maximum wavelength photon that can cause ionization will have energy $hf = 54.4\,\text{eV}$ and wavelength

$$\lambda = \frac{c}{f} = \frac{hc}{hf} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.00 \times 10^{8}\,\text{m/s})}{(54.4\,\text{eV})(1.60 \times 10^{-19}\,\text{J/eV})} = 22.8\,\text{nm}.$$

If $\lambda > 22.8\,\text{nm}$, ionization can not occur.

**NOTE** If the atom absorbed a photon of greater energy (wavelength shorter than 22.8 nm), the atom could be ionized and the freed electron would have kinetic energy of its own.

In Example 37–16, we saw that $E_1$ for the $He^+$ ion is four times more negative than that for hydrogen. Indeed, the energy-level diagram for $He^+$ looks just like that for hydrogen, Fig. 37–26, except that the numerical values for each energy level are four times larger. Note, however, that we are talking here about the $He^+$ *ion*. Normal (neutral) helium has two electrons and its energy level diagram is entirely different.

**CONCEPTUAL EXAMPLE 37–17** **Hydrogen at 20°C.** (*a*) Estimate the average kinetic energy of whole hydrogen atoms (not just the electrons) at room temperature. (*b*) Use the result to explain why, at room temperature, very few H atoms are in excited states and nearly all are in the ground state, and hence emit no light.

**RESPONSE** According to kinetic theory (Chapter 18), the average kinetic energy of atoms or molecules in a gas is given by Eq. 18–4:

$$\overline{K} = \tfrac{3}{2}kT,$$

where $k = 1.38 \times 10^{-23}\,\text{J/K}$ is Boltzmann's constant, and $T$ is the kelvin (absolute) temperature. Room temperature is about $T = 300\,\text{K}$, so

$$\overline{K} = \tfrac{3}{2}(1.38 \times 10^{-23}\,\text{J/K})(300\,\text{K}) = 6.2 \times 10^{-21}\,\text{J},$$

or, in electron volts:

$$\overline{K} = \frac{6.2 \times 10^{-21}\,\text{J}}{1.6 \times 10^{-19}\,\text{J/eV}} = 0.04\,\text{eV}.$$

The average kinetic energy of an atom as a whole is thus very small compared to the energy between the ground state and the next higher energy state ($13.6\,\text{eV} - 3.4\,\text{eV} = 10.2\,\text{eV}$). Any atoms in excited states quickly fall to the ground state and emit light. Once in the ground state, collisions with other atoms can transfer energy of only 0.04 eV on the average. A small fraction of atoms can have much more energy (see Section 18–2 on the distribution of molecular speeds), but even a kinetic energy that is 10 times the average is not nearly enough to excite atoms into states above the ground state. Thus, at room temperature, practically all atoms are in the ground state. Atoms can be excited to upper states by very high temperatures, or by applying a high voltage so a current of high-energy electrons passes through the gas as in a discharge tube (Fig. 37–19).

## Correspondence Principle

We should note that Bohr made some radical assumptions that were at variance with classical ideas. He assumed that electrons in fixed orbits do not radiate light even though they are accelerating (moving in a circle), and he assumed that angular momentum is quantized. Furthermore, he was not able to say how an electron moved when it made a transition from one energy level to another. On the other hand, there is no real reason to expect that in the tiny world of the atom electrons would behave as ordinary-sized objects do. Nonetheless, he felt that where quantum theory overlaps with the macroscopic world, it should predict classical results. This is the **correspondence principle**, already mentioned in regard to relativity (Section 36–13). This principle does work for Bohr's theory of the hydrogen atom. The orbit sizes and energies are quite different for $n = 1$ and $n = 2$, say. But orbits with $n = 100{,}000{,}000$ and 100,000,001 would be very close in radius and energy. Indeed, transitions between such large orbits (which would approach macroscopic sizes) would be imperceptible. Such orbits would thus appear to be continuously spaced, which is what we expect in the everyday world. [Don't confuse the correspondence principle with the principle of complementarity, page 1106.]

Finally, it must be emphasized that the well-defined orbits of the Bohr model do not actually exist. The Bohr model is only a model, not reality. The idea of electron orbits was rejected a few years later, and today electrons are thought of (Chapter 39) as forming "probability clouds."

# 37–12 de Broglie's Hypothesis Applied to Atoms

Bohr's theory of 1913 was largely of an *ad hoc* nature. Assumptions were made so that theory would agree with experiment. But Bohr could give no reason why the orbits were quantized, nor why there should be a stable ground state. Finally, ten years later, a reason was proposed by Louis de Broglie. We saw in Section 37–7 that in 1923, de Broglie proposed that material particles, such as electrons, have a wave nature; and that this hypothesis was confirmed by experiment several years later.

One of de Broglie's original arguments in favor of the wave nature of electrons was that it provided an explanation for Bohr's theory of the hydrogen atom. According to de Broglie, a particle of mass $m$ moving with a nonrelativistic speed $v$ would have a wavelength (Eq. 37–7) of

$$\lambda = \frac{h}{mv}.$$

Each electron orbit in an atom, he proposed, is actually a standing wave. As we saw in Chapter 15, when a violin or guitar string is plucked, a vast number of wavelengths are excited. But only certain ones—those that have nodes at the ends—are sustained (Fig. 15–26). These are the *resonant* modes of the string. Waves with other wavelengths interfere with themselves upon reflection and their amplitudes quickly drop to zero. With electrons moving in circles, according to Bohr's theory, de Broglie argued that the electron wave was a *circular* standing wave that closes on itself, Fig. 37–27. If the wavelength of a wave does not close on itself, as in Fig. 37–28, destructive interference takes place as the wave travels repeatedly around the loop, and the wave quickly dies out. Thus, the only waves that persist are those for which the circumference of the circular orbit contains a whole number of wavelengths, Fig. 37–29. The circumference of a Bohr orbit of radius $r_n$ is $2\pi r_n$, so to have constructive interference, we need

$$2\pi r_n = n\lambda, \qquad n = 1, 2, 3, \cdots.$$

When we substitute $\lambda = h/mv$, we get $2\pi r_n = nh/mv$, or

$$mvr_n = \frac{nh}{2\pi}.$$

This is just the *quantum condition* proposed by Bohr on an *ad hoc* basis, Eq. 37–10. It is from this equation that the discrete orbits and energy levels were derived. Thus we have a first explanation for the quantized orbits and energy states in the Bohr model: they are due to the wave nature of the electron, and only resonant "standing" waves can persist.[†] This implies that the *wave–particle duality* is at the root of atomic structure.

In viewing the circular electron waves of Fig. 37–29, the electron is not to be thought of as following the oscillating wave pattern. In the Bohr model of hydrogen, the electron moves in a circle. The circular wave, on the other hand, represents the *amplitude* of the electron "matter wave," and in Fig. 37–29 the wave amplitude is shown superimposed on the circular path of the particle orbit for convenience.

Bohr's theory worked well for hydrogen and for one-electron ions. But it did not prove successful for multi-electron atoms. Bohr's theory could not predict line spectra even for the next simplest atom, helium. It could not explain why some emission lines are brighter than others, nor why some lines are split into two or more closely spaced lines ("fine structure"). A new theory was needed and was indeed developed in the 1920s. This new and radical theory is called *quantum mechanics*. It finally solved the problem of atomic structure, and it gives us a very different view of the atom: the idea of electrons in well-defined orbits was replaced with the idea of electron "clouds." This new theory of quantum mechanics has given us a wholly different view of the basic mechanisms underlying physical processes.

[†]We note, however, that Eq. 37–10 is no longer considered valid, as discussed in Chapter 39.

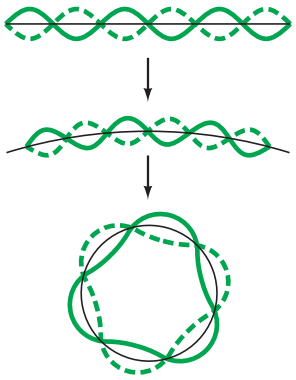

**FIGURE 37–27** An ordinary standing wave compared to a circular standing wave.

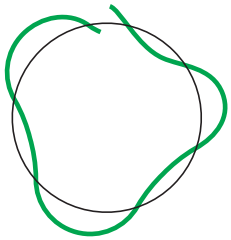
**FIGURE 37–28** When a wave does not close (and hence interferes destructively with itself), it rapidly dies out.



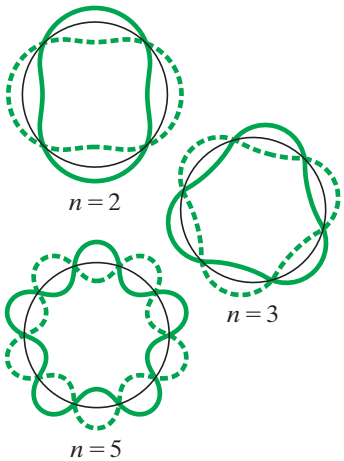


**FIGURE 37–29** Standing circular waves for two, three, and five wavelengths on the circumference; $n$, the number of wavelengths, is also the quantum number.

# Summary

Quantum theory has its origins in **Planck's quantum hypothesis**, that the energy contained in molecular oscillations is **quantized**: the energy $E$ can only be integer ($n$) multiples of $hf$, where $h$ is Planck's constant and $f$ is the natural frequency of oscillation:

$$E = nhf. \quad \textbf{(37–2)}$$

This hypothesis explained the spectrum of radiation emitted by a **blackbody** at high temperature.

Einstein proposed that for some experiments, light could be pictured as being emitted and absorbed as **quanta** (particles), which we now call **photons**, each with energy

$$E = hf \quad \textbf{(37–3)}$$

and momentum

$$p = \frac{E}{c} = \frac{hf}{c} = \frac{h}{\lambda}. \quad \textbf{(37–5)}$$

He proposed the photoelectric effect as a test for the photon theory of light. In the **photoelectric effect**, the photon theory says that each incident photon can strike an electron in a material and eject it if the photon has sufficient energy. The maximum energy of ejected electrons is then linearly related to the frequency of the incident light.

The photon theory is also supported by the **Compton effect** and the observation of electron–positron **pair production**.

The **wave–particle duality** refers to the idea that light and matter (such as electrons) have both wave and particle properties. The wavelength of a material particle is given by

$$\lambda = \frac{h}{p}, \quad \textbf{(37–7)}$$

where $p$ is the momentum of the object ($p = mv$ for a particle of mass $m$ and speed $v$).

The **principle of complementarity** states that we must be aware of both the particle and wave properties of light and of matter for a complete understanding of them.

Electron microscopes (EM) make use of the wave properties of electons to form an image: their "lenses" are magnetic. Various types of EM exist: some can magnify 100,000× (1000× better than a light mciroscope); others can give a 3-D image.

Early models of the atom include the plum-pudding model, and Rutherford's planetary (or nuclear) model of an atom which consists of a tiny but massive positively charged nucleus surrounded (at a relatively great distance) by electrons.

To explain the **line spectra** emitted by atoms, as well as the stability of atoms, **Bohr's theory** postulated that: (1) electrons bound in an atom can only occupy orbits for which the angular momentum is quantized, which results in discrete values for the radius and energy; (2) an electron in such a **stationary state** emits no radiation; (3) if an electron jumps to a lower state, it emits a photon whose energy equals the difference in energy between the two states; (4) the angular momentum $L$ of atomic electrons is quantized by the rule

$$L = \frac{nh}{2\pi}, \quad \textbf{(37–10)}$$

where $n$ is an integer called the **principal quantum number**. The $n = 1$ state is the **ground state**, which in hydrogen has an energy $E_1 = -13.6\,\text{eV}$. Higher values of $n$ correspond to **excited states**, and their energies are

$$E_n = -(13.6\,\text{eV})\frac{Z^2}{n^2}, \quad \textbf{(37–14b)}$$

where $Ze$ is the electric charge on the nucleus.

Atoms are excited to these higher states by collisions with other atoms or electrons, or by absorption of a photon of just the right frequency.

De Broglie's hypothesis that electrons (and other matter) have a wavelength $\lambda = h/mv$ gave an explanation for Bohr's quantized orbits by bringing in the wave–particle duality: the orbits correspond to circular standing waves in which the circumference of the orbit equals a whole number ($n$) of wavelengths.

# Questions

1. What can be said about the relative temperatures of whitish-yellow, reddish, and bluish stars? Explain.
2. If energy is radiated by all objects, why can we not see most of them in the dark?
3. Does a lightbulb at a temperature of 2500 K produce as white a light as the Sun at 6000 K? Explain.
4. Explain why the existence of a cutoff frequency in the photoelectric effect more strongly favors a particle theory rather than a wave theory of light.
5. If the threshold wavelength in the photoelectric effect increases when the emitting metal is changed to a different metal, what can you say about the work functions of the two metals?
6. The work functions for sodium and cesium are 2.28 eV and 2.14 eV, respectively. For incident photons of a given frequency, which metal will give a higher maximum kinetic energy for the electrons?
7. UV light causes sunburn, whereas visible light does not. Suggest a reason.
8. Light of 450-nm wavelength strikes a metal surface, and a stream of electrons emerges from the metal. If light of the same intensity but of wavelength 400 nm strikes the surface, are more electrons emitted? Does the energy of the emitted electrons change? Explain.
9. (*a*) Does a beam of infrared photons always have less energy than a beam of ultraviolet photons? Explain. (*b*) Does a single photon of infrared light always have less energy than a single photon of ultraviolet light?
10. If an X-ray photon is scattered by an electron at rest, does the photon's wavelength change? If so, does it increase or decrease?
11. In both the photoelectric effect and in the Compton effect, a photon collides with an electron causing the electron to fly off. What then, is the difference between the two processes?
12. Consider a point source of light. How would the intensity of light vary with distance from the source according to (*a*) wave theory, (*b*) particle (photon) theory? Would this help to distinguish the two theories?

**13.** If an electron and a proton travel at the same speed, which has the shorter de Broglie wavelength? Explain.

**14.** Why do we say that light has wave properties? Why do we say that light has particle properties?

**15.** Why do we say that electrons have wave properties? Why do we say that electrons have particle properties?

**16.** What are the differences between a photon and an electron? Be specific: make a list.

**17.** In Rutherford's planetary model of the atom, what keeps the electrons from flying off into space?

**18.** How can you tell if there is oxygen near the surface of the Sun?

**19.** When a wide spectrum of light passes through hydrogen gas at room temperature, absorption lines are observed that correspond only to the Lyman series. Why don't we observe the other series?

**20.** Explain how the closely spaced energy levels for hydrogen near the top of Fig. 37–26 correspond to the closely spaced spectral lines at the top of Fig. 37–21.

**21.** (*a*) List at least three successes of the Bohr model of the atom, according to Section 37–11. (*b*) List at least two observations that the Bohr model could not explain, according to Section 37–12.

**22.** Is it possible for the de Broglie wavelength of a "particle" to be greater than the dimensions of the particle? To be smaller? Is there any direct connection? Explain.

**23.** How can the spectrum of hydrogen contain so many lines when hydrogen contains only one electron?

**24.** An electron and a proton are accelerated through the same voltage. Which has the longer wavelength? Explain why.

**25.** The Lyman series is brighter than the Balmer series, because this series of transitions ends up in the most common state for hydrogen, the ground state. Why then was the Balmer series discovered first?

**26.** Use conservation of momentum to explain why photons emitted by hydrogen atoms have slightly less energy than that predicted by Eq. 37–9.

**27.** State if a continuous or a line spectrum is produced by each of the following: (*a*) a hot solid object; (*b*) an excited, rarefied gas; (*c*) a hot liquid; (*d*) light from a hot solid that passes through a cooler rarefied gas; (*e*) a hot dense gas. For each, if a line spectrum is produced, is it an emission or an absorption spectrum?

**28.** Compare the emission spectrum for hydrogen at very high temperature (when some of the atoms are in excited states) with the absorption spectrum of hydrogen at room temperature (when all atoms are in the ground state). Will the two spectra contain identical lines? Explain.

**29.** In a helium atom, which contains two electrons, do you think that on average the electrons are closer to the nucleus or farther away than in a hydrogen atom? Why?

**30.** Does each of the following support the wave nature or the particle nature of light? (*a*) The existence of the cutoff frequency in the photoelectric effect; (*b*) Young's double-slit experiment; (*c*) the shift in the photon frequency in Compton scattering; (*d*) the diffraction of light.

## MisConceptual Questions

**1.** Which of the following statements is true regarding how blackbody radiation changes as the temperature of the radiating object increases?
(*a*) Both the maximum intensity and the peak wavelength increase.
(*b*) The maximum intensity increases, and the peak wavelength decreases.
(*c*) Both the maximum intensity and the peak wavelength decrease.
(*d*) The maximum intensity decreases, and the peak wavelength increases.

**2.** A beam of red light and a beam of blue light have equal intensities. Which statement is true?
(*a*) There are more photons in the blue beam.
(*b*) There are more photons in the red beam.
(*c*) Both beams contain the same number of photons.
(*d*) The number of photons is not related to intensity.

**3.** Which of the following is necessarily true?
(*a*) Red light has more energy than violet light.
(*b*) Violet light has more energy than red light.
(*c*) A single photon of red light has more energy than a single photon of violet light.
(*d*) A single photon of violet light has more energy than a single photon of red light.
(*e*) None of the above.
(*f*) A combination of the above (specify).

**4.** If a photon of energy $E$ ejects electrons from a metal with kinetic energy $K$, then a photon with energy $E/2$
(*a*) will eject electrons with kinetic energy $K/2$.
(*b*) will eject electrons with an energy greater than $K/2$.
(*c*) will eject electrons with an energy less than $K/2$.
(*d*) might not eject any electrons.

**5.** Monochromatic light is incident on a metal surface, and electrons are ejected. If the intensity of that light increases, what will happen to the maximum energy of the electrons?
(*a*) The maximum energy will increase.
(*b*) The maximum energy will decrease.
(*c*) The maximum energy will remain the same.
(*d*) Changes in the maximum energy cannot be determined without additional information.

**6.** Monochromatic light is incident on a metal surface, but no photoelectrons are emitted. If electrons are to be ejected from the surface, how should the incident light be adjusted?
(*a*) Light of a shorter wavelength should be used.
(*b*) The intensity of the light should be increased.
(*c*) Light of a longer wavelength should be used.
(*d*) The intensity of the light should be decreased.

**7.** If the momentum of an electron is doubled, how would its wavelength change?
(*a*) No change.
(*b*) It would be halved.
(*c*) It would double.
(*d*) It would be quadrupled.
(*e*) It would be reduced to one-fourth.

8. Which of the following can be thought of as either a wave or a particle?
(*a*) Light.
(*b*) An electron.
(*c*) A proton.
(*d*) All of the above.

9. An electron
(*a*) is a particle.
(*b*) is a wave.
(*c*) is both a particle and a wave.
(*d*) exhibits particle properties, or wave properties, depending on the experiment being performed.

10. When you throw a baseball, its de Broglie wavelength is
(*a*) the same size as the ball.
(*b*) about the same size as an atom $(10^{-10}\,\text{m})$.
(*c*) about the same size as an atom's nucleus $(10^{-15}\,\text{m})$.
(*d*) much smaller than the size of an atom's nucleus.

11. Electrons and photons of light are similar in that
(*a*) both have momentum given by $h/\lambda$.
(*b*) both exhibit wave–particle duality.
(*c*) both are used in diffraction experiments to explore structure.
(*d*) All of the above.
(*e*) None of the above.

12. In Rutherford's famous set of experiments described in Section 37–9, the fact that some alpha particles were deflected at large angles indicated that
(*a*) the nucleus was positive.
(*b*) charge was quantized.
(*c*) the nucleus was concentrated in a small region of space.
(*d*) most of the atom is empty space.
(*e*) None of the above.

13. Which of the following is the currently accepted model of the atom?
(*a*) The plum-pudding model.
(*b*) The Rutherford atom.
(*c*) The Bohr atom.
(*d*) None of the above.

14. Which of the following electron transitions between two energy states ($n$) in the hydrogen atom corresponds to the emission of a photon with the longest wavelength?
(*a*) $2 \rightarrow 5$.
(*b*) $5 \rightarrow 2$.
(*c*) $5 \rightarrow 8$.
(*d*) $8 \rightarrow 5$.

15. If we set the potential energy of an electron and a proton to be zero when they are an infinite distance apart, then the lowest energy a bound electron in a hydrogen atom can have is
(*a*) 0.
(*b*) −13.6 eV.
(*c*) any possible value.
(*d*) any value between −13.6 eV and 0.

# Problems

## 37–1 Blackbodies; Planck's Quantum Hypothesis

1. (I) What is the peak wavelength for radiation from (*a*) ice at 273 K, (*b*) a floodlamp at 3500 K, (*c*) helium at 4.2 K, (*d*) for the universe at $T = 2.725$ K, assuming blackbody emission? In what region of the EM spectrum is each?

2. (I) How hot is metal being welded if it radiates most strongly at 490 nm?

3. (I) An HCl molecule vibrates with a natural frequency of $8.1 \times 10^{13}$ Hz. What is the difference in energy (in joules and electron volts) between successive values of the oscillation energy?

4. (I) (*a*) What is the temperature if the peak of a blackbody spectrum is at 16.0 nm? (*b*) What is the wavelength at the peak of a blackbody spectrum if the body is at a temperature of 2200 K?

5. (II) The steps of a flight of stairs are 20.0 cm high (vertically). If a 68.0-kg person stands with both feet on the same step, what is the gravitational potential energy of this person, relative to the ground, on (*a*) the first step, (*b*) the second step, (*c*) the third step, (*d*) the $n^{\text{th}}$ step? (*e*) What is the change in energy as the person descends from step 6 to step 2?

6. (II) Estimate the peak wavelength of light issuing from the pupil of the human eye (which approximates a blackbody) assuming normal body temperature.

7. (III) Planck's radiation law is given by:

$$I(\lambda, T) = \frac{2\pi hc^2\lambda^{-5}}{e^{hc/\lambda kT} - 1}$$

where $I(\lambda, T)$ is the rate energy is radiated per unit surface area per unit wavelength interval at wavelength $\lambda$ and Kelvin temperature $T$. (*a*) Show that Wien's displacement law follows from this relationship. (*b*) Determine the value of $h$ from the experimental value of $\lambda_P T$ given in the text. [You may want to use graphing techniques.] (*c*) Derive the $T^4$ dependence of the rate at which energy is radiated (as in the Stefan-Boltzmann law, Eq. 19–18), by integrating Planck's formula over all wavelengths; that is, show that

$$\int I(\lambda, T)\, d\lambda \propto T^4.$$

## 37–2 and 37–3 Photons and the Photoelectric Effect

8. (I) What is the energy of photons (in joules) emitted by an 88.5-MHz FM radio station?

9. (I) What is the energy range (in joules and eV) of photons in the visible spectrum, of wavelength 410 nm to 750 nm?

**10.** (I) What minimum frequency of light is needed to eject electrons from a metal whose work function is $5.2 \times 10^{-19}$ J?

**11.** (I) What is the longest wavelength of light that will emit electrons from a metal whose work function is 3.55 eV?

**12.** (I) A gamma ray emitted from a nucleus during radioactive decay has an energy of 420 keV. What is its wavelength? Would we expect significant diffraction of this type of light when it passes through an everyday opening, such as a door?

**13.** (II) About 0.1 eV is required to break a "hydrogen bond" in a protein molecule. Calculate the minimum frequency and maximum wavelength of a photon that can accomplish this.

**14.** (II) What wavelength photon would have the same energy as a 145-gram baseball moving 27.0 m/s?

**15.** (II) The human eye can respond to as little as $10^{-18}$ J of light energy. For a wavelength at the peak of visual sensitivity, 550 nm, how many photons lead to an observable flash?

**16.** (II) The work functions for sodium, cesium, copper, and iron are 2.3, 2.1, 4.7, and 4.5 eV, respectively. Which of these metals will not emit electrons when visible light shines on it?

**17.** (II) In a photoelectric-effect experiment it is observed that no current flows unless the wavelength is less than 540 nm. (*a*) What is the work function of this material? (*b*) What is the stopping voltage required if light of wavelength 480 nm is used?

**18.** (II) What is the maximum kinetic energy of electrons ejected from barium $(W_0 = 2.48\,\text{eV})$ when illuminated by white light, $\lambda = 410$ to 750 nm?

**19.** (II) When UV light of wavelength 285 nm falls on a metal surface, the maximum kinetic energy of emitted electrons is 1.55 eV. What is the work function of the metal?

**20.** (II) The threshold wavelength for emission of electrons from a given surface is 330 nm. What will be the maximum kinetic energy of ejected electrons when the wavelength is changed to (*a*) 290 nm, (*b*) 370 nm?

**21.** (II) When 230-nm light falls on a metal, the current through a photoelectric circuit (Fig. 37–4) is brought to zero at a stopping voltage of 1.74 V. What is the work function of the metal?

**22.** (II) A certain type of film is sensitive only to light whose wavelength is less than 670 nm. What is the energy (eV and kcal/mol) needed for the chemical reaction to occur which causes the film to change?

**23.** (II) The range of visible light wavelengths extends from about 410 nm to 700 nm. (*a*) Estimate the minimum energy (eV) required for the retina to respond and initiate vision. (*b*) Speculate as to why, at the other end of the visible range, there is a threshold photon energy beyond which the eye registers no sensation of sight. Determine this threshold photon energy (eV).

**24.** (II) At the atomic scale, the electron volt and nanometer are well-suited units for energy and distance, respectively. (*a*) Show that the energy $E$ (in electron volts) of a photon whose wavelength is $\lambda$ (nm) is given by

$$E = \frac{1.240 \times 10^3\,\text{eV}\cdot\text{nm}}{\lambda\,(\text{nm})}.$$

Use at least four significant figures for values of $h$, $c$, $e$ (see inside front cover). (*b*) How much energy (eV) does a 610-nm photon have?

**25.** (II) A **photomultiplier tube** (a very sensitive light sensor), is based on the photoelectric effect: incident photons strike a metal surface and the resulting ejected electrons are collected. By counting the number of collected electrons, the number of incident photons (i.e., the incident light intensity) can be determined. (*a*) If a photomultiplier tube is to respond properly for incident wavelengths throughout the visible range (410 nm to 750 nm), what is the maximum value for the work function $W_0$ (eV) of its metal surface? (*b*) If $W_0$ for its metal surface is above a certain threshold value, the photomultiplier will only function for incident ultraviolet wavelengths and be unresponsive to visible light. Determine this threshold value (eV).

**26.** (III) A group of atoms is confined to a very small (point-like) volume in a laser-based **atom trap**. The incident laser light causes each atom to emit $1.3 \times 10^6$ photons of wavelength 780 nm every second. A sensor of area 1.0 $\text{cm}^2$ measures the power emanating from the trap to be 1.6 nW when placed 25 cm away from the trapped atoms. Assuming each atom emits photons with equal probability in all directions, determine the number of trapped atoms.

**27.** (III) Assume light of wavelength $\lambda$ is incident on a metal surface, whose work function is known precisely (i.e., its uncertainty is better than 0.1% and can be ignored). Show that if the stopping voltage can be determined to an accuracy of $\Delta V_0$, the fractional uncertainty (magnitude) in wavelength is

$$\frac{\Delta\lambda}{\lambda} = \frac{\lambda e}{hc}\Delta V_0.$$

Determine this fractional uncertainty if $\Delta V_0 = 0.01$ V and $\lambda = 550$ nm.

## 37–4 Compton Effect

**28.** (I) A high-frequency photon is scattered off of an electron and experiences a change of wavelength of $1.2 \times 10^{-4}$ nm. At what angle must a detector be placed to detect the scattered photon (relative to the direction of the incoming photon)?

**29.** (II) Determine the Compton wavelength for (*a*) an electron, (*b*) a proton. (*c*) Show that if a photon has wavelength equal to the Compton wavelength of a particle, the photon's energy is equal to the rest energy of the particle.

**30.** (II) X-rays of wavelength $\lambda = 0.135$ nm are scattered from carbon. What is the expected Compton wavelength shift for photons detected at angles (relative to the incident beam) of exactly (*a*) 60°, (*b*) 90°, (*c*) 180°?

**31.** (II) In the Compton effect, determine the ratio $(\Delta\lambda/\lambda)$ of the maximum change $\Delta\lambda$ in a photon's wavelength to the photon's initial wavelength $\lambda$, if the photon is (*a*) a visible-light photon with $\lambda = 550$ nm, (*b*) an X-ray photon with $\lambda = 0.10$ nm.

**32.** (II) A 1.0-MeV gamma-ray photon undergoes a sequence of Compton-scattering events. If the photon is scattered at an angle of 0.50° in each event, estimate the number of events required to convert the photon into a visible-light photon with wavelength 555 nm. You can use an expansion for small $\theta$; see Appendix A. [Gamma rays created near the center of the Sun are transformed to visible wavelengths as they travel to the Sun's surface through a sequence of small-angle Compton scattering events.]

33. (III) In the Compton effect, a 0.140-nm photon strikes a free electron in a head-on collision and knocks it into the forward direction. The rebounding photon recoils directly backward. Use conservation of (relativistic) energy and momentum to determine (*a*) the kinetic energy of the electron, and (*b*) the wavelength of the recoiling photon. Use Eq. 37–5, but not Eqs. 37–6.

34. (III) In the Compton effect (see Fig. 37–7), use the relativistic equations for conservation of energy and of linear momentum to derive, showing all details, the Compton shift in wavelength as given by Eqs. 37–6.

## 37–5 Pair Production

35. (I) How much total kinetic energy will an electron–positron pair have if produced by a 2.85-MeV photon?

36. (II) What is the longest wavelength photon that could produce a proton–antiproton pair? (Each has a mass of $1.67\times10^{-27}$ kg.)

37. (II) What is the minimum photon energy needed to produce a $\mu^+ - \mu^-$ pair? The mass of each $\mu$ (muon) is 207 times the mass of an electron. What is the wavelength of such a photon?

38. (II) An electron and a positron, each moving at $2.5\times10^5$ m/s, collide head on, disappear, and produce two photons moving in opposite directions, each with the same energy and momentum. Determine the energy and momentum of each photon.

39. (II) A gamma-ray photon produces an electron and a positron, each with a kinetic energy of 345 keV. Determine the energy and wavelength of the photon.

## 37–7 Wave Nature of Matter

40. (I) Calculate the wavelength of a 0.21-kg ball traveling at 0.10 m/s.

41. (I) What is the wavelength of a neutron $(m = 1.67\times10^{-27}\,\text{kg})$ traveling at $1.6\times10^5$ m/s?

42. (II) The speed of an electron in a particle accelerator is 0.95*c*. Find its de Broglie wavelength. (Use relativistic momentum.)

43. (II) Calculate the ratio of the kinetic energy of an electron to that of a proton if their wavelengths are equal. Assume that the speeds are nonrelativistic.

44. (II) A Ferrari with a mass of 1400 kg approaches a freeway underpass that is 12 m across. At what speed must the car be moving, in order for it to have a wavelength such that it might somehow "diffract" after passing through this "single slit"? How do these conditions compare to normal freeway speeds of 30 m/s?

45. (II) Neutrons can be used in diffraction experiments to probe the lattice structure of crystalline solids. Since the neutron's wavelength needs to be on the order of the spacing between atoms in the lattice, about 0.3 nm, what should the speed of the neutrons be?

46. (II) An electron has a de Broglie wavelength $\lambda = 7.0\times10^{-10}$ m. (*a*) What is its momentum? (*b*) What is its speed? (*c*) What voltage was needed to accelerate it to this speed?

47. (II) What is the wavelength of an electron of energy (*a*) 20 eV, (*b*) 200 eV, (*c*) 2.0 keV?

48. (II) Show that if an electron and a proton have the same nonrelativistic kinetic energy, the proton has the shorter wavelength.

49. (II) After passing through two slits separated by a distance of 3.0 $\mu$m, a beam of electrons creates an interference pattern with its second-order maximum at an angle of 45°. Find the speed of the electrons in this beam.

## 37–8 Electron Microscope

50. (II) What voltage is needed to produce electron wavelengths of 0.33 nm? (Assume that the electrons are nonrelativistic.)

51. (II) Electrons are accelerated by 6450 V in an electron microscope. Estimate the maximum possible resolution of the microscope.

## 37–10 and 37–11 Spectra and the Bohr Model

52. (I) For the three hydrogen transitions indicated below, with $n$ being the initial state and $n'$ being the final state, is the transition an absorption or an emission? Which is higher, the initial state energy or the final state energy of the atom? Finally, which of these transitions involves the largest energy photon? (*a*) $n = 1$, $n' = 3$; (*b*) $n = 6$, $n' = 2$; (*c*) $n = 4$, $n' = 5$.

53. (I) How much energy is needed to ionize a hydrogen atom in the $n = 3$ state?

54. (I) (*a*) Determine the wavelength of the second Balmer line ($n = 4$ to $n = 2$ transition) using Fig. 37–26. Determine likewise (*b*) the wavelength of the third Lyman line.

55. (I) Calculate the ionization energy of doubly ionized lithium, $Li^{2+}$, which has $Z = 3$.

56. (I) Evaluate the Rydberg constant $R$ using the Bohr model (compare Eqs. 37–8 and 37–15) and show that its value is $R = 1.0974\times10^7\,\text{m}^{-1}$. (Use values inside front cover to 5 or 6 significant figures.)

57. (II) What is the longest wavelength light capable of ionizing a hydrogen atom in the ground state?

58. (II) In the Sun, an ionized helium $(He^+)$ atom makes a transition from the $n = 6$ state to the $n = 2$ state, emitting a photon. Can that photon be absorbed by hydrogen atoms present in the Sun? If so, between what energy states will the hydrogen atom transition occur?

59. (II) What wavelength photon would be required to ionize a hydrogen atom in the ground state and give the ejected electron a kinetic energy of 17.5 eV?

60. (II) For what maximum kinetic energy is a collision between an electron and a hydrogen atom in its ground state definitely elastic?

61. (II) Construct the energy-level diagram for the $He^+$ ion (like Fig. 37–26).

62. (II) Determine the electrostatic potential energy and the kinetic energy of an electron in the ground state of the hydrogen atom, according to the Bohr model.

63. (II) An excited hydrogen atom could, in principle, have a diameter of 0.10 mm. What would be the approximate value of $n$ for a Bohr orbit of this size? What would its energy be?

64. (II) Is the use of nonrelativistic formulas justified in the Bohr atom? To check, calculate the electron's velocity, $v$, in terms of $c$, for the ground state of hydrogen, and then calculate $\sqrt{1 - v^2/c^2}$.

**65.** (II) Assume hydrogen atoms in a gas are all initially in their ground state. If free electrons with kinetic energy 12.75 eV collide with these atoms, what photon wavelengths will be emitted by the gas?

**66.** (II) Suppose an electron was bound to a proton, as in the hydrogen atom, but by the gravitational force rather than by the electric force. What would be the radius, and energy, of the first Bohr orbit?

**67.** (II) *Correspondence principle*: Show that for large values of $n$, the difference in radius $\Delta r$ between two adjacent orbits (with quantum numbers $n$ and $n - 1$) is given by

$$\Delta r = r_n - r_{n-1} \approx \frac{2r_n}{n},$$

so $\Delta r/r_n \rightarrow 0$ as $n \rightarrow \infty$ in accordance with the correspondence principle. [Note that we can check the correspondence principle by either considering large values of $n$ $(n \rightarrow \infty)$ or by letting $h \rightarrow 0$. Are these equivalent?]

# General Problems

**68.** If a lightbulb emits 4.5 W as visible light (average wavelength 550 nm) uniformly in all directions, estimate how many photons per second of visible light will strike the pupil (4.0 mm diameter) of the eye of an observer (*a*) 1.0 m away, (*b*) 1.0 km away.

**69.** At low temperatures, nearly all the atoms in hydrogen gas will be in the ground state. What minimum frequency photon is needed if the photoelectric effect is to be observed?

**70.** A beam of 125-eV electrons is scattered from a crystal, as in X-ray diffraction, and a first-order peak is observed at $\theta = 43°$. What is the spacing between planes in the diffracting crystal? (See Section 35–11.)

**71.** A microwave oven produces electromagnetic radiation at $\lambda = 12.2$ cm and produces a power of 830 W. Calculate the number of microwave photons produced by the microwave oven each second.

**72.** Sunlight reaching the Earth's atmosphere has an intensity of about 1350 W/m$^2$. Estimate how many photons per square meter per second this represents. Take the average wavelength to be 550 nm.

**73.** Estimate the number of photons emitted by the Sun in a year. (Take the average wavelength to be 550 nm and the intensity of sunlight reaching the Earth (outer atmosphere) as 1350 W/m$^2$.)

**74.** The Big Bang theory (Chapter 44) states that the beginning of the universe was accompanied by a huge burst of photons. Those photons are still present today and make up the so-called cosmic *microwave background radiation*. The universe radiates like a blackbody with a temperature today of about 2.7 K. Calculate the peak wavelength of this radiation.

**75.** In some of Rutherford's experiments (Fig. 37–17) the $\alpha$ particles $(\text{mass} = 6.64 \times 10^{-27}\,\text{kg})$ had a kinetic energy of 4.8 MeV. How close could they get to the surface of a gold nucleus $(\text{radius} \approx 7 \times 10^{-15}\,\text{m}, Z = 79)$? Ignore the recoil motion of the nucleus.

**76.** Show that the magnitude of the electrostatic potential energy of an electron in any Bohr orbit of a hydrogen atom is twice the magnitude of its kinetic energy in that orbit.

**77.** Calculate the ratio of the gravitational force to the electric force for the electron in a hydrogen atom. Can the gravitational force be safely ignored?

**78.** In an X-ray tube (see Fig. 35–26 and discussion in Section 35–11), the high voltage between filament and target is $V$. After being accelerated through this voltage, an electron strikes the target where it is decelerated (by positively charged nuclei) and in the process one or more X-ray photons are emitted. (*a*) Show that the photon of shortest wavelength will have

$$\lambda_0 = \frac{hc}{eV}.$$

(*b*) What is the shortest wavelength of X-ray emitted when accelerated electrons strike a target at 31-kV?

**79.** Visible light incident on a diffraction grating with slit spacing of 0.010 mm has the first maximum at an angle of 3.5° from the central peak. If electrons could be diffracted by the same grating, what electron velocity would produce the same diffraction pattern as the visible light?

**80.** (*a*) Suppose an unknown element has an absorption spectrum with lines corresponding to 2.5, 4.7, and 5.1 eV above its ground state, and an ionization energy of 11.5 eV. Draw an energy level diagram for this element. (*b*) If a 5.1-eV photon is absorbed by an atom of this substance, in which state was the atom before absorbing the photon? What will be the energies of the photons that can subsequently be emitted by this atom?

**81.** Light of wavelength 408 nm falls on a metal which has a work function of 2.28 eV. (*a*) How much voltage should be applied to bring the current to zero? (*b*) What is the maximum speed of the emitted electrons? (*c*) What is the de Broglie wavelength of these electrons?

**82.** (*a*) Apply Bohr's assumptions to the Earth–Moon system to calculate the allowed energies and radii of motion. (*b*) Given the known distance between Earth and the Moon, is the quantization of the energy and radius apparent?

**83.** Show that the wavelength of a particle of mass $m$ with kinetic energy $K$ is given by the relativistic formula $\lambda = hc/\sqrt{K^2 + 2mc^2K}$.

**84.** What would be the theoretical limit of resolution for an electron microscope whose electrons are accelerated through 78 kV? (Relativistic formulas should be used.)

**85.** A flashlight emits 2.8 W of light. As the light leaves the flashlight in one direction, a reaction force is exerted on the flashlight in the opposite direction. Estimate the size of this reaction force.

*86. Three fundamental constants of nature—the gravitational constant $G$, Planck's constant $h$, and the speed of light $c$—have the **dimensions** of $[L^3/MT^2]$, $[ML^2/T]$, and $[L/T]$, respectively. (*a*) Find the mathematical combination of these fundamental constants that has the dimension of time. This combination is called the **Planck time** $t_P$ and is thought to be the earliest time, after the creation of the universe, at which the currently known laws of physics can be applied. (*b*) Determine the numerical value of $t_P$. (*c*) Find the mathematical combination of these fundamental constants that has the dimension of length. This combination is called the **Planck length** $\lambda_P$ and is thought to be the smallest length over which the currently known laws of physics can be applied. (*d*) Determine the numerical value of $\lambda_P$.

87. Imagine a free particle of mass $m$ bouncing back and forth between two perfectly reflecting walls, separated by distance $\ell$. Imagine that the two oppositely directed matter waves associated with this particle interfere to create a standing wave with a node at each of the walls. Show that the ground state (first harmonic) and first excited state (second harmonic) have (non-relativistic) kinetic energies $h^2/8m\ell^2$ and $h^2/2m\ell^2$, respectively.

88. A photon of momentum $3.53 \times 10^{-28}\,\text{kg}\cdot\text{m/s}$ is emitted from a hydrogen atom. To what spectrum series does this photon belong, and from what energy level was it ejected?

89. Imagine the following Young's double-slit experiment using matter rather than light: electrons are accelerated through a potential difference of 18 V, pass through two closely spaced slits separated by a distance $d$, and create an interference pattern. (*a*) Using Example 37–11 and Section 34–3 as guides, find the required value for $d$ if the first-order interference fringe is to be produced at an angle of 10°. (*b*) Given the approximate size of atoms, would it be possible to construct the required two-slit set-up for this experiment?

90. A beam of red laser light $(\lambda = 633\,\text{nm})$ hits a black wall and is fully absorbed. If this light exerts a total force $F = 7.5\,\text{nN}$ on the wall, how many photons per second are hitting the wall?

91. At what temperature would the average kinetic energy (Chapter 18) of a molecule of hydrogen gas $(H_2)$ be sufficient to excite a hydrogen atom out of the ground state?

92. (*a*) From Sections 31–6, 32–8, and 37–2, estimate the minimum energy (eV) that initiates the chemical process on the retina responsible for vision, (*b*) Estimate the threshold photon energy above which the eye registers no sensation of sight.

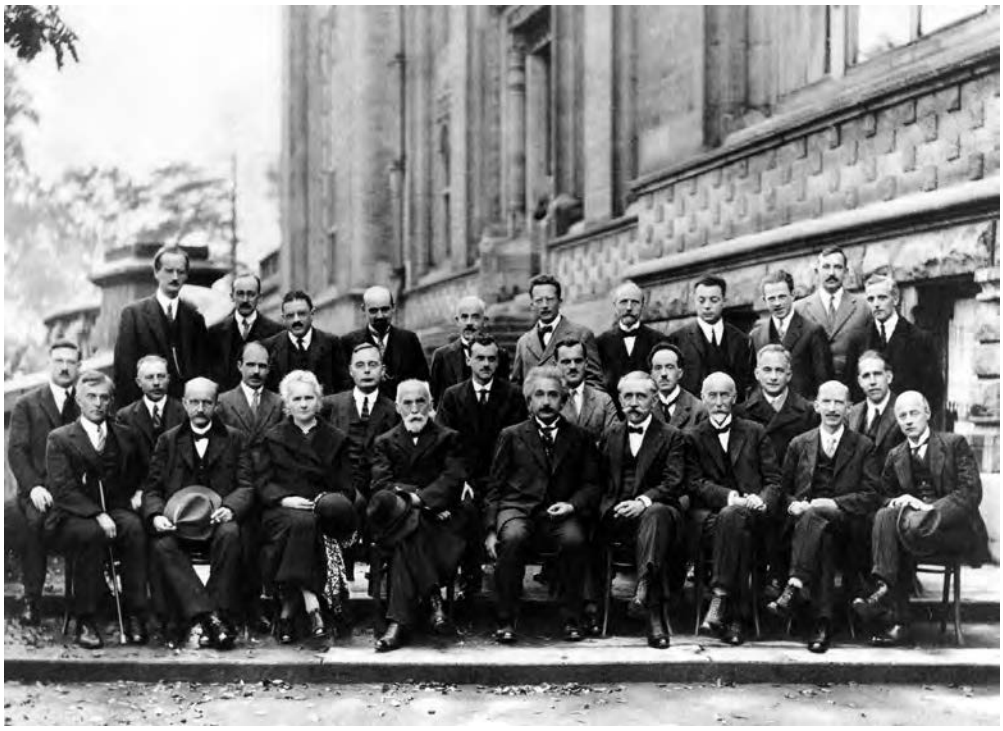
93. Suppose a particle of mass $m$ is confined to a one-dimensional box of width $L$. According to quantum theory, the particle's wave (with $\lambda = h/mv$) is a standing wave with nodes at the edges of the box. (*a*) Show the possible modes of vibration on a diagram. (*b*) Show that the kinetic energy of the particle has quantized energies given by $K = n^2h^2/8mL^2$, where $n$ is an integer. (*c*) Calculate the ground-state energy $(n = 1)$ for an electron confined to a box of width $0.50 \times 10^{-10}\,\text{m}$. (*d*) What is the ground-state energy, and speed, of a baseball $(m = 140\,\text{g})$ in a box 0.55 m wide? (*e*) An electron confined to a box has a ground-state energy of 18 eV. What is the width of the box? [*Hint*: See Sections 37–7, 37–12, and 15–9.]

94. A photon and an electron both have the same wavelength, 560 nm. What is the ratio of their speeds?

95. When a photon ionizes an atom, the event can be viewed as the photoelectric effect. What is the work function for H atoms?

96. (*a*) A rubidium atom ($m = 85$ u) is at rest with one electron in an excited energy level. When the electron jumps to the ground state, the atom emits a photon of wavelength $\lambda = 780\,\text{nm}$. Determine the resulting (nonrelativistic) recoil speed $v$ of the atom. (*b*) The recoil speed sets the lower limit on the temperature to which an ideal gas of rubidium atoms can be cooled in a laser-based **atom trap**. Using the kinetic theory of gases (Chapter 18), estimate this "lowest achievable" temperature.

97. A rubidium atom (atomic mass 85) is initially at room temperature and has a velocity $v = 260\,\text{m/s}$ due to its thermal motion. Consider the absorption of photons by this atom from a laser beam of wavelength $\lambda = 780\,\text{nm}$. Assume the rubidium atom's initial velocity $v$ is directed into the laser beam (the photons are moving right and the atom is moving left) and that the atom absorbs a new photon every 25 ns. How long will it take for this process to completely stop ("cool") the rubidium atom? [*Note*: A more detailed analysis predicts that the atom can be slowed to about 1 cm/s by this light absorption process, but it cannot be completely stopped.]



98. By what fraction does the mass of an H atom decrease when it makes an $n = 3$ to $n = 1$ transition?

99. In Chapter 31, the intensity of light striking a surface was related to the electric field of the associated electromagnetic wave. For photons, the intensity is the number of photons striking a 1-$m^2$ area per second. Suppose $1.0 \times 10^{12}$ photons of 521-nm light are incident on a 1-$m^2$ surface every second. What is the intensity of the light? Using the wave model of light, what is the maximum electric field of the electromagnetic wave?

## ANSWERS TO EXERCISES

**A:** $\lambda_P = 725\,\text{nm}$, so red.
**B:** More 1000-nm photons (each has lower energy).
**C:** $5.50 \times 10^{14}\,\text{Hz}$, 545 nm.
**D:** Only $\lambda$.
**E:** Decrease.
**F:** (*e*).
**G:** (*c*).

Participants in the 1927 Solvay Conference. Albert Einstein, seated at front center, had difficulty accepting that nature could behave according to the rules of quantum mechanics. We present a brief summary of quantum mechanics in this Chapter starting with the wave function and the uncertainty principle. We examine the Schrödinger equation and its solutions for some simple cases: free particles, the square well, and tunneling through a barrier.

38 – 8 Particle in an Infinitely Deep Square Well Potential (a Rigid Box)
38 – 9 Finite Potential Well
38–10 Tunneling through a Barrier

**CHAPTER-OPENING QUESTION—Guess now!**

The uncertainty principle states that

**(a)** no measurement can be perfect because it is technologically impossible to make perfect measuring instruments.
**(b)** it is impossible to measure exactly where a particle is, unless it is at rest.
**(c)** it is impossible to simultaneously know both the position and the momentum of a particle with complete certainty.
**(d)** a particle cannot actually have a completely certain value of momentum.

Bohr's model of the atom gave us a first (though rough) picture of what an atom is like. It proposed explanations for why there is emission and absorption of light by atoms at only certain wavelengths. The wavelengths of the line spectra and the ionization energy for hydrogen (and one-electron ions) are in excellent agreement with experiment. But the Bohr model had important limitations. It was not able to predict line spectra for more complex atoms—atoms with more than one electron—not even for the neutral helium atom, which has only two electrons. Nor could it explain why emission lines, when viewed with great precision, consist of two or more very closely spaced lines (referred to as *fine structure*). The Bohr model also did not explain why some spectral lines were brighter than others. And it could not explain the bonding of atoms in molecules or in solids and liquids.

From a theoretical point of view, too, the Bohr model was not satisfactory: it was a strange mixture of classical and quantum ideas. Moreover, the wave–particle duality was not really resolved.

**FIGURE 38–1** Erwin Schrödinger with Lise Meitner. (She was a codiscoverer of nuclear fission, Chapter 42.)

**FIGURE 38–2** Werner Heisenberg (center) on Lake Como with Enrico Fermi (left) and Wolfgang Pauli (right).

We mention these limitations of the Bohr model not to disparage it—for it was a landmark in the history of science. Rather, we mention them to show why, in the early 1920s, it became increasingly evident that a new, more comprehensive theory was needed. It was not long in coming. Less than two years after de Broglie gave us his matter–wave hypothesis, Erwin Schrödinger (1887–1961; Fig. 38–1) and Werner Heisenberg (1901–1976; Fig. 38–2) independently developed a new comprehensive theory.

## 38–1 Quantum Mechanics—A New Theory

The new theory, called **quantum mechanics**, has been extremely successful. It unifies the wave–particle duality into a single consistent theory and has successfully dealt with the spectra emitted by complex atoms, even the fine details. It also explains the relative brightness of spectral lines and how atoms form molecules. It is a much more general theory that covers all quantum phenomena from blackbody radiation to atoms and molecules. It has explained a wide range of natural phenomena and from its predictions many new practical devices have become possible. Indeed, it has been so successful that it is accepted today by nearly all physicists as the fundamental theory underlying physical processes.

Quantum mechanics deals mainly with the microscopic world of atoms and light. But this new theory, when it is applied to macroscopic phenomena, must be able to produce the old classical laws. This, the **correspondence principle** (already mentioned in Section 37–11), is satisfied fully by quantum mechanics.

This doesn't mean we should throw away classical theories such as Newton's laws. In the everyday world, classical laws are far easier to apply and they give sufficiently accurate descriptions. But when we deal with high speeds, close to the speed of light, we must use the theory of relativity; and when we deal with the tiny world of the atom, we use quantum mechanics.

Although we won't go into the detailed mathematics of quantum mechanics in this Chapter, we will discuss the main ideas and how they involve the wave and particle properties of matter to explain atomic structure and other applications.

## 38–2 The Wave Function and Its Interpretation; the Double-Slit Experiment

The important properties of any wave are its wavelength, frequency, and amplitude. For an electromagnetic wave, the frequency (or wavelength) determines whether the wave is light in the visible spectrum or not, and if so, what color it is. We also have seen (Eq. 37–3) that the frequency is a measure of the energy of the corresponding photons ($E = hf$). The amplitude or displacement of an electromagnetic wave at any point is the strength of the electric (or magnetic) field at that point, and is related to the intensity of the wave (the brightness of the light).

For material particles such as electrons, quantum mechanics relates the wavelength to momentum according to de Broglie's formula, $\lambda = h/p$, Eq. 37–7. But what corresponds to the *amplitude* or *displacement* of a matter wave? The amplitude of an electromagnetic wave is represented by the electric and magnetic fields, $E$ and $B$. In quantum mechanics, this role is played by the **wave function**, which is given the symbol $\Psi$ (the Greek capital letter psi, pronounced "sigh" or "psigh"). Thus $\Psi$ represents the wave displacement, as a function of time and position, of a new kind of field which we might call a "matter" field or a matter wave.

To understand how to interpret the wave function $\Psi$, we make an analogy with light using the wave–particle duality.

We saw in Chapter 15 that the intensity $I$ of any wave is proportional to the square of the amplitude. This holds true for light waves as well, as we saw in Chapter 31. That is,

$$I \propto E^2,$$

where $E$ is the electric field strength. From the *particle* point of view, the intensity of a light beam (of given frequency) is proportional to the number of photons, $N$, that pass through a given area per unit time. The more photons there are, the greater the intensity. Thus

$$I \propto E^2 \propto N.$$

This proportion can be turned around so that we have

$$N \propto E^2.$$

That is, the number of photons (striking a page of this book, say) is proportional to the square of the electric field strength.

If the light beam is very weak, only a few photons will be present. Indeed, it is possible to "build up" a photograph in a camera using very weak light so the effect of individual photons arriving can be seen.

If we are dealing with only one photon, the relationship above $(N \propto E^2)$ can be interpreted in a slightly different way. At any point, the square of the electric field strength $E^2$ is a measure of the *probability* that a photon will be at that location. At points where $E^2$ is large, there is a high probability the photon will be there; where $E^2$ is small, the probability is low.

We can interpret matter waves in the same way, as was first suggested by Max Born (1882–1970) in 1927. The wave function $\Psi$ may vary in magnitude from point to point in space and time. If $\Psi$ describes a collection of many electrons, then $|\Psi|^2$ at any point will be proportional to the number of electrons expected to be found at that point.[†] When dealing with small numbers of electrons we can't make very exact predictions, so $|\Psi|^2$ takes on the character of a probability. If $\Psi$, which depends on time and position, represents a single electron (say, in an atom), then $|\Psi|^2$ is interpreted as follows: $|\Psi|^2$ *at a certain point in space and time represents the probability of finding the electron at the given position and time*. Thus $|\Psi|^2$ is often referred to as the **probability density** or **probability distribution**.

## Double-Slit Interference Experiment for Electrons

To understand this better, we take as a thought experiment the familiar double-slit experiment, and consider it both for light and for electrons.

Consider two slits whose size and separation are on the order of the wavelength of whatever we direct at them, either light or electrons, Fig. 38–3. We know very well what would happen in this case for light, since this is just Young's double-slit experiment (Section 34–3): an interference pattern would be seen on the screen behind. If light were replaced by electrons with wavelength comparable to the slit size, they too would produce an interference pattern (recall Fig. 37–11). In the case of light, the pattern would be visible to the eye or could be recorded on film, semiconductor sensor, or screen. For electrons, a fluorescent screen could be used (it glows where an electron strikes).

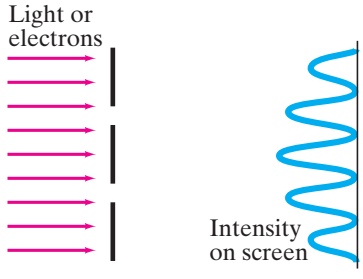

**FIGURE 38–3** Parallel beam, of light or electrons, falls on two slits whose sizes are comparable to the wavelength. An interference pattern is observed.

[†]The wave function $\Psi$ is generally a complex quantity (that is, it involves $i = \sqrt{-1}$) and hence is not directly observable. On the other hand, $|\Psi|^2$, the absolute value of $\Psi$ squared, is always a real quantity and it is to $|\Psi|^2$ that we can give a physical interpretation.

If we reduced the flow of electrons (or photons) so they passed through the slits one at a time, we would see a flash each time one struck the screen. At first, the flashes would seem random. Indeed, there is no way to predict just where any one electron would hit the screen. If we let the experiment run for a long time, and kept track of where each electron hit the screen, we would soon see a pattern emerging—the interference pattern predicted by the wave theory; see Fig. 38–4. Thus, although we could not predict where a given electron would strike the screen, we could predict probabilities. (The same can be said for photons.) The probability, as we saw, is proportional to $|\Psi|^2$. Where $|\Psi|^2$ is zero, we would get a minimum in the interference pattern. And where $|\Psi|^2$ is a maximum, we would get a peak in the interference pattern.

The interference pattern would thus occur even when electrons (or photons) passed through the slits one at a time. So the interference pattern could not arise from the interaction of one electron with another. It is as if an electron passed through both slits at the same time, interfering with itself. This is possible because an electron is not precisely a particle. It is as much a wave as it is a particle, and a wave could travel through both slits at once. But what would happen if we covered one of the slits so we knew that the electron passed through the other slit, and a little later we covered the second slit so the electron had to have passed through the first slit? The result would be that no interference pattern would be seen. We would see, instead, two bright areas (or single-slit diffraction patterns) on the screen behind the slits.

If both slits are open, the screen shows an interference pattern as if each electron passed through both slits, like a wave. Yet each electron would make a tiny spot on the screen as if it were a particle.

The main point of this discussion is this: if we treat electrons (and other particles) as if they were waves, then $\Psi$ represents the wave amplitude. If we treat them as particles, then we must treat them on a *probabilistic* basis. The square of the wave function, $|\Psi|^2$, gives the probability of finding a given electron at a given point. We cannot predict—or even follow—the path of a single electron precisely through space and time.

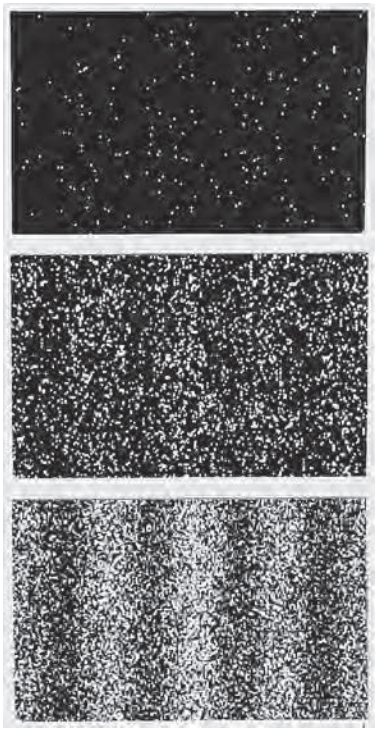

**FIGURE 38–4** Young's double-slit experiment done with electrons—note that the pattern is not evident with only a few electrons (top photo), but with more and more electrons (second and third photos), the familiar double-slit interference pattern (Chapter 34) is seen.

## 38–3 The Heisenberg Uncertainty Principle

Whenever a measurement is made, some uncertainty is always involved. For example, you cannot make an absolutely exact measurement of the length of a table. Even with a measuring stick that has markings 1 mm apart, there will be an inaccuracy of perhaps $\frac{1}{2}$ mm or so. More precise instruments will produce more precise measurements. But there is always some uncertainty involved in a measurement, no matter how good the measuring device. We expect that by using more precise instruments, the uncertainty in a measurement can be made indefinitely small.

But according to quantum mechanics, there is actually a limit to the precision of certain measurements. This limit is not a restriction on how well instruments can be made; rather, it is inherent in nature. It is the result of two factors: the wave–particle duality, and the unavoidable interaction between the thing observed and the observing instrument. Let us look at this in more detail.

To make a measurement on an object without disturbing it, at least a little, is not possible. Consider trying to locate a Ping-Pong ball in a dark room: you could probe about with your hand or a stick; or you could shine a light and detect the photons reflecting off the ball. When you search with your hand or a stick, you find the ball's position when you touch it, but at the same time you unavoidably bump it and give it some momentum. Thus you won't know its *future* position. If you search for the Ping-Pong ball using light, in order to "see" the ball, at least one photon (actually quite a few) must scatter from it, and the reflected photon must enter your eye or some other detector. When a photon strikes an ordinary-sized object, it only slightly alters the motion or position of the object.

But a photon striking a tiny object like an electron transfers enough momentum to greatly change the electron's motion and position in an unpredictable way. The mere act of measuring the position of an object at one time makes our knowledge of its future position imprecise.

Now let us see where the wave–particle duality comes in. Imagine a thought experiment in which we are trying to measure the position of an object, say an electron, with photons, Fig. 38–5. (The arguments would be similar if we were using, instead, an electron microscope.) As we saw in Chapter 35, objects can be seen to a precision at best of about the wavelength of the radiation used due to diffraction. If we want a precise position measurement, we must use a short wavelength. But a short wavelength corresponds to high frequency and large momentum $(p = h/\lambda)$; and the more momentum the photons have, the more momentum they can give the object when they strike it. If we use photons of longer wavelength, and correspondingly smaller momentum, the object's motion when struck by the photons will not be affected as much. But the longer wavelength means lower resolution, so the object's position will be less accurately known. Thus the act of observing produces an uncertainty in both the *position* and the *momentum* of the electron. This is the essence of the *uncertainty principle* first enunciated by Heisenberg in 1927.

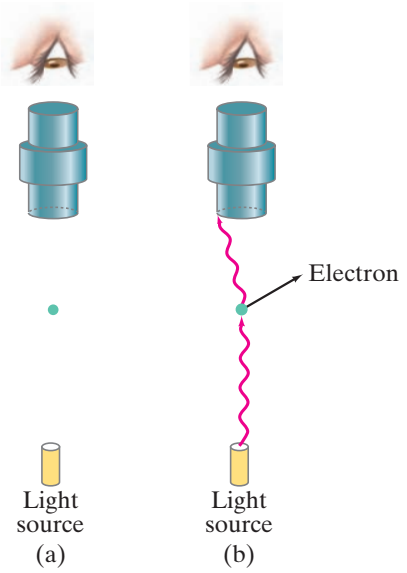

**FIGURE 38–5** Thought experiment for observing an electron with a powerful light microscope. At least one photon must scatter from the electron (transferring some momentum to it) and enter the microscope.

Quantitatively, we can make an approximate calculation of the magnitude of the uncertainties. If we use light of wavelength $\lambda$, the position can be measured at best to a precision of about $\lambda$. That is, the uncertainty in the position measurement, $\Delta x$, is approximately

$$\Delta x \approx \lambda.$$

Suppose that the object can be detected by a single photon. The photon has a momentum $p_x = h/\lambda$ (Eq. 37–5). When the photon strikes our object, it will give some or all of this momentum to the object, Fig. 38–5. Therefore, the final $x$ momentum of our object will be uncertain in the amount

$$\Delta p_x \approx \frac{h}{\lambda}$$

since we can't tell how much momentum will be transferred. The product of these uncertainties is

$$(\Delta x)(\Delta p_x) \approx (\lambda)\left(\frac{h}{\lambda}\right) \approx h.$$

The uncertainties could be larger than this, depending on the apparatus and the number of photons needed for detection. A more careful mathematical

PSE5_CH38_v1.7_19-Jun-18

calculation shows the product of the uncertainties as, at best, about

$$(\Delta x)(\Delta p_x) \gtrsim \frac{h}{2\pi} \qquad \textbf{(38–1)}$$

*UNCERTAINTY PRINCIPLE ($\Delta x$ and $\Delta p$)*

where $\Delta p_x$ is the uncertainty of the momentum in the $x$ direction.[†] This is a mathematical statement of the **Heisenberg uncertainty principle**, or, as it is sometimes called, the **indeterminancy principle**. It tells us that we cannot measure both the position *and* momentum of an object precisely at the same time. The more accurately we try to measure the position so that $\Delta x$ is small, the greater will be the uncertainty in momentum, $\Delta p_x$. If we try to measure the momentum very accurately, then the uncertainty in the position becomes large.

The uncertainty principle does not forbid individual precise measurements, however. For example, in principle we could measure the position of an object exactly. But then its momentum would be completely unknown. Thus, although we might know the position of the object exactly at one instant, we could have no idea at all where it would be a moment later. The uncertainties expressed here are inherent in nature, and reflect the best precision theoretically attainable even with the best instruments.

**⚠ CAUTION**

*Uncertainties are not due to instrument deficiency, but are inherent in nature (wave–particle)*

**EXERCISE A** Return to the Chapter-Opening Question, page 1128, and answer it again now. Try to explain why you may have answered differently the first time.

Another useful form of the uncertainty principle relates energy and time, and we examine this as follows. The object to be detected has an uncertainty in position $\Delta x \approx \lambda$. The photon that detects it travels with speed $c$, and it takes a time $\Delta t \approx \Delta x/c \approx \lambda/c$ to pass through the distance of uncertainty. Hence, the measured time when our object is at a given position is uncertain by about

$$\Delta t \approx \frac{\lambda}{c}.$$

Since the photon can transfer some or all of its energy $(= hf = hc/\lambda)$ to our object, the uncertainty in energy of our object as a result is

$$\Delta E \approx \frac{hc}{\lambda}.$$

The product of these two uncertainties is

$$(\Delta E)(\Delta t) \approx \left(\frac{hc}{\lambda}\right)\left(\frac{\lambda}{c}\right) \approx h.$$

A more careful calculation gives

$$(\Delta E)(\Delta t) \gtrsim \frac{h}{2\pi}. \qquad \textbf{(38–2)}$$

*UNCERTAINTY PRINCIPLE ($\Delta E$ and $\Delta t$)*

This form of the uncertainty principle tells us that the energy of an object can be uncertain (or can be interpreted as briefly nonconserved) by an amount $\Delta E$ for a time $\Delta t \approx h/(2\pi\,\Delta E)$.

The quantity $(h/2\pi)$ appears so often in quantum mechanics that for convenience it is given the symbol $\hbar$ ("h-bar"). That is,

$$\hbar = \frac{h}{2\pi} = \frac{6.626 \times 10^{-34}\,\text{J}\cdot\text{s}}{2\pi} = 1.055 \times 10^{-34}\,\text{J}\cdot\text{s}.$$

By using this notation, Eqs. 38–1 and 38–2 for the uncertainty principle can be written

$$(\Delta x)(\Delta p_x) \gtrsim \hbar \qquad \text{and} \qquad (\Delta E)(\Delta t) \gtrsim \hbar.$$

We have been discussing the position and velocity of an electron as if it were a particle. But it isn't simply a particle. Indeed, we have the uncertainty principle because an electron—and matter in general—has wave as well as particle properties.

[†]Note, however, that quantum mechanics does allow simultaneous precise measurements of $p_x$ and $y$: that is, $(\Delta y)(\Delta p_x) \gtrsim 0$.

What the uncertainty principle really tells us is that if we insist on thinking of the electron as a particle, then there are certain limitations on this simplified view—namely, that the position and velocity cannot both be known precisely at the same time; and even that the electron does not *have* a precise position and momentum at the same time (because it is not simply a particle). Similarly, the energy can be uncertain (or nonconserved) by an amount $\Delta E$ for a time $\Delta t \approx \hbar/\Delta E$.

Because Planck's constant, $h$, is so small, the uncertainties expressed in the uncertainty principle are usually negligible on the macroscopic level. But at the level of atomic sizes, the uncertainties are significant. Because we consider ordinary objects to be made up of atoms containing nuclei and electrons, the uncertainty principle is relevant to our understanding of all of nature. The uncertainty principle expresses, perhaps most clearly, the probabilistic nature of quantum mechanics. It thus is often used as a basis for philosophic discussion.

**EXAMPLE 38–1** **Position uncertainty of an electron.** An electron moves in a straight line with a constant speed $v = 1.10 \times 10^6\,\text{m/s}$ which has been measured to a precision of 0.10%. What is the maximum precision with which its position could be simultaneously measured?

**APPROACH** The momentum is $p = mv$, and the uncertainty in $p$ is $\Delta p = 0.0010p$. The uncertainty principle (Eq. 38–1) gives us the smallest uncertainty in position $\Delta x$ using the equals sign.

**SOLUTION** The momentum of the electron is

$$p = mv = (9.11 \times 10^{-31}\,\text{kg})(1.10 \times 10^6\,\text{m/s}) = 1.00 \times 10^{-24}\,\text{kg}\cdot\text{m/s}.$$

The uncertainty in the momentum is 0.10% of this, or $\Delta p = 1.0 \times 10^{-27}\,\text{kg}\cdot\text{m/s}$. From the uncertainty principle, the best simultaneous position measurement will have an uncertainty of

$$\Delta x \approx \frac{\hbar}{\Delta p} = \frac{1.055 \times 10^{-34}\,\text{J}\cdot\text{s}}{1.0 \times 10^{-27}\,\text{kg}\cdot\text{m/s}} = 1.1 \times 10^{-7}\,\text{m},$$

or 110 nm.

**NOTE** This is about 1000 times the diameter of an atom.

**EXERCISE B** An electron's position is measured with a precision of $0.50 \times 10^{-10}\,\text{m}$. Find the minimum uncertainty in its momentum and velocity.

**EXAMPLE 38–2** **Position uncertainty of a baseball.** What is the uncertainty in position, imposed by the uncertainty principle, on a 150-g baseball thrown at $(93 \pm 2)\,\text{mi/h} = (42 \pm 1)\,\text{m/s}$?

**APPROACH** The uncertainty in the speed is $\Delta v = 1\,\text{m/s}$. We multiply $\Delta v$ by $m$ to get $\Delta p$ and then use the uncertainty principle, solving for $\Delta x$.

**SOLUTION** The uncertainty in the momentum is

$$\Delta p = m\,\Delta v = (0.150\,\text{kg})(1\,\text{m/s}) = 0.15\,\text{kg}\cdot\text{m/s}.$$

Hence the uncertainty in a position measurement could be as small as

$$\Delta x = \frac{\hbar}{\Delta p} = \frac{1.055 \times 10^{-34}\,\text{J}\cdot\text{s}}{0.15\,\text{kg}\cdot\text{m/s}} = 7 \times 10^{-34}\,\text{m}.$$

**NOTE** This distance is far smaller than any we could imagine observing or measuring. It is trillions of trillions of times smaller than an atom. Indeed, the uncertainty principle sets no relevant limit on measurement for macroscopic objects.

**EXAMPLE 38–3** **ESTIMATE** **$J/\psi$ lifetime calculated.** The $J/\psi$ meson, discovered in 1974, was measured to have an average mass of $3100\,\text{MeV}/c^2$ (note the use of energy units since $E = mc^2$) and a mass "width" of $63\,\text{keV}/c^2$. By this we mean that the masses of different $J/\psi$ mesons were actually measured to be slightly different from one another. This mass "width" is related to the very short lifetime of the $J/\psi$ before it decays into other particles. From the uncertainty principle, if the particle exists for only a time $\Delta t$, its mass (or rest energy) will be uncertain by $\Delta E \approx \hbar/\Delta t$. Estimate the $J/\psi$ lifetime.

**APPROACH** We use the energy–time version of the uncertainty principle, Eq. 38–2.

**SOLUTION** The uncertainty of $63\,\text{keV}/c^2$ in the $J/\psi$'s mass is an uncertainty in its rest energy, which in joules is

$$\Delta E = (63 \times 10^3\,\text{eV})(1.60 \times 10^{-19}\,\text{J/eV}) = 1.01 \times 10^{-14}\,\text{J}.$$

Then we expect its lifetime $\tau$ $(= \Delta t$ using Eq. 38–2) to be

$$\tau \approx \frac{\hbar}{\Delta E} = \frac{1.055 \times 10^{-34}\,\text{J}\cdot\text{s}}{1.01 \times 10^{-14}\,\text{J}} \approx 1 \times 10^{-20}\,\text{s}.$$

Lifetimes this short are difficult to measure directly, and the assignment of very short lifetimes depends on this use of the uncertainty principle. (See Chapter 43.)

The uncertainty principle applies also for angular variables:

$$(\Delta L_z)(\Delta\phi) \gtrsim \hbar$$

where $L$ is the component of angular momentum along a given axis ($z$) and $\phi$ is the angular position in a plane perpendicular to that axis.

## 38–4 Philosophic Implications; Probability versus Determinism

The classical Newtonian view of the world is a deterministic one (see Section 6–5). One of its basic ideas is that once the position and velocity of an object are known at a particular time, its future position can be predicted if the forces on it are known. For example, if a stone is thrown a number of times with the same initial velocity and angle, and the forces on it remain the same, the path of the projectile will always be the same. If the forces are known (gravity and air resistance, if any), the stone's path can be precisely predicted. This mechanistic view implies that the future unfolding of the universe, assumed to be made up of particulate objects, is completely determined.

This classical deterministic view of the physical world has been radically altered by quantum mechanics. As we saw in the analysis of the double-slit experiment (Section 38–2), electrons all prepared in the same way will not all end up in the same place. According to quantum mechanics, certain probabilities exist that an electron will arrive at different points. This is very different from the classical view, in which the path of a particle is precisely predictable from the initial position and velocity and the forces exerted on it. According to quantum mechanics, the position and velocity of an object cannot even be known accurately at the same time. This is expressed in the uncertainty principle, and arises because basic entities, such as electrons, are not considered simply as particles: they have wave properties as well. Quantum mechanics allows us to calculate only the probability[†] that, say, an electron (when thought of as a particle) will be observed at various places.

[†]Note that these probabilities can be calculated precisely, just like exact predictions of probabilities at rolling dice or playing cards, but they are unlike predictions of probabilities at sporting events or for natural or man-made disasters, which are only estimates.

Quantum mechanics says there is some inherent unpredictability in nature. This is very different from the deterministic view of classical mechanics.

Because matter is considered to be made up of atoms, even ordinary-sized objects are expected to be governed by probability, rather than by strict determinism. For example, quantum mechanics predicts a finite (but negligibly small) probability that when you throw a stone, its path might suddenly curve upward instead of following the downward-curved parabola of normal projectile motion. Quantum mechanics predicts with extremely high probability that ordinary objects will behave just as the classical laws of physics predict. But these predictions are considered probabilities, not absolute certainties. The reason that macroscopic objects behave in accordance with classical laws with such high probability is due to the large number of molecules involved: when large numbers of objects are present in a statistical situation, deviations from the average (or most probable) approach zero. It is the average configuration of vast numbers of molecules that follows the so-called fixed laws of classical physics with such high probability, and gives rise to an apparent "determinism." Deviations from classical laws are observed when small numbers of molecules are dealt with. We can say, then, that although there are no precise deterministic laws in quantum mechanics, there are statistical laws based on probability.

It is important to note that there is a difference between the probability imposed by quantum mechanics and that used in the nineteenth century to understand thermodynamics and the behavior of gases in terms of molecules (Chapters 18 and 20). In thermodynamics, probability is used because there are far too many particles to keep track of. But the molecules are still assumed to move and interact in a deterministic way following Newton's laws. Probability in quantum mechanics is quite different; it is seen as *inherent* in nature, and not as a limitation on our abilities to calculate or to measure.

The view presented here is the generally accepted one and is called the **Copenhagen interpretation** of quantum mechanics in honor of Niels Bohr's home, since it was largely developed there through discussions between Bohr and other prominent physicists.

Because electrons are not simply particles, they cannot be thought of as following particular paths in space and time. This suggests that a description of matter in space and time may not be completely correct. This deep and far-reaching conclusion has been a lively topic of discussion among philosophers. Perhaps the most important and influential philosopher of quantum mechanics was Bohr. He argued that a space–time description of actual atoms and electrons is not possible. Yet a description of experiments on atoms or electrons must be given in terms of space and time and other concepts familiar to ordinary experience, such as waves and particles. We must not let our *descriptions* of experiments lead us into believing that atoms or electrons themselves actually move in space and time as classical particles.

## 38–5 The Schrödinger Equation in One Dimension—Time-Independent Form

In order to describe physical systems quantitatively using quantum mechanics, we must have a means of determining the wave function $\Psi$ mathematically. The basic equation (in the nonrelativistic realm) for determining $\Psi$ is the *Schrödinger equation*. We cannot, however, derive the Schrödinger equation from some higher principles, just as Newton's second law, for example, cannot be derived. The relation $\vec{\mathbf{F}} = m\vec{\mathbf{a}}$ was *invented* by Newton to describe how the motion of an object is related to the net applied force. As we saw early in this book, Newton's second law works exceptionally well. In the realm of classical physics it is the starting point for analytically solving a wide range of problems, and the solutions it yields are fully consistent with experiment. The validity of any fundamental equation resides in its agreement with experiment.

PSE5_CH38_v1.7_19-Jun-18

The Schrödinger equation forms part of a new theory, and it too had to be *invented*—and then checked against experiment, a test that it passed splendidly.

The Schrödinger equation can be written in two forms: the time-dependent version and the time-independent version. We will mainly be interested in steady-state situations—that is, when there is no time dependence—and so we mainly deal with the time-independent version. (We briefly discuss the time-dependent version in the optional Section 38–6.) The time-independent version involves a wave function with only spatial dependence which we represent by lowercase psi, $\psi(x)$, for the simple one-dimensional case we deal with here. In three dimensions, we write $\psi(x, y, z)$ or $\psi(r, \theta, \phi)$.

In classical mechanics, we solved problems using two approaches: via Newton's laws with the concept of force, and by using the energy concept with the conservation laws. The Schrödinger equation is based on the energy approach. Even though the Schrödinger equation cannot be derived, we can suggest what form it might take by using conservation of energy and considering a very simple case: that of a free particle on which no forces act, so that its potential energy $U$ is constant. We assume that our particle moves along the $x$ axis, and since no force acts on it, its momentum remains constant and its wavelength $(\lambda = h/p)$ is fixed. To describe a wave for a free particle such as an electron, we expect that its wave function will satisfy a differential equation that is akin to (but not identical to) the classical wave equation (Section 15–4 and 15–5, and Eq. 15–16). Let us see what we can infer about this equation. Consider a simple traveling wave of a single wavelength $\lambda$ whose wave displacement, as we saw in Chapter 15 for mechanical waves and in Chapter 31 for electromagnetic waves, is given by $A\sin(kx - \omega t)$, or more generally as a superposition of sine and cosine: $A\sin(kx - \omega t) + B\cos(kx - \omega t)$. We are only interested in the spatial dependence, so we consider the wave at a specific moment, say $t = 0$. Thus we write as the wave function for our free particle

$$\psi(x) = A\sin kx + B\cos kx, \qquad \textbf{(38–3a)}$$

where $A$ and $B$ are constants† and $k = 2\pi/\lambda$ (Eq. 15–11). For a particle of mass $m$ and velocity $v$, the de Broglie wavelength is $\lambda = h/p$, where $p = mv$ is the particle's momentum. Hence

$$k = \frac{2\pi}{\lambda} = \frac{2\pi p}{h} = \frac{p}{\hbar}. \qquad \textbf{(38–3b)}$$

One requirement for our wave equation, then, is that it have the wave function $\psi(x)$ as given by Eqs. 38–3 as a solution for a free particle. A second requirement is that it be consistent with the conservation of energy, which we can express as

$$\frac{p^2}{2m} + U = E,$$

where $E$ is the total energy, $U$ is the potential energy, and (since we are considering the nonrelativistic realm) the kinetic energy $K$ of our particle of mass $m$ is $K = \frac{1}{2}mv^2 = p^2/2m$. Since $p = \hbar k$ (Eq. 38–3b), we can write the conservation of energy condition as

$$\frac{\hbar^2 k^2}{2m} + U = E. \qquad \textbf{(38–4)}$$

Thus we are seeking a differential equation that satisfies conservation of energy (Eq. 38–4) when $\psi(x)$ is its solution. Now, note that if we take two derivatives of our expression for $\psi(x)$, Eq. 38–3a, we get a factor $-k^2$ multiplied by $\psi(x)$:

$$\frac{d\psi(x)}{dx} = \frac{d}{dx}(A\sin kx + B\cos kx) = k(A\cos kx - B\sin kx)$$

$$\frac{d^2\psi(x)}{dx^2} = k\frac{d}{dx}(A\cos kx - B\sin kx) = -k^2(A\sin kx + B\cos kx) = -k^2\psi(x).$$

†In quantum mechanics, constants can be complex (i.e., with a real and/or imaginary part).

Can this last term be related to the $k^2$ term in Eq. 38–4? Indeed, if we multiply this last relation by $-\hbar^2/2m$, we obtain

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} = \frac{\hbar^2 k^2}{2m}\psi(x).$$

The right side is just the first term on the left in Eq. 38–4 multiplied by $\psi(x)$. If we multiply Eq. 38–4 through by $\psi(x)$, and make this substitution, we obtain

*SCHRÖDINGER EQUATION (time-independent form)*

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x). \qquad \textbf{(38–5)}$$

This is, in fact, the one-dimensional **time-independent Schrödinger equation**, where for generality we have written $U = U(x)$. It is the basis for solving problems in nonrelativistic quantum mechanics. For a particle moving in three dimensions there would be additional derivatives with respect to $y$ and $z$ (see Chapter 39).

Note that we have by no means derived the Schrödinger equation. Although we have made a good argument in its favor, other arguments could also be made which might or might not lead to the same equation. The Schrödinger equation as written (Eq. 38–5) is useful and valid only because it has given results in accord with experiment for a wide range of situations.

There are some requirements we impose on any wave function that is a solution of the Schrödinger equation in order that it be physically meaningful. First, we insist that it be a continuous function; after all, if $|\psi|^2$ represents the probability of finding a particle at a certain point, we expect the probability to be continuous from point to point and not to take discontinuous jumps. Second, we want the wave function to be *normalized*. By this we mean that for a single particle, the probability of finding the particle at one point or another (i.e., the probabilities summed over all space) must be exactly 1 (or 100%). For a single particle, $|\psi|^2$ represents the probability of finding the particle in unit volume. Then

**CAUTION**
*Wave function must (1) be continuous and (2) normalized*

$$|\psi|^2\, dV \qquad \textbf{(38–6a)}$$

is the probability of finding the particle within a volume $dV$, where $\psi$ is the value of the wave function in this infinitesimal volume $dV$. For the one-dimensional case, $dV$ becomes $dx$, so the probability of finding a particle within $dx$ of position $x$ is

$$|\psi(x)|^2\, dx. \qquad \textbf{(38–6b)}$$

Then the sum of the probabilities over all space—that is, the probability of finding the particle somewhere—becomes

$$\int_{\text{all space}} |\psi|^2\, dV = \int |\psi|^2\, dx = 1. \qquad \textbf{(38–6c)}$$

This is called the **normalization condition**, and the integral is taken over whatever region of space in which the particle has a chance of being found, which sometimes can be all of space, from $x = -\infty$ to $x = \infty$.

## *38–6 Time-Dependent Schrödinger Equation

The more general form of the Schrödinger equation, including time dependence, for a particle of mass $m$ moving in one dimension, is

$$-\frac{\hbar^2}{2m}\frac{\partial^2\Psi(x,t)}{\partial x^2} + U(x)\Psi(x,t) = i\hbar\frac{\partial\Psi(x,t)}{\partial t}. \qquad \textbf{(38–7)}$$

This is the **time-dependent Schrödinger equation**; here $U(x)$ is the potential energy of the particle as a function of position, and $i$ is the imaginary number $i = \sqrt{-1}$.

PSE5_CH38_v1.7_19-Jun-18

For a particle moving in three dimensions, there would be additional derivatives with respect to $y$ and $z$, just as for the classical wave equation discussed in Section 15–5. Indeed, it is worth noting the similarity between the Schrödinger wave equation for zero potential energy $(U = 0)$ and the classical wave equation: $\partial^2 D/\partial t^2 = v^2 \partial^2 D/\partial x^2$, where $D$ is the wave displacement (equivalent of the wave function). In both equations there is the second derivative with respect to $x$; but in the Schrödinger equation there is only the first derivative with respect to time, whereas the classical wave equation has the second derivative for time.

As we pointed out in the preceding Section, we cannot derive the time-dependent Schrödinger equation. But we can show how the time-independent Schrödinger equation (Eq. 38–5) is obtained from it. For many problems in quantum mechanics, it is possible to write the wave function as a product of separate functions of space and time:

$$\Psi(x, t) = \psi(x) f(t).$$

Substituting this into the time-dependent Schrödinger equation (Eq. 38–7), we get:

$$-\frac{\hbar^2}{2m} f(t) \frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) f(t) = i\hbar\psi(x) \frac{df(t)}{dt}.$$

We divide both sides of this equation by $\psi(x) f(t)$ and obtain an equation that involves only $x$ on one side and only $t$ on the other:

$$-\frac{\hbar^2}{2m} \frac{1}{\psi(x)} \frac{d^2\psi(x)}{dx^2} + U(x) = i\hbar \frac{1}{f(t)} \frac{df(t)}{dt}.$$

This **separation of variables** is very convenient. Since the left side is a function only of $x$, and the right side is a function only of $t$, the equality can be valid for all values of $x$ and all values of $t$ only if each side is equal to a constant (the same constant), which we call $C$:

$$-\frac{\hbar^2}{2m} \frac{1}{\psi(x)} \frac{d^2\psi(x)}{dx^2} + U(x) = C \qquad \textbf{(38–8a)}$$

$$i\hbar \frac{1}{f(t)} \frac{df(t)}{dt} = C. \qquad \textbf{(38–8b)}$$

We multiply the first of these (Eq. 38–8a) through by $\psi(x)$ and obtain

$$-\frac{\hbar^2}{2m} \frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = C\psi(x). \qquad \textbf{(38–8c)}$$

This we recognize immediately as the time-independent Schrödinger equation, Eq. 38–5, where the constant $C$ equals the total energy $E$. Thus we have obtained the time-independent form of Schrödinger's equation from the time-dependent form.

Equation 38–8b is easy to solve. Putting $C = E$, we rewrite Eq. 38–8b as

$$\frac{df(t)}{dt} = -i\frac{E}{\hbar} f(t)$$

(note that since $i^2 = -1$, $i = -1/i$), and then as

$$\frac{df(t)}{f(t)} = -i\frac{E}{\hbar} dt.$$

We integrate both sides to obtain

$$\ln f(t) = -i\frac{E}{\hbar} t$$

or

$$f(t) = e^{-i\left(\frac{E}{\hbar}\right)t}.$$

Thus the total wave function is

$$\Psi(x,t) = \psi(x)e^{-i\left(\frac{E}{\hbar}\right)t}, \tag{38–9}$$

where $\psi(x)$ satisfies Eq. 38–5. It is, in fact, the solution of the time-independent Schrödinger equation (Eq. 38–5) that is the major task of nonrelativistic quantum mechanics. Nonetheless, we should note that in general the wave function $\Psi(x,t)$ is a complex function since it involves $i = \sqrt{-1}$. It has both a real and an imaginary part.[†] Since $\Psi(x,t)$ is not purely real, it cannot itself be physically measurable. Rather it is only $|\Psi|^2$, which *is* real, that can be measured physically.

Note also that

$$|f(t)| = |e^{-i\left(\frac{E}{\hbar}\right)t}| = 1,$$

so $|f(t)|^2 = 1$. Hence the probability density in space does not depend on time:

$$|\Psi(x,t)|^2 = |\psi(x)|^2.$$

We thus will be interested only in the time-independent Schrödinger equation, Eq. 38–5, which we will now examine for a number of simple situations.

## 38–7 Free Particles; Plane Waves and Wave Packets

A **free particle** is one that is not subject to any force, and we can therefore take its potential energy to be zero. (Although we dealt with the free particle in Section 38–5 in arguing for Schrödinger's equation, here we treat it directly using Schrödinger's equation as the basis.) Schrödinger's equation (Eq. 38–5) with $U(x) = 0$ becomes

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} = E\psi(x),$$

which can be written

$$\frac{d^2\psi}{dx^2} + \frac{2mE}{\hbar^2}\psi = 0.$$

This is a familiar equation that we encountered in Chapter 14 (Eq. 14–3) in connection with the simple harmonic oscillator. The solution to this equation, but with appropriate variable changes[‡] for our case here, is

$$\psi = A\sin kx + B\cos kx, \qquad \text{[free particle]} \tag{38–10}$$

where

$$k = \sqrt{\frac{2mE}{\hbar^2}}. \tag{38–11a}$$

Since $U = 0$, the total energy $E$ of the particle is $E = \frac{1}{2}mv^2 = p^2/2m$ (where $p$ is the momentum); thus

$$k = \frac{p}{\hbar} = \frac{h}{\lambda\hbar} = \frac{2\pi}{\lambda}. \tag{38–11b}$$

So a free particle of momentum $p$ and energy $E$ can be represented by a plane wave that varies sinusoidally. If we are not interested in the phase, we can choose $B = 0$ in Eq. 38–10, and we show this sine wave in Fig. 38–6a.

[†]Recall that $e^{-i\theta} = \cos\theta - i\sin\theta$.

[‡]In Eq. 14–3, $t$ becomes $x$ and $\omega$ becomes $k = \sqrt{2mE/\hbar^2}$. (Don't confuse this $k$ with the spring constant $k$ of Chapter 14.) We could also write our solution (Eq. 38–10) as $\psi = A\cos(kx + \phi)$ where $\phi$ is a phase constant.

PSE5_CH38_v1.7_19-Jun-18

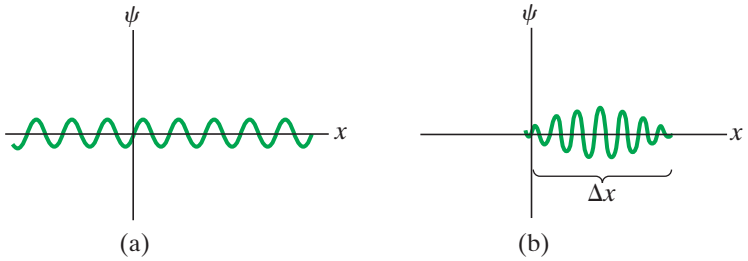

**FIGURE 38–6** (a) A plane wave describing a free particle. (b) A wave packet of "width" $\Delta x$.

**EXAMPLE 38–4** **Free electron.** An electron with energy $E = 6.3\,\text{eV}$ is in free space (where $U = 0$). Find (*a*) the wavelength $\lambda$ and (*b*) the wave function $\psi$ for the electron, assuming $B = 0$.

**APPROACH** The wavelength $\lambda = 2\pi/k$ (Eq. 38–11b) where the wave number $k$ is given by Eq. 38–11a. The wave function is given by $\psi = A \sin kx$.

**SOLUTION**

$$(a)\ \lambda = \frac{2\pi}{k} = \frac{2\pi\hbar}{\sqrt{2mE}}$$

$$= \frac{2\pi(1.055\times10^{-34}\,\text{J}\cdot\text{s})}{\sqrt{2(9.11\times10^{-31}\,\text{kg})(6.3\,\text{eV})(1.60\times10^{-19}\,\text{J/eV})}}$$

$$= 4.9\times10^{-10}\,\text{m} = 0.49\,\text{nm}.$$

$$(b)\ k = \frac{2\pi}{\lambda}$$

$$= 1.28\times10^{10}\,\text{m}^{-1},$$

so

$$\psi = A\sin kx = A\sin\left[(1.28\times10^{10}\,\text{m}^{-1})(x)\right].$$

Note in Fig. 38–6a that the sine wave will extend indefinitely[†] in the $+x$ and $-x$ directions. Thus, since $|\psi|^2$ represents the probability of finding the particle, the particle could be anywhere between $x = -\infty$ and $x = \infty$. This is fully consistent with the uncertainty principle (Section 38–3): the momentum of the particle was given and hence is known precisely $(p = \hbar k)$, so the particle's position must be totally unpredictable. Mathematically, if $\Delta p = 0$, $\Delta x \gtrsim \hbar/\Delta p = \infty$.

To describe a particle whose position is well localized—that is, it is known to be within a small region of space—we can use the concept of a **wave packet**. Figure 38–6b shows an example of a wave packet whose width is about $\Delta x$ as shown, meaning that the particle is most likely to be found within this region of space. A well-localized particle moving through space can thus be represented by a moving wave packet.

A wave packet can be represented mathematically as the sum of many plane waves (sine waves) of slightly different wavelengths. That this will work can be seen by looking carefully at Fig. 16–17. There we combined only two nearby frequencies (to explain why there are "beats") and found that the sum of two sine waves looked like a series of wave packets. If we add additional waves with other nearby frequencies, we can eliminate all but one of the packets and arrive at Fig. 38–6b. Thus a wave packet consists of waves of a *range* of wavelengths; hence it does not have a definite momentum $p\ (= h/\lambda)$, but rather, a range of momenta. This is consistent with the uncertainty principle: we have made $\Delta x$ small, so the momentum cannot be precise; that is, $\Delta p$ cannot be zero. Instead, our particle can be said to have a range of momenta, $\Delta p$, or to have an uncertainty in its momentum, $\Delta p$. It is not hard to show, even for this simple situation (see Problem 21), that $\Delta p \approx h/\Delta x$, in accordance with the uncertainty principle.

[†]Such an infinite wave makes problems for normalization since $\int_{-\infty}^{\infty}|\psi|^2\,dx = A^2\int_{-\infty}^{\infty}\sin^2 kx\,dx$ is infinite for any nonzero value for $A$. For practical purposes we can usually normalize the waves $(A \neq 0)$ by assuming that the particle is in a large but finite region of space. The region can be chosen large enough so that momentum is still rather precisely fixed.

## 38–8 Particle in an Infinitely Deep Square Well Potential (a Rigid Box)

The Schrödinger equation can be solved analytically only for a few possible forms of the potential energy $U$. We consider some simple cases here which at first may not seem realistic, but have simple solutions that can be used as approximations to understand a variety of phenomena.

In our first case, we assume that a particle of mass $m$ is confined to a one-dimensional box of width $\ell$ whose walls are perfectly rigid. (This can serve as an approximation for an electron in a metal, for example.) The particle is trapped in this box and collisions with the walls are perfectly elastic. The potential energy for this situation, which is commonly known as an **infinitely deep square well potential** or **rigid box**, is shown in Fig. 38–7. We can write the potential energy $U(x)$ as

$$U(x) = 0 \qquad 0 < x < \ell$$
$$U(x) = \infty \qquad x \le 0 \quad \text{and} \quad x \ge \ell.$$

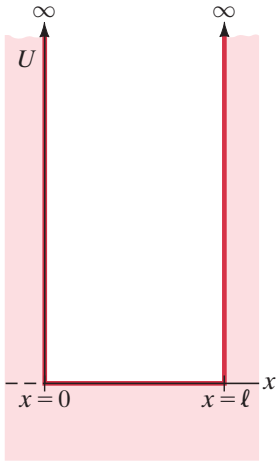

**FIGURE 38–7** A plot of potential energy $U$ vs. $x$ for an infinitely deep square well potential.

For the region $0 < x < \ell$, where $U(x) = 0$, we already know the solution of the Schrödinger equation from our discussion in Section 38–7: it is just Eq. 38–10,

$$\psi(x) = A \sin kx + B \cos kx,$$

where (from Eq. 38–11a)

$$k = \sqrt{\frac{2mE}{\hbar^2}}.$$

(We could also use $\psi(x) = A \sin(kx + \phi)$ where $\phi$ is a phase constant.) Outside the well $U(x) = \infty$, so $\psi(x)$ must be zero. (If it weren't, the product $U\psi$ in the Schrödinger equation wouldn't be finite; besides, if $U = \infty$, we can't expect a particle of finite total energy to be in such a region.) So we are concerned only with the wave function within the well, and we must determine the constants $A$ and $B$ as well as any restrictions on the value of $k$ (and hence on the energy $E$).

We insist that the wave function be continuous. Hence, if $\psi = 0$ outside the well, it must be zero at $x = 0$ and at $x = \ell$:

$$\psi(0) = 0 \quad \text{and} \quad \psi(\ell) = 0.$$

These are the **boundary conditions** for this problem. At $x = 0$, $\sin kx = 0$ but $\cos kx = 1$, so at this point Eq. 38–10 yields

$$0 = \psi(0) = A \sin 0 + B \cos 0 = 0 + B.$$

Thus $B$ must be zero. Our solution is reduced to

$$\psi(x) = A \sin kx.$$

Now we apply the other boundary condition, $\psi = 0$ at $x = \ell$:

$$0 = \psi(\ell) = A \sin k\ell.$$

We don't want $A = 0$ or we won't have a particle at all ($|\psi|^2 = 0$ everywhere). Therefore, we set

$$\sin k\ell = 0.$$

The sine is zero for angles of $0, \pi, 2\pi, 3\pi, \cdots$ radians, which means that $k\ell = 0, \pi, 2\pi, 3\pi, \cdots$. In other words,

$$k\ell = n\pi, \qquad n = 1, 2, 3, \cdots, \tag{38–12}$$

where $n$ is an integer. We eliminate the case $n = 0$ since that would make $\psi = 0$ everywhere. Thus $k$, and hence $E$, cannot have just any value; rather, $k$ is limited to values

$$k = \frac{n\pi}{\ell}.$$

PSE5_CH38_v1.7_19-Jun-18

Putting this expression in Eq. 38–11a (and substituting $h/2\pi$ for $\hbar$), we find that $E$ can have only the values

$$E = n^2 \frac{h^2}{8m\ell^2}, \qquad n = 1, 2, 3, \cdots. \tag{38–13}$$

A particle trapped in a rigid box thus can only have certain (quantized) *energies*. The lowest energy (the ground state) has $n = 1$ and is given by

$$E_1 = \frac{h^2}{8m\ell^2}. \qquad \text{[ground state]}$$

The next highest energy $(n = 2)$ is

$$E_2 = 4E_1,$$

and for higher energies (see Fig. 38–8),

$$E_3 = 9E_1$$
$$\vdots$$
$$E_n = n^2 E_1.$$

The integer $n$ is called the **quantum number** of the state.

That the lowest energy, $E_1$, is not zero means that the particle in the box can never be at rest. This is contrary to classical ideas, according to which a particle can have $E = 0$. $E_1$ is called the **zero-point energy**. One outcome of this result is that even at a temperature of absolute zero $(0\ \text{K})$, quantum mechanics predicts that particles in a box would not be at rest but would have a zero-point energy.

We also note that both the energy $E_1$ and momentum $p_1 = \hbar k = \hbar\pi/\ell$ (Eq. 38–11b) in the ground state are related inversely to the width of the box. The smaller the width $\ell$, the larger the momentum (and energy). This can be considered a direct result of the uncertainty principle (see Problem 26).

The wave function $\psi = A \sin kx$ for each of the quantum states is (since $k = n\pi/\ell$)

$$\psi_n = A \sin\left(\frac{n\pi}{\ell} x\right). \tag{38–14}$$

We can determine the constant $A$ by imposing the normalization condition (Eq. 38–6c):

$$1 = \int_{-\infty}^{\infty} \psi^2\, dx = \int_0^{\ell} A^2 \sin^2\left(\frac{n\pi}{\ell} x\right) dx, \tag{38–15}$$

where the integral needs to be done only over the range $0 < x < \ell$ because outside these limits $\psi = 0$. The integral (see Example 38–6) is equal to $A^2\ell/2$, so we have

$$A = \sqrt{\frac{2}{\ell}} \qquad \text{and} \qquad \psi_n = \sqrt{\frac{2}{\ell}} \sin\left(\frac{n\pi}{\ell} x\right).$$

The amplitude $A$ is the same for all the quantum numbers. Figure 38–9 shows the wave functions (Eq. 38–14) for $n = 1, 2, 3$, and 10. They look just like standing waves on a string—see Fig. 15–26. This is not surprising since the wave function solutions, Eq. 38–14, are the same as for the standing waves on a string, and the condition $k\ell = n\pi$ is the same in the two cases (page 448).

Figure 38–10 shows the probability distribution, $|\psi|^2$, for the same states $(n = 1, 2, 3, 10)$ for which $\psi$ is shown in Fig. 38–9. We see immediately that the particle is more likely to be found in some places than in others. For example, in the ground state $(n = 1)$, the electron is much more likely to be found near the center of the box than near the walls. This is clearly at variance with classical ideas, which predict a uniform probability density—the particle would be as likely to be found at one point in the box as at any other. The quantum-mechanical probability densities for higher states are even more complicated, with areas of low probability not only near the walls but also at regular intervals in between.

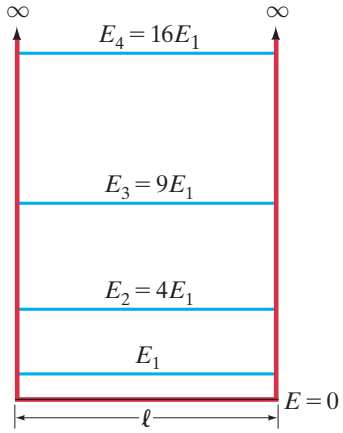

**FIGURE 38–8** Possible energy levels for a particle in a box with perfectly rigid walls (infinite square well potential).

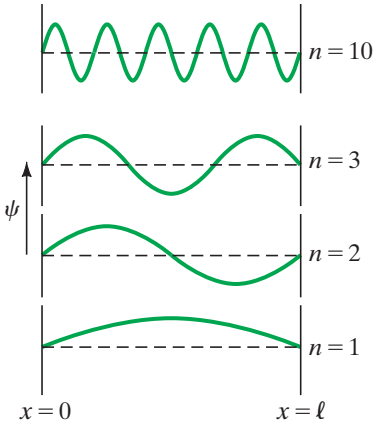

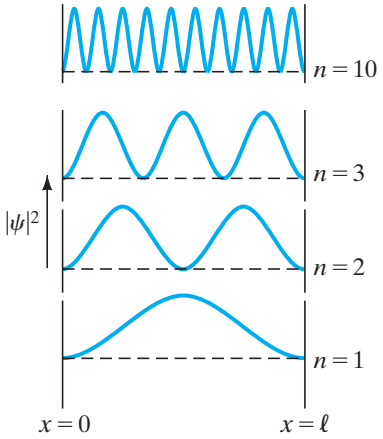

**FIGURE 38–9** Wave functions corresponding to the quantum number $n$ being 1, 2, 3, and 10 for a particle confined to a rigid box.

**FIGURE 38–10** The probability distribution for a particle in a rigid box for the states with $n = 1, 2, 3$, and 10.

**EXAMPLE 38–5** **Electron in an infinite potential well.** (*a*) Calculate the three lowest energy levels for an electron trapped in an infinitely deep square well potential of width $\ell = 1.00 \times 10^{-10}\,\text{m}$ (about the diameter of a hydrogen atom in its ground state). (*b*) If a photon were emitted when the electron jumps from the $n = 2$ state to the $n = 1$ state, what would its wavelength be?

**APPROACH** The energy levels are given by Eq. 38–13. In (*b*), $hf = hc/\lambda = E_2 - E_1$.

**SOLUTION** (*a*) The ground state $(n = 1)$ has energy

$$E_1 = \frac{h^2}{8m\ell^2} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})^2}{8(9.11 \times 10^{-31}\,\text{kg})(1.00 \times 10^{-10}\,\text{m})^2} = 6.03 \times 10^{-18}\,\text{J}.$$

In electron volts this is

$$E_1 = \frac{6.03 \times 10^{-18}\,\text{J}}{1.60 \times 10^{-19}\,\text{J/eV}} = 37.7\,\text{eV}.$$

Then

$$E_2 = (2)^2 E_1 = 151\,\text{eV}$$
$$E_3 = (3)^2 E_1 = 339\,\text{eV}.$$

(*b*) The energy difference is $E_2 - E_1 = 151\,\text{eV} - 38\,\text{eV} = 113\,\text{eV}$ or $1.81 \times 10^{-17}\,\text{J}$, and this would equal the energy of the emitted photon (energy conservation). Its wavelength would be

$$\lambda = \frac{c}{f} = \frac{hc}{E} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.00 \times 10^{8}\,\text{m/s})}{1.81 \times 10^{-17}\,\text{J}} = 1.10 \times 10^{-8}\,\text{m}$$

or 11.0 nm, which is in the ultraviolet region of the spectrum.

**EXERCISE C** The wavelength of a photon emitted in an $n = 3$ to $n = 1$ transition is (*a*) 0.062 nm, (*b*) 620 nm, (*c*) 301 nm, (*d*) $3.2 \times 10^{-15}\,\text{m}$, (*e*) 4.1 nm.

**EXAMPLE 38–6** **Calculating a normalization constant.** Show that the normalization constant $A$ for all wave functions describing a particle in an infinite potential well of width $\ell$ has a value of $A = \sqrt{2/\ell}$.

**APPROACH** The wave functions for various $n$ are

$$\psi = A \sin\frac{n\pi x}{\ell}.$$

To normalize $\psi$, we must have (Eq. 38–15)

$$1 = \int_0^\ell |\psi|^2\,dx = \int_0^\ell A^2 \sin^2\frac{n\pi x}{\ell}\,dx.$$

**SOLUTION** We need integrate only from 0 to $\ell$ since $\psi = 0$ for all other values of $x$. To evaluate this integral we let $\theta = n\pi x/\ell$ and use the trigonometric identity $\sin^2\theta = \frac{1}{2}(1 - \cos 2\theta)$. Then, with $dx = \ell\,d\theta/n\pi$, we have

$$1 = A^2 \int_0^{n\pi} \sin^2\theta \left(\frac{\ell}{n\pi}\right) d\theta = \frac{A^2\ell}{2n\pi} \int_0^{n\pi} (1 - \cos 2\theta)\,d\theta$$
$$= \frac{A^2\ell}{2n\pi}\left(\theta - \tfrac{1}{2}\sin 2\theta\right)\Big|_0^{n\pi}$$
$$= \frac{A^2\ell}{2}.$$

Thus $A^2 = 2/\ell$ and

$$A = \sqrt{\frac{2}{\ell}}.$$

**EXAMPLE 38–7** **ESTIMATE** **Probability near center of rigid box.** An electron is in an infinitely deep square well potential of width $\ell = 1.00 \times 10^{-10}\,\text{m}$. If the electron is in the ground state, what is the probability of finding it in a region of width $\Delta x = 1.0 \times 10^{-12}\,\text{m}$ at the center of the well (at $x = 0.50 \times 10^{-10}\,\text{m}$)?

**APPROACH** The probability of finding a particle in a small region of width $dx$ is $|\psi|^2\,dx$ (Eq. 38–6b). Using $A$ from Example 38–6, the wave function for the ground state is

$$\psi(x) = \sqrt{\frac{2}{\ell}}\sin\frac{\pi x}{\ell}.$$

**SOLUTION** The $n = 1$ curve in Fig. 38–9 shows that $\psi$ is roughly constant near the center of the well. So we can avoid doing an integral over $dx$ and just set $dx \approx \Delta x$ and find

$$|\psi|^2\,\Delta x = \frac{2}{\ell}\sin^2\left[\frac{\pi x}{\ell}\right]\Delta x$$

$$= \frac{2}{(1.00 \times 10^{-10}\,\text{m})}\sin^2\left[\frac{\pi(0.50 \times 10^{-10}\,\text{m})}{(1.00 \times 10^{-10}\,\text{m})}\right](1.0 \times 10^{-12}\,\text{m}) = 0.02.$$

The probability of finding the electron in this region at the center of the well is thus 2%.

**NOTE** Since $\Delta x = 1.0 \times 10^{-12}\,\text{m}$ is 1% of the well width of $1.00 \times 10^{-10}\,\text{m}$, our result of 2% probability is not what would be expected classically. Classically, the electron would be equally likely to be anywhere in the box, and we would expect the probability to be 1% instead of 2%.

**EXAMPLE 38–8** **Probability of $e^-$ in $\frac{1}{4}$ of box.** Determine the probability of finding an electron in the left quarter of a rigid box—i.e., between one wall at $x = 0$ and position $x = \ell/4$. Assume the electron is in the ground state.

**APPROACH** We cannot make the assumption we did in Example 38–7 that $|\psi|^2 \approx$ constant and $\Delta x$ is small. Here we need to integrate $|\psi|^2\,dx$ from $x = 0$ to $x = \ell/4$, which is equal to the area under the curve shown colored in Fig. 38–11.

**SOLUTION** The wave function in the ground state is $\psi_1 = \sqrt{2/\ell}\sin(\pi x/\ell)$. To find the probability of the electron in the left quarter of the box, we integrate just as in Example 38–6 but with different limits on the integral (and now we know that $A = \sqrt{2/\ell}$). That is, we set $\theta = \pi x/\ell$ (then $x = \ell/4$ corresponds to $\theta = \pi/4$) and use the identity $\sin^2\theta = \frac{1}{2}(1 - \cos 2\theta)$. Thus, with $dx = (\ell/\pi)\,d\theta$,

$$\int_0^{\ell/4} |\psi|^2\,dx = \frac{2}{\ell}\int_0^{\ell/4}\sin^2\left(\frac{\pi}{\ell}x\right)dx$$

$$= \frac{1}{\ell}\int_0^{\pi/4}(1 - \cos 2\theta)\left(\frac{\ell}{\pi}\right)d\theta$$

$$= \frac{1}{\pi}\left(\theta - \frac{1}{2}\sin 2\theta\right)\Big|_0^{\pi/4}$$

$$= \frac{1}{4} - \frac{1}{2\pi} = 0.091.$$

**NOTE** The electron spends only 9.1% of its time in the left quarter of the box. Classically it would spend 25%.

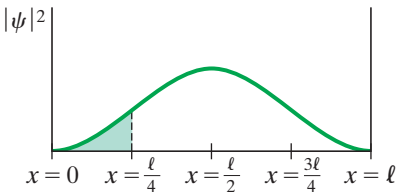

**FIGURE 38–11** Ground-state probability distribution $|\psi|^2$ for an electron in a rigid box. Same as $n = 1$ graph of Fig. 38–10; but here we show the area under the curve from $x = 0$ to $x = \ell/4$ which represents the probability of finding the electron in that region.

**EXERCISE D** What is the probability of finding the electron between $x = \ell/4$ and $x = \ell/2$? (Do you need to integrate?) (*a*) 9.1%; (*b*) 18.2%; (*c*) 25%; (*d*) 33%; (*e*) 40.9%.

**EXAMPLE 38–9** **Most likely and average positions.** Two interesting quantities are the most likely position of a particle and the average position of the particle. Consider an electron in a rigid box of width $1.00 \times 10^{-10}\,\text{m}$ in the first excited state $n = 2$. (*a*) What is its most likely position? (*b*) What is its average position?

**APPROACH** To find (*a*) the most likely position (or positions), we find the maximum value(s) of the probability distribution $|\psi|^2$ by taking its derivative and setting it equal to zero. For (*b*), the average position, we integrate $\bar{x} = \int_0^\ell x\,|\psi|^2\,dx$.

**SOLUTION** (*a*) The wave function for $n = 2$ is $\psi(x) = \sqrt{\frac{2}{\ell}}\sin\left(\frac{2\pi}{\ell}x\right)$, so $|\psi(x)|^2 = \frac{2}{\ell}\sin^2\left(\frac{2\pi}{\ell}x\right)$. To find maxima and minima, we set $d|\psi|^2/dx = 0$:

$$\frac{d}{dx}|\psi|^2 = \frac{2}{\ell}(2)\frac{2\pi}{\ell}\sin\left(\frac{2\pi}{\ell}x\right)\cos\left(\frac{2\pi}{\ell}x\right).$$

This quantity is zero when either the sine is zero $(2\pi x/\ell = 0, \pi, 2\pi, \cdots)$, or the cosine is zero $(2\pi x/\ell = \pi/2, 3\pi/2, \cdots)$. The maxima and minima occur at $x = 0,\ \ell/2,\ \ell$, and $x = \ell/4,\ 3\ell/4$. The latter $(\ell/4, 3\ell/4)$ are the maxima—see the $n = 2$ curve of Fig. 38–10; the others are minima. [To confirm, you can take the second derivative, $d^2|\psi|^2/dx^2$, which is $> 0$ for minima and $< 0$ for maxima.] (*b*) The average position is (again we use $\sin^2\theta = \frac{1}{2}(1 - \cos 2\theta)$):

$$\bar{x} = \int_0^\ell x|\psi|^2\,dx = \int_0^\ell \frac{2}{\ell}x\sin^2\left(\frac{2\pi}{\ell}x\right)dx = \frac{1}{\ell}\int_0^\ell x\left[1 - \cos\left(\frac{4\pi}{\ell}x\right)\right]dx,$$

which gives (integrating by parts, Appendix B: $u = x,\ dv = \cos(4\pi x/\ell)\,dx$):

$$\bar{x} = \frac{1}{\ell}\left[\frac{x^2}{2} - \frac{x\ell}{4\pi}\sin\left(\frac{4\pi}{\ell}x\right) - \frac{\ell^2}{16\pi^2}\cos\left(\frac{4\pi}{\ell}x\right)\right]_0^\ell = \frac{\ell}{2}.$$

Since the curves for $|\psi|^2$ are symmetric about the center of the box, we expect this answer. But note that for $n = 2$, the probability of finding the particle at the point $x = \ell/2$ is actually zero (Fig. 38–10).

**EXAMPLE 38–10** **ESTIMATE** **Confined bacterium.** A tiny bacterium with a mass of about $10^{-14}\,\text{kg}$ is confined between two rigid walls 0.1 mm apart. (*a*) Estimate its minimum speed. (*b*) If, instead, its speed is about 1 mm in 100 s, estimate the quantum number of its state.

**APPROACH** We assume $U = 0$ inside the potential well, so $E = \frac{1}{2}mv^2$. In (*a*) the minimum speed occurs in the ground state, $n = 1$, so $v = \sqrt{2E/m}$ where $E$ is the ground-state energy. In (*b*) we solve Eq. 38–13 for $n$.

**SOLUTION** (*a*) With $n = 1$, Eq. 38–13 gives $E = h^2/8m\ell^2$ so

$$v = \sqrt{\frac{2E}{m}} = \sqrt{\frac{h^2}{4m^2\ell^2}} = \frac{h}{2m\ell} = \frac{6.6 \times 10^{-34}\,\text{J}\cdot\text{s}}{2(10^{-14}\,\text{kg})(10^{-4}\,\text{m})} \approx 3 \times 10^{-16}\,\text{m/s}.$$

This is a speed so small that we could not measure it and the object would seem at rest, consistent with classical physics.

(*b*) Given $v = 10^{-3}\,\text{m}/100\,\text{s} = 10^{-5}\,\text{m/s}$, the kinetic energy of the bacterium is

$$E = \tfrac{1}{2}mv^2 = \tfrac{1}{2}(10^{-14}\,\text{kg})(10^{-5}\,\text{m/s})^2 = 0.5 \times 10^{-24}\,\text{J}.$$

From Eq. 38–13, the quantum number of this state is

$$n = \sqrt{E\left(\frac{8m\ell^2}{h^2}\right)} = \sqrt{\frac{(0.5 \times 10^{-24}\,\text{J})(8)(10^{-14}\,\text{kg})(10^{-4}\,\text{m})^2}{(6.6 \times 10^{-34}\,\text{J}\cdot\text{s})^2}} \approx 3 \times 10^{10}.$$

**NOTE** This number is so large that we could never distinguish between adjacent energy states (between $n = 3 \times 10^{10}$ and $3 \times 10^{10} + 1$). The energy states would appear to form a continuum. Thus, even though the energies involved here are small $(\ll 1\,\text{eV})$, we are still dealing with a macroscopic object (though visible only under a microscope) and the quantum result is not distinguishable from a classical one. This is in accordance with the correspondence principle.

# 38–9 Finite Potential Well

Let us now look at a particle in a box whose walls are not perfectly rigid. That is, the potential energy outside the box or well is not infinite, but rises to some level $U_0$, as shown in Fig. 38–12. This is called a **finite potential well**. It can serve as an approximation for, say, a neutron in a nucleus. There are some significant new features that arise for the finite well as compared to the infinite well. We divide the well into three regions as shown in Fig. 38–12. In region II, inside the well, the Schrödinger equation is the same as before $(U = 0)$, although the boundary conditions will be different. So we write the solution for region II as

$$\psi_{II} = A \sin kx + B \cos kx \qquad (0 < x < \ell)$$

but we don't immediately set $B = 0$ or assume that $k$ is given by Eq. 38–12.

In regions I and III, the Schrödinger equation, now with $U(x) = U_0$, is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + U_0\psi = E\psi.$$

We rewrite this as

$$\frac{d^2\psi}{dx^2} - \left[\frac{2m(U_0 - E)}{\hbar^2}\right]\psi = 0.$$

Let us assume that $E$ is less than $U_0$, so the particle is "trapped" in the well (at least classically). There might be only one such **bound state**, or several, or even none, as we shall discuss later. We define the constant $G$ by

$$G^2 = \frac{2m(U_0 - E)}{\hbar^2} \qquad \textbf{(38–16)}$$

and rewrite the Schrödinger equation as

$$\frac{d^2\psi}{dx^2} - G^2\psi = 0.$$

This equation has the general solution

$$\psi_{I,\,III} = Ce^{Gx} + De^{-Gx},$$

which can be confirmed by direct substitution, since

$$\frac{d^2}{dx^2}\left(e^{\pm Gx}\right) = G^2 e^{\pm Gx}.$$

In region I, $x$ is always negative, so $D$ must be zero (otherwise, $\psi \to \infty$ as $x \to -\infty$, giving the unacceptable result that $\int |\psi|^2\, dx \neq 1$). Similarly in region III, where $x$ is always positive, $C$ must be zero. Hence

$$\psi_I = Ce^{Gx} \qquad (x < 0)$$
$$\psi_{III} = De^{-Gx} \qquad (x > \ell).$$

In regions I and III, the wave function decreases exponentially with distance from the well boundaries. The mathematical forms of the wave function inside and outside the well are different, but we insist that the wave function be continuous even at the two walls. Schrödinger also imposed a second condition: that the slope of $\psi$, which is its first derivative, must be continuous at the walls. Hence we have the boundary conditions:

$$\psi_I = \psi_{II} \quad \text{and} \quad \frac{d\psi_I}{dx} = \frac{d\psi_{II}}{dx} \quad \text{at} \quad x = 0$$
$$\psi_{II} = \psi_{III} \quad \text{and} \quad \frac{d\psi_{II}}{dx} = \frac{d\psi_{III}}{dx} \quad \text{at} \quad x = \ell.$$

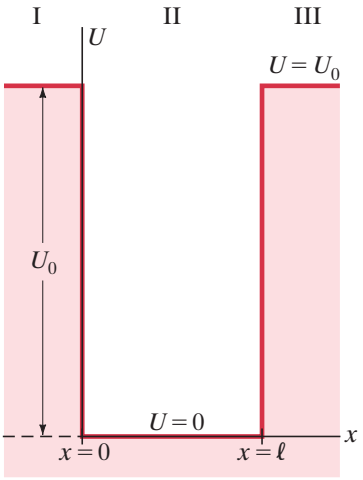

**FIGURE 38–12** Potential energy $U$ vs. $x$ for a finite one-dimensional square well.

At the left-hand wall $(x = 0)$ these boundary conditions become

$$Ce^0 = A\sin 0 + B\cos 0 \qquad \text{or} \qquad C = B$$

and

$$GCe^0 = kA\cos 0 - kB\sin 0 \qquad \text{or} \qquad GC = kA.$$

These are two of the relations that link the constants $A, B, C, D$ and the energy $E$. We get two more relations from the boundary conditions at $x = \ell$, and a fifth relation from normalizing the wave functions over all space, $\int_{-\infty}^{\infty} |\psi|^2\, dx = 1$. These five relations allow us to solve for the five unknowns, including the energy $E$. We will not go through the detailed mathematics, but we will discuss some of the results.

Figure 38–13a shows the wave function $\psi$ for the three lowest possible states, and Fig. 38–13b shows the probability distributions $|\psi|^2$. We see that the wave functions are smooth at the walls of the well. Within the well $\psi$ has the form of a sinusoidal wave; for the ground state, there is less than a half wavelength. Compare this to the infinite well (Fig. 38–9), where the ground-state wave function is exactly a half wavelength: $\lambda = 2\ell$. For our finite well, $\lambda > 2\ell$. Thus for a finite well the momentum of a particle $(p = h/\lambda)$, and hence its ground-state energy, will be less than for an infinite well of the same width $\ell$.

Outside the finite well we see that the wave function drops off exponentially on either side of the walls. That $\psi$ is not zero beyond the walls means that the particle can sometimes be found outside the well. This completely contradicts classical ideas. Outside the well, the potential energy of the particle is greater than its total energy: $U_0 > E$. This violates conservation of energy. But we clearly see in Fig. 38–13b that the particle can spend some time outside the well, where $U_0 > E$ (although the penetration into this classically forbidden region is generally not far since $|\psi|^2$ decreases exponentially with distance from either wall). The penetration of a particle into a classically forbidden region is a very important result of quantum mechanics. But how can it be? How can we accept this nonconservation of energy? We can look to the uncertainty principle, in the form

$$\Delta E\, \Delta t \gtrsim \hbar.$$

It tells us that the energy can be uncertain, and can even be nonconserved, by an amount $\Delta E$ for very short times $\Delta t \sim \hbar/\Delta E$.

Now let us consider the situation when the total energy $E$ of the particle is greater than $U_0$. In this case the particle is a free particle and everywhere its wave function is sinusoidal, Fig. 38–14. Its wavelength is different outside the well than inside, as shown. Since $K = \frac{1}{2}mv^2 = p^2/2m$, the wavelength in region II $(U = 0)$ is

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2mE}} \qquad 0 < x < \ell,$$

whereas in regions I and III, where $p^2/2m = K = E - U_0$, the wavelength is longer and is given by

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2m(E - U_0)}} \qquad x < 0 \quad \text{and} \quad x > \ell.$$

For $E > U_0$, any energy $E$ is possible. But for $E < U_0$, as we saw above, the energy is quantized and only certain states are possible.

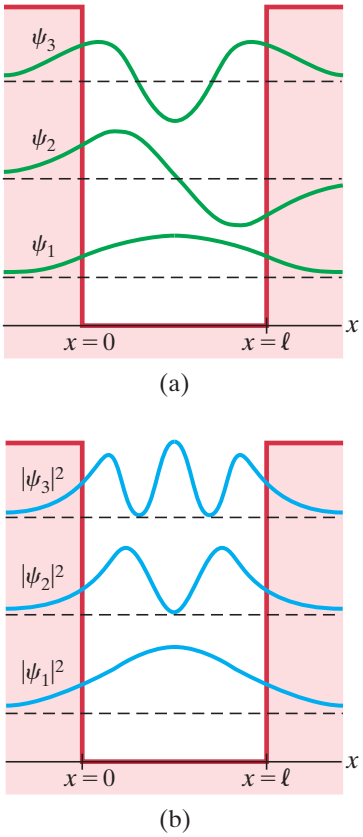

**FIGURE 38–13** The wave functions (a), and probability distributions (b), for the three lowest possible states of a particle in a finite potential well. Each of the $\psi$ and $|\psi|^2$ curves has been superposed on its energy level (dashed lines) for convenience.

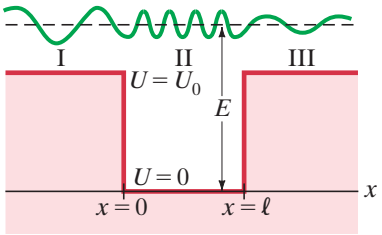

**FIGURE 38–14** The wave function of a particle of energy $E$ traveling over a potential well whose depth $U_0$ is less than $E$ (measured in the well).

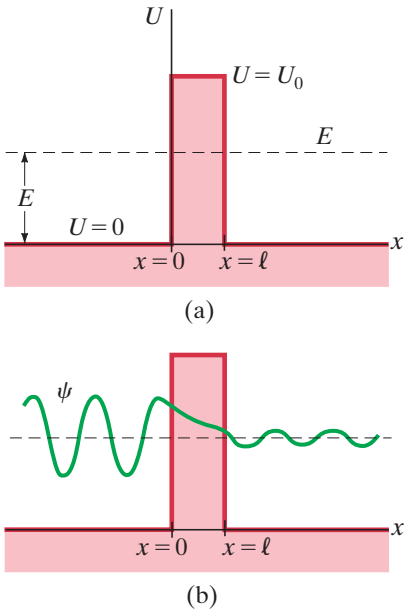
PSE5_CH38_v1.7_19-Jun-18

**EXERCISE E** An electron with energy $E = 6.0\,\text{eV}$ is near a potential well of depth $U_0 = 4.5\,\text{eV}$ and width $\ell = 10.0\,\text{nm}$. What is the wavelength of the electron when it is inside the well? (*a*) 0.50 nm; (*b*) 0.58 nm; (*c*) 1.0 nm; (*d*) 10 nm; (*e*) 20 nm.



[Another very interesting but more complicated well is the **simple harmonic oscillator** which has $U(x) = \frac{1}{2}Cx^2$ as we discussed in Chapter 14. Some quantum mechanical results, such as a zero-point energy of $\frac{1}{2}\hbar\omega$ ($E$ cannot be zero), are treated briefly in Problem 57.]

## 38–10 Tunneling through a Barrier

We saw in Section 38–9 that, according to quantum mechanics, a particle such as an electron can penetrate a barrier into a region forbidden by classical mechanics. There are a number of important applications of this phenomenon, particularly as applied to penetration of a thin barrier.

We consider a particle of mass $m$ and energy $E$ traveling to the right along the $x$ axis in free space where the potential energy $U = 0$ so the energy is all kinetic energy ($E = K$). The particle encounters a narrow potential barrier whose height $U_0$ (in energy units) is greater than $E$, and whose thickness is $\ell$ (distance units); see Fig. 38–15a. Since $E < U_0$, we would expect from classical physics that the particle could not penetrate the barrier but would simply be reflected and would return in the opposite direction. Indeed, this is what happens for macroscopic objects. But quantum mechanics predicts a nonzero probability for finding the particle on the other side of the barrier. We can see how this can happen in part (b) of Fig. 38–15, which shows the wave function. The approaching particle has a sinusoidal wave function. Within the barrier the solution to the Schrödinger equation is a decaying exponential just as for the finite well of Section 38–9. However, before the exponential dies away to zero, the barrier ends (at $x = \ell$), and for $x > \ell$ there is again a sinusoidal wave function, since $U = 0$ and $E = K > 0$. But it is a sine wave of greatly reduced amplitude. Nonetheless, because $|\psi|^2$ is nonzero beyond the barrier, we see that there is a nonzero probability that the particle penetrates the barrier. This process is called **tunneling** through the barrier, or **barrier penetration**. Although we cannot observe the particle within the barrier (it would violate conservation of energy), we can detect it after it has penetrated the barrier.

**FIGURE 38–15** (a) A potential barrier of height $U_0$ and thickness $\ell$. (b) The wave function for a particle of energy $E\ (< U_0)$ that approaches from the left. The curve for $\psi$ is superposed, for convenience, on the energy level line (dashed).

Quantitatively, we can describe the tunneling probability with a *transmission coefficient*, $T$, and a *reflection coefficient*, $R$. Suppose, for example, that $T = 0.03$ and $R = 0.97$; then if 100 particles struck the barrier, on the average 3 would tunnel through and 97 would be reflected. Note that $T + R = 1$, since an incident particle must either reflect or tunnel through. The transmission coefficient can be determined by writing the wave function for each of the three regions, just as we did for the finite well, and then applying the boundary conditions that $\psi$ and $d\psi/dx$ must be continuous at the edges of the barrier ($x = 0$ and $x = \ell$). The calculation shows (see Problem 46) that if $T$ is small ($\ll 1$), then

$$T \approx e^{-2G\ell}, \tag{38–17a}$$

where

$$G = \sqrt{\frac{2m(U_0 - E)}{\hbar^2}}. \tag{38–17b}$$

(This is the same $G$ as in Section 38–9, Eq. 38–16.) We note that increasing the height of the barrier, $U_0$, or increasing its thickness, $\ell$, will drastically reduce $T$. Indeed, for macroscopic situations, $T$ is extremely small, in accord with classical physics, which predicts no tunneling (again the correspondence principle).

**EXAMPLE 38–11** **Barrier penetration.** A 50-eV electron approaches a square barrier 70 eV high and (*a*) 1.0 nm thick, (*b*) 0.10 nm thick. What is the probability that the electron will tunnel through?

**APPROACH** We convert eV to joules and use Eqs. 38–17.

**SOLUTION** (*a*) Inside the barrier $U_0 - E = (70\,\text{eV} - 50\,\text{eV})(1.6 \times 10^{-19}\,\text{J/eV}) = 3.2 \times 10^{-18}\,J$. Then, using Eqs. 38–17, we have

$$2G\ell = 2\sqrt{\frac{2(9.11 \times 10^{-31}\,\text{kg})(3.2 \times 10^{-18}\,\text{J})}{(1.055 \times 10^{-34}\,\text{J}\cdot\text{s})^2}}\,(1.0 \times 10^{-9}\,\text{m}) = 46$$

and

$$T = e^{-2G\ell} = e^{-46} \approx 1 \times 10^{-20},$$

which is extremely small.

(*b*) or $\ell = 0.10\,\text{nm}$, $2G\ell = 4.6$ and

$$T = e^{-4.6} = 0.010.$$

Thus the electron has a 1% chance of penetrating a 0.1-nm-thick barrier, but only 1 chance in $10^{20}$ to penetrate a 1-nm barrier. By reducing the barrier thickness by a factor of 10, the probability of tunneling through increases $10^{18}$ times! Clearly the transmission coefficient is extremely sensitive to the values of $\ell$, $U_0 - E$, and $m$.

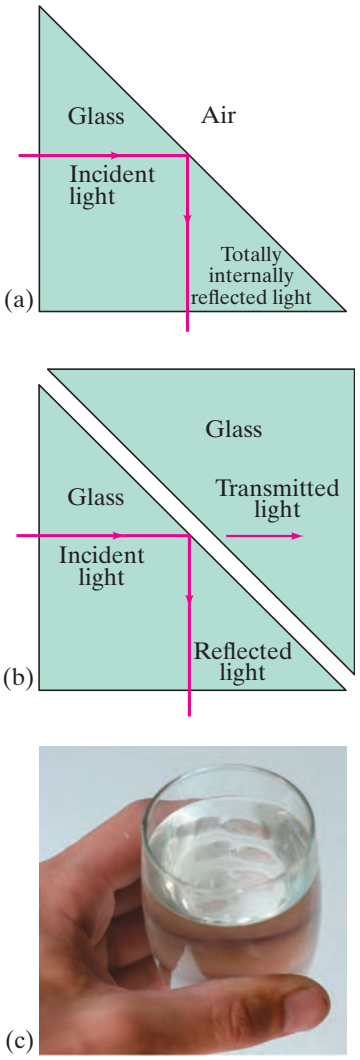


**FIGURE 38–16** (a) Light traveling in glass strikes the interface with air at an angle greater than the critical angle, and is totally internally reflected. (b) A small amount of light tunnels through a narrow air gap between two pieces of glass. (c) caption to come.

## Tunneling of Light Wave

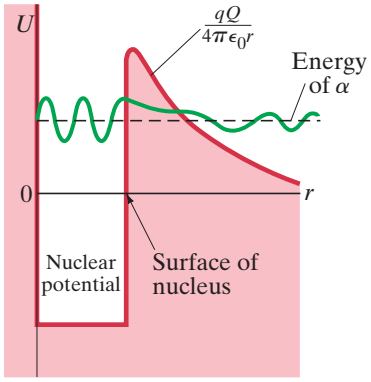
Tunneling is a result of the wave properties of material particles, and also occurs for classical waves. For example, we saw in Section 32–7 that, when light traveling in glass strikes a glass–air boundary at an angle greater than the critical angle, the light is 100% totally reflected. We studied this phenomenon of total internal reflection from the point of view of ray optics, and we show it here in Fig. 38–16a. The wave theory, however, predicts that waves actually penetrate the air for a few wavelengths—almost as if they "needed" to pass the interface to find out there is air beyond and hence need to be totally reflected. Indeed, if a second piece of glass is brought near the first as shown in Fig. 38–16b, a transmitted wave that has tunneled through the air gap can be experimentally observed. You can actually observe this for yourself by looking down into a glass of water at an angle such that light entering your eye has been totally internally reflected from the (outer) glass surface (it will look silvery). (See Fig. 38–16c.)

If you press a moistened fingertip against the glass, you can see the whorls of the ridges on your fingerprints, because at the ridges you have interfered with the total internal reflection at the outer surface of the glass. So you see light that has penetrated the gap and reflected off the ridges on your finger.

## Applications of Tunneling

Tunneling thus occurs even for classical waves. What is new in quantum mechanics is that material particles have wave properties and hence can tunnel. Tunneling has provided the basis for a number of useful devices, as well as helped to explain a number of important phenomena, some of which we mention briefly now.

Some atomic nuclei undergo **radioactive decay** by the emission of an alpha ($\alpha$) particle, which consists of two protons and two neutrons. Inside a radioactive nucleus, we can imagine that the protons and neutrons are moving about, and sometimes two of each come together and form this stable entity, the alpha particle. We will study alpha decay in more detail in Chapter 41, but for now we note that the potential energy diagram for the alpha particle inside this type of nucleus looks something like Fig. 38–17. The square well represents the attractive nuclear force that holds the nucleus together. To this is added the $1/r$ Coulomb potential energy of repulsion between the positive alpha particle and the remaining positively charged nucleus. The barrier that results is called the **Coulomb barrier**. The wave function for the tunneling particle shown must have energy greater than zero (or the barrier would be infinitely wide and tunneling could not occur), but less than the height of the barrier. If the alpha particle had energy higher than the barrier, it would always be free and the original nucleus wouldn't exist. Thus the barrier keeps the nucleus together, but occasionally a nucleus of this type can decay by the tunneling of an alpha particle. The probability of an $\alpha$ particle escaping, and hence the "lifetime" of a nucleus, depends on the height and width of the barrier, and can take on a very wide range of values for only a limited change in barrier width as we saw in Example 38–11. Lifetimes of $\alpha$-decaying radioactive nuclei range from less than 1 $\mu$s to $10^{10}$ yr.



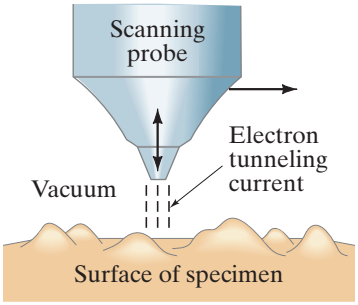


**FIGURE 38–17** Potential energy seen by an alpha particle (charge $q$) in presence of nucleus (charge $Q$), showing the wave function for tunneling out.

A so-called **tunnel diode** is an electronic device made of two types of semiconductor carrying opposite-sign charge carriers, separated by a very thin neutral region. Current can tunnel through this thin barrier and can be controlled by the voltage applied to it, which affects the height of the barrier.

The **scanning tunneling electron microscope** (STM), developed in the 1980s, makes use of tunneling through a vacuum.[†] A tiny probe, whose tip may be only one (or a few) atoms wide, is moved across the specimen to be examined in a series of linear passes. The tip, as it scans, remains very close to the surface of the specimen, about 1 nm above it, Fig. 38–18. A small voltage applied between the probe and the surface causes electrons to tunnel through the vacuum between them. This "tunneling" current is very sensitive to the gap width (see Example 38–11), so a feedback mechanism can be used to raise and lower the probe so as to maintain a constant electron tunneling current. The probe's vertical motion, following the surface of the specimen, is then plotted as a function of position, scan after scan, producing a three-dimensional image of the surface. Surface features as fine as the size of an atom can be resolved: a resolution better than 50 pm (0.05 nm) laterally and $10^{-2}$ to $10^{-3}$ nm vertically. This kind of resolution has given a great impetus to the study of the surface structure of materials. The "topographic" image of a surface actually represents the distribution of electron charge (electron wave probability distributions) on the surface.

**FIGURE 38–18** The probe tip of a scanning tunneling microscope, as it is moved horizontally, automatically moves up and down to maintain a constant tunneling current, thus producing an image of the surface.

The new **atomic force microscope** (AFM), developed in the 1980s, is in many ways similar to an STM, but can be used on a wider range of sample materials. Instead of detecting an electric current, the AFM measures the force between a cantilevered tip and the sample, a force which depends strongly on the tip–sample separation at each point. The tip is moved as for the STM.

[†]Other types of electron microscopes were discussed in Chapter 37.

PSE5_CH38_v1.7_19-Jun-18

# Summary

In 1925, Schrödinger and Heisenberg separately worked out a new theory, **quantum mechanics**, which is now considered to be the fundamental theory at the atomic level. It is a statistical theory rather than a deterministic one.

An important aspect of quantum mechanics is the Heisenberg **uncertainty principle**. It results from the wave–particle duality and the unavoidable interaction between an observed object and the observer.

One form of the uncertainty principle states that the position $x$ and momentum $p_x$ of an object cannot both be measured precisely at the same time. The products of the uncertainties, $(\Delta x)(\Delta p_x)$, can be no less than $\hbar$ $(=h/2\pi)$:

$$(\Delta x)(\Delta p_x) \gtrsim \hbar. \qquad \textbf{(38–1)}$$

Another form of the uncertainty principle states that the energy can be uncertain (or nonconserved) by an amount $\Delta E$ for a time $\Delta t$ where

$$(\Delta E)(\Delta t) \gtrsim \hbar. \qquad \textbf{(38–2)}$$

A particle such as an electron is represented by a **wave function** $\psi$. The square of the wave function, $|\psi|^2$, at any point in space represents the **probability** of finding the particle at that point. The wave function must be **normalized**, meaning that $\int |\psi|^2\, dV$ over all space must equal 1, since the particle must be found at one place or another.

In nonrelativistic quantum mechanics, $\psi$ satisfies the **Schrödinger equation**:

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2} + U\psi = E\psi, \qquad \textbf{(38–5)}$$

here in its one-dimensional time-independent form, where $U$ is the potential energy as a function of position and $E$ is the total energy of the particle.

A **free particle** subject to no forces has a sinusoidal wave function $\psi = A\sin kx + B\cos kx$ with $k = p/\hbar$ and $p$ is the particle's momentum. Such a wave of fixed momentum is spread out indefinitely in space as a plane wave.

A **wave packet**, localized in space, is a superposition of sinusoidal waves with a range of momenta.

For a particle confined to an **infinitely deep square well potential**, or **rigid box**, the Schrödinger equation gives the wave functions as

$$\psi = A\sin k\ell,$$

where $\ell$ is the width of the box, $A = \sqrt{2/\ell}$, and $k = n\pi/\ell$ with $n$ an integer, as solutions inside the well. The energy is quantized,

$$E = \frac{\hbar^2 k^2}{2m} = \frac{n^2 h^2}{8m\ell^2}. \qquad \textbf{(38–13)}$$

In a **finite potential well**, the wave function extends into the classically forbidden region where the total energy is less than the potential energy. That this is possible is consistent with the uncertainty principle. The solutions to the Schrödinger equation in these areas are decaying exponentials.

Because quantum-mechanical particles can penetrate such classically forbidden areas, they can **tunnel** through thin barriers even though the potential energy in the barrier is greater than the total energy of the particle.

# Questions

1. Compare a matter wave $\psi$ to $(a)$ a wave on a string, $(b)$ an EM wave. Discuss similarities and differences.
2. Explain why Bohr's model of the atom is not compatible with quantum mechanics, particularly the uncertainty principle.
3. Explain why it is that the more massive an object is, the easier it becomes to predict its future position.
4. In view of the uncertainty principle, why does a baseball seem to have a well-defined position and speed, whereas an electron does not?
5. Would it ever be possible to balance a very sharp needle precisely on its point? Explain.
6. When you check the pressure in a tire, doesn't some air inevitably escape? Is it possible to avoid this escape of air altogether? What is the relation to the uncertainty principle?
7. It has been said that the ground-state energy in the hydrogen atom can be precisely known but that the excited states have some uncertainty in their values (an "energy width"). Is this consistent with the uncertainty principle in its energy form? Explain.
8. If Planck's constant were much larger than it is, how would this affect our everyday life?
9. In what ways is Newtonian mechanics contradicted by quantum mechanics? In what ways is Newtonian mechanics still relevant?
10. If you knew the position of an object precisely, with no uncertainty, how well would you know its momentum?
11. A cold thermometer is placed in a hot bowl of soup. Will the temperature reading of the thermometer be the same as the temperature of the hot soup before the measurement was made? Explain.
12. Does the uncertainty principle set a limit to how well you can make any single measurement of position? Explain.
13. Discuss the connection between the zero-point energy for a particle in a rigid box and the uncertainty principle.
14. The wave function for a particle in a rigid box is zero at points within the box (except for $n = 1$). Does this mean that the probability of finding the particle at these points is zero? Does it mean that the particle cannot pass by these points? Explain.
15. What does the probability density look like for a particle in an infinite potential well for large values of $n$, say $n = 100$ or $n = 1000$? As $n$ becomes very large, do your predictions approach classical predictions in accord with the correspondence principle?
16. For a particle in an infinite potential well the separation between energy states increases as $n$ increases (see Eq. 38–13). But doesn't the correspondence principle require closer spacing between states as $n$ increases so as to approach a classical (nonquantized) situation? Explain.
17. A particle is trapped in an infinite potential well. Describe what happens to the particle's ground-state energy and wave function as the potential walls become finite and get lower and lower until they finally reach zero ($U = 0$ everywhere).

PSE5_CH38_v1.7_19-Jun-18

# MisConceptual Questions

**1.** If a parallel beam of electrons is fired throught a slit,
(*a*) the electrons can be deflected because of their wave properties.
(*b*) only electrons that hit the edge of the slit are deflected.
(*c*) electrons can interact with electromagnetic waves in the slit, forming a diffraction pattern.
(*d*) the probability of an electron making it through the slit depends on the uncertainty principle.

**2.** According to the uncertainty principle,
(*a*) there is always an uncertainty in a measurement of the position of a particle.
(*b*) there is always an uncertainty in a measurement of the momentum of a particle.
(*c*) there is always an uncertainty in a simultaneous measurement of both the position and momentum of a particle.
(*d*) All of the above.

**3.** Which of the following is the best paraphrasing of the Heisenberg uncertainty principle?
(*a*) Only if you know the exact position of a particle can you know the exact momentum of a particle.
(*b*) The larger the momentum of a particle, the smaller the position of the particle.
(*c*) The more precisely you know the position of a particle, the less well you can know the momentum of the particle.
(*d*) The better you know the position of a particle, the better you can know the momentum of the particle.
(*e*) How well you can determine the position and momentum of a particle depends on the particle's quantum numbers.

**4.** If you knew the position of an object precisely, with no uncertainty, how well would you know its momentum?
(*a*) Perfectly, no uncertainty.
(*b*) Not at all—completely uncertain.
(*c*) You would know the direction of the momentum but not its magnitude.
(*d*) You would know the magnitude but not the direction of the momentum.

**5.** What is uncertain in the Heisenberg uncertainty principle?
(*a*) Position.
(*b*) Momentum.
(*c*) Energy.
(*d*) Time interval.
(*e*) All of the above.

**6.** A hydrogen atom and a helium atom, each with 4 eV of kinetic energy, approach a thin barrier 6 MeV high. Which has the greater probability of tunneling through?
(*a*) Hydrogen.
(*b*) Helium.
(*c*) Both the same.
(*d*) Cannot evaluate.

**7.** Why is the wavelike nature of a moving baseball not ever observed?
(*a*) The baseball's frequency is too small.
(*b*) The baseball's wavelength is too small.
(*c*) The baseball's energy is too small.
(*d*) The baseball's velocity is too small.

**8.** What is a main difference between Newtonian mechanics and quantum mechanics?
(*a*) Newtonian mechanics can be used to predict exactly where a particle will be at any given time, whereas quantum mechanics gives probabilities.
(*b*) Momentum is conserved only in quantum mechanics, not in Newtonian mechanics.
(*c*) Newtonian mechanics is valid only for large objects, whereas quantum mechanics is valid only for very small objects.
(*d*) Energy is conserved only in Newtonian mechanics, not in quantum mechanics.

**9.** For the wave function $\Psi$, what is actually waving?
(*a*) The electromagnetic field.
(*b*) The gravitational field.
(*c*) Both (*a*) and (*b*).
(*d*) Neither (*a*) nor (*b*).

**10.** An electron is in an infinite square well. Which statement(s) are true about the electron?
(*a*) The electron can be at rest or it can be moving.
(*b*) The electron can have only certain energies.
(*c*) The electron can have any energy, but some values are more probable than others.
(*d*) Some locations of the electron are more probable than others.
(*e*) None of these statements is true.

**11.** A particle trapped in a finite square well has kinetic energy less than the potential energy of the well. The particle
(*a*) will always be found inside the well.
(*b*) may be found occasionally outside the well.
(*c*) may completely escape from the well.
(*d*) Both (*b*) and (*c*).

**12.** According to quantum mechanics, the energy of a particle will be quantized (only certain discrete values allowed) in all circumstances.
(*a*) True.
(*b*) No, the energy is never quantized.
(*c*) Not all: the energy of a free particle ($U = 0$ for all $x$) is not quantized.

**13.** A wave function $\Psi$ must satisfy the normalization condition because
(*a*) $\Psi$ can be infinite.
(*b*) $\Psi$ can be complex.
(*c*) the particle must exist somewhere.
(*d*) the particle may have an uncertain momentum.

# Problems

## 38–2 Wave Function, Double-Slit

**1.** (II) The neutrons in a parallel beam, each having kinetic energy 0.025 eV, are directed through two slits 0.35 mm apart. How far apart will the interference peaks be on a screen 1.0 m away? [*Hint*: First find the wavelength of the neutron.]

**2.** (II) Pellets of mass 2.0 g are fired in parallel paths with speeds of 150 m/s through a hole 3.0 mm in diameter. How far from the hole must you be to detect a 1.0-cm-diameter spread in the beam of pellets?

**3.** (II) A beam of electrons with kinetic energy 45 keV is shot through two narrow slits in a barrier. The slits are a distance $1.6 \times 10^{-6}$ m apart. If a screen is placed 45.0 cm behind the barrier, calculate the spacing between the "bright" fringes of the interference pattern produced on the screen.

## 38–3 Uncertainty Principle

**4.** (I) A proton is traveling with a speed of $(8.940 \pm 0.016) \times 10^5$ m/s. With what maximum precision can its position be ascertained? [*Hint*: $\Delta p = m\,\Delta v$.]

**5.** (I) If an electron's position can be measured to a precision of $2.1 \times 10^{-8}$ m, how precisely can its speed be known?

**6.** (I) An electron remains in an excited state of an atom for typically $10^{-8}$ s. What is the minimum uncertainty in the energy of the state (in eV)?

**7.** (II) What is the uncertainty in the mass of a muon $(m = 105.7\ \text{MeV}/c^2)$, specified in $\text{eV}/c^2$, given its lifetime of 2.20 $\mu$s?

**8.** (II) A free neutron $(m = 1.67 \times 10^{-27}\ \text{kg})$ has a mean life of 880 s. What is the uncertainty in its mass (in kg)?

**9.** (II) An electron and a 140-g baseball are each traveling 120 m/s measured to a precision of 0.075%. Calculate and compare the uncertainty in position of each.

**10.** (II) A radioactive element undergoes an alpha decay with a lifetime of 12 $\mu$s. If alpha particles are emitted with 5.2-MeV kinetic energy, find the percent uncertainty $\Delta E/E$ in the particle energy.

**11.** (II) If an electron's position can be measured to a precision of $2.6 \times 10^{-8}$ m, what is the uncertainty in its momentum? Assuming its momentum must be at least equal to its uncertainty, estimate the electron's wavelength.

**12.** (II) Estimate the lowest possible energy of a neutron contained in a typical nucleus of radius $1.2 \times 10^{-15}$ m. [*Hint*: Assume a particle can have an energy as large as its uncertainty.]

**13.** (II) How accurately can the position of a 4.75-keV electron be measured assuming its energy is known to 1.00%?

**14.** (III) Use the uncertainty principle to show that if an electron were present in the nucleus $(r \approx 10^{-15}\ \text{m})$, its kinetic energy (use relativity) would be hundreds of MeV. (Since such electron energies are not observed, we conclude that electrons are not present in the nucleus.) [*Hint*: Assume a particle can have an energy as large as its uncertainty.]

**15.** (II) An electron in the $n = 2$ state of hydrogen remains there on average about $10^{-8}$ s before jumping to the $n = 1$ state. (*a*) Estimate the uncertainty in the energy of the $n = 2$ state. (*b*) What fraction of the transition energy is this? (*c*) What is the wavelength, and width (in nm), of this line in the spectrum of hydrogen?

**16.** (III) In a double-slit experiment on electrons (or photons), suppose that we use indicators to determine which slit each electron went through (Section 38–2). These indicators must tell us the $y$ coordinate to within $d/2$, where $d$ is the distance between slits. Use the uncertainty principle to show that the interference pattern will be destroyed. [*Note*: First show that the angle $\theta$ between maxima and minima of the interference pattern is given by $\frac{1}{2}\lambda/d$, Fig. 38–19.]

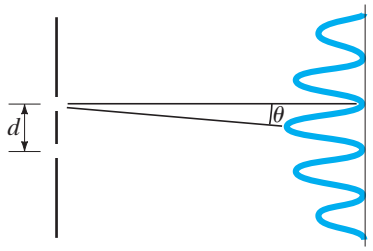

**FIGURE 38–19**
Problem 16.

## *38–6 Time-Dependent Schrödinger Equation

***17.** (II) Show that the superposition principle holds for the time-dependent Schrödinger equation. That is, show that if $\Psi_1(x,t)$ and $\Psi_2(x,t)$ are solutions, then $A\Psi_1(x,t) + B\Psi_2(x,t)$ is also a solution where $A$ and $B$ are arbitrary constants.

***18.** (III) (*a*) Show that $\Psi(x,t) = Ae^{i(kx-\omega t)}$ is a solution to the time-dependent Schrödinger equation for a free particle $[U(x) = U_0 = \text{constant}]$ but that $\Psi(x,t) = A\cos(kx - \omega t)$ and $\Psi(x,t) = A\sin(kx - \omega t)$ are not. (*b*) Show that the valid solution of part (*a*) satisfies conservation of energy if the de Broglie relations hold; $\lambda = h/p$, $\omega = E/\hbar$. That is, show that direct substitution into Eq. 38–7 gives

$$\hbar\omega = \frac{\hbar^2 k^2}{2m} + U_0.$$

## 38–7 Free Particles; Plane Waves; Wave Packets

**19.** (I) A free electron has a wave function $\psi(x) = A\sin(2.4 \times 10^{10}\,x)$, where $x$ is given in meters. Determine the electron's (*a*) wavelength, (*b*) momentum, (*c*) speed, and (*d*) kinetic energy.

**20.** (I) Write the wave function for (*a*) a free electron and (*b*) a free proton, each having a constant velocity $v = 2.7 \times 10^5$ m/s.

**21.** (III) Show that the uncertainty principle holds for a "wave packet" that is formed by two waves of similar wavelength $\lambda_1$ and $\lambda_2$. To do so, follow the argument leading up to Eq. 16–8, but use as the two waves $\psi_1 = A\sin k_1 x$ and $\psi_2 = A\sin k_2 x$. Then show that the width of each "wave packet" is $\Delta x = 2\pi/(k_1 - k_2) = 2\pi/\Delta k$ (from $t = 0.05$ s to $t = 0.15$ s in Fig. 16–17). Finally, show that $\Delta x\,\Delta p = h$ for this simple situation.

## 38–8 Infinite Square Well

**22.** (II) What is the minimum speed of an electron trapped in a 0.25-nm-wide infinitely deep square well?

**23.** (II) Show that for a particle in a perfectly rigid box, the wavelength of the wave function for any state is the de Broglie wavelength.

**24.** (II) An electron trapped in an infinitely deep square well has a ground-state energy $E = 8.4\,\text{eV}$. (*a*) What is the longest wavelength photon that an excited state of this system can emit? (*b*) What is the width of the well?

**25.** (II) An $n = 4$ to $n = 1$ transition for an electron trapped in a rigid box produces a 370-nm photon. What is the width of the box?

**26.** (II) For a particle in a box with rigid walls, determine whether our results for the ground state are consistent with the uncertainty principle by calculating the product $\Delta p\,\Delta x$. Take $\Delta x \approx \ell$, since the particle is somewhere within the box. For $\Delta p$, note that although $p$ is known ($= \hbar k$), the direction of $\vec{\mathbf{p}}$ is not known, so the $x$ component could vary from $-p$ to $+p$; hence take $\Delta p \approx 2p$.

**27.** (II) The longest-wavelength line in the spectrum emitted by an electron trapped in an infinitely deep square well is 580 nm. What is the width of the well?

**28.** (II) Determine the lowest four energy levels and wave functions for an electron trapped in an infinitely deep potential well of width 2.4 nm.

**29.** (II) Write a formula for the positions of (*a*) the maxima and (*b*) the minima in $|\psi|^2$ for a particle in the $n$th state in an infinite square well.

**30.** (II) Consider an atomic nucleus to be a rigid box of width $1.8 \times 10^{-14}\,\text{m}$. What would be the ground-state energy for (*a*) an electron, (*b*) a neutron, and (*c*) a proton in this nucleus?

**31.** (II) A proton in a nucleus can be roughly modeled as a particle in a box of nuclear dimensions. Calculate the energy released when a proton confined in a nucleus of width $1.2 \times 10^{-14}\,\text{m}$ makes a transition from the first excited state to the ground state.

**32.** (II) Consider a single oxygen molecule confined in a one-dimensional rigid box of width 3.0 mm. (*a*) Treating this as a particle in a rigid box, determine the ground-state energy. (*b*) If the molecule has an energy equal to the one-dimensional average thermal energy $\frac{1}{2}kT$ at $T = 300\,\text{K}$, what is the quantum number $n$? (*c*) What is the energy difference between the $n$th state and the next higher state?

**33.** (II) An electron is trapped in a 1.50-nm-wide rigid box. Determine the probability of finding the electron within 0.15 nm of the center of the box (on either side of center) for (*a*) $n = 1$, (*b*) $n = 5$, and (*c*) $n = 20$. (*d*) Compare to the classical prediction.

**34.** (III) If an infinitely deep well of width $\ell$ is redefined to be located from $x = -\frac{1}{2}\ell$ to $x = \frac{1}{2}\ell$ (as opposed to $x = 0$ to $x = \ell$), speculate how this will change the wave function for a particle in this well. Investigate your speculation(s) by determining the wave functions and energy levels for this newly defined well. [*Hint*: Try $\psi = A\sin(kx + \phi)$.]

## 38–9 Finite Potential Well

**35.** (II) An electron with 180 eV of kinetic energy in free space passes over a finite potential well 48 eV deep that stretches from $x = 0$ to $x = 0.50\,\text{nm}$. What is the electron's wavelength (*a*) in free space, (*b*) when over the well? (*c*) Draw a diagram showing the potential energy and total energy as a function of $x$, and on the diagram sketch a possible wave function.

**36.** (II) Sketch the wave functions and the probability distributions for the $n = 4$ and $n = 5$ states for a particle trapped in a finite square well.

**37.** (II) An electron having kinetic energy 3.0 eV is trapped in an 8.0-eV-high potential well of width 8.0 nm. What is the probability of finding the electron outside the confines of the well?

**38.** (II) Suppose that a particle of mass $m$ is trapped in a finite potential well that has a rigid wall at $x = 0$ ($U = \infty$ for $x < 0$) and a finite wall of height $U = U_0$ at $x = \ell$, Fig. 38–20. (*a*) Sketch the wave functions for the lowest three states. (*b*) What is the form of the wave function in the ground state in the three regions $x < 0$, $0 < x < \ell$, $x < \ell$?

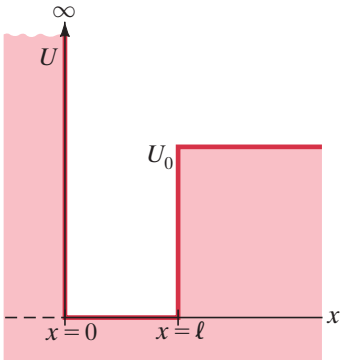

**FIGURE 38–20** Problem 38.

**39.** (II) An electron is trapped in a 0.16-nm-wide finite square well of height $U_0 = 1.8\,\text{keV}$. Estimate at what distance outside the walls of the well the ground state wave function drops to 1.0% of its value at the walls.

## 38–10 Tunneling

**40.** (II) A potential barrier has a height $U_0 = 14\,\text{eV}$ and thickness $\ell = 0.85\,\text{nm}$. If the transmission coefficient for an incident electron is 0.00080, what is the electron's energy?

**41.** (II) An electron approaches a potential barrier 18 eV high and 0.48 nm wide. If the electron has a 1.0% probability of tunneling through the barrier, what is the electron's energy?

**42.** (II) A proton and a helium nucleus approach a 25-MeV potential energy barrier. If each has a kinetic energy of 7.5 MeV, what is the probability of each to tunnel through the barrier, assuming it is rectangular and 3.6 fm thick?

**43.** (II) An electron with an energy of 7.2 eV is incident on a potential barrier which is 9.2 eV high and 0.25 nm wide. (*a*) What is the probability that the electron will pass through the barrier? (*b*) What is the probability that the electron will be reflected?

**44.** (II) A 1.5-mA current of 1.6-MeV protons strikes a 2.6-MeV-high potential barrier $2.8 \times 10^{-13}\,\text{m}$ thick. Estimate the transmitted current.

**45.** (II) For part (*b*) of Example 38–11, what effect will there be on the transmission coefficient if (*a*) the barrier height is raised 3.0%, (*b*) the barrier thickness is increased by 3.0%?

**46.** (II) Show that the transmission coefficient is given roughly by Eqs. 38–17 for a high or thick barrier, by calculating $|\psi(x=\ell)|^2/|\psi(0)|^2$. [*Hint*: Assume that $\psi$ is a decaying exponential inside the barrier.]

**47.** (II) or (III) (*a*) What is the probability that an electron with kinetic energy $E$ can pass through two successive barriers of width $\ell$, a distance $\ell$ apart, both being of height $U_0$? (*b*) What would be the probability for the electron to pass through one barrier $U_0$ of thickness $2\ell$? Which is greater?

**48.** (III) A uranium-238 nucleus $(Q = +92e)$ lasts about $4.5 \times 10^9$ years before it decays by emission of an alpha particle $(q = +2e,\ M = 4M_{\text{proton}})$. (*a*) Assuming that the $\alpha$ particle is a point, and the nucleus is roughly 8 fm in radius, estimate the height of the Coulomb barrier (the peak in Fig. 38–17). (*b*) The alpha particle, when free, has kinetic energy $\approx 4$ MeV. Estimate the width of the barrier. (*c*) Assuming that the square well has $U = 0$ inside (and $U = 0$ far from the nucleus), calculate the speed of the alpha particle and how often it hits the barrier inside, and from this (and Eqs. 38–17) estimate the uranium lifetime. [*Hint*: Replace the $1/r$ Coulomb barrier with an "averaged" rectangular barrier (as in Fig. 38–15) of width equal to $\frac{1}{3}$ that calculated in (*b*).]

# General Problems

**49.** The $Z^0$ boson, discovered in 1985, is the mediator of the weak nuclear force, and it typically decays very quickly. Its average rest energy is 91.19 GeV, but its short lifetime shows up as an intrinsic width of 2.5 GeV. What is the lifetime of this particle?

**50.** Protons are accelerated from rest across 650 V. They are then directed at two slits 0.80 mm apart. How far apart will the interference peaks be on a screen 15 m away?

**51.** An electron and a proton, each initially at rest, are accelerated across the same voltage. Assuming that the uncertainty in their position is given by their de Broglie wavelength, find the ratio of the uncertainty in their momentum.

**52.** A neutron is trapped in an infinitely deep potential well 2.5 fm in width. Determine (*a*) the four lowest possible energy states and (*b*) their wave functions. (*c*) What is the wavelength and energy of a photon emitted when the neutron makes a transition between the two lowest states? In what region of the EM spectrum does this photon lie? [*Note*: This is a rough model of an atomic nucleus.]

**53.** The lifetime of a typical excited state in an atom is about 10 ns. Suppose an atom falls from one such excited state to a lower one, and emits a photon of wavelength about 400 nm. Find the fractional energy uncertainty $\Delta E/E$ and wavelength uncertainty $\Delta\lambda/\lambda$ of this photon.

**54.** Estimate the kinetic energy and speed of an alpha particle $(q = +2e,\ M = 4M_{\text{proton}})$ trapped in a nucleus $1.8 \times 10^{-14}$ m wide. Assume an infinitely deep square well potential.

**55.** Use the uncertainty principle to estimate the position uncertainty for the electron in the ground state of the hydrogen atom. [*Hint*: Determine the momentum using the Bohr model of Section 37–11 and assume the momentum can be anywhere between this value and zero.] How does this result compare to the Bohr radius?

**56.** Show that the function $\psi(x) = Ae^{ikx}$, where $A$ is a constant and $k$ is given by Eq. 38–11, is a solution of the time-independent Schrödinger equation for the case $U = 0$.

**57.** Show that the average value of the square of the position $x$ of a particle in state $n$ inside an infinite well of width $\ell$ is $\overline{x^2} = \int x^2|\psi_n|^2\,dx = \ell^2\left[\frac{1}{3} - \frac{1}{2}(n\pi)^{-2}\right]$. Calculate the values of $\overline{x^2}$ for $n = 1$ to 20 and make a graph of $\overline{x^2}$ versus $n$. [*Hint*: You may want to consult a detailed Table of integrals.]

**58.** If your de Broglie wavelength were 0.50 m, how fast would you be moving if your mass is 64.0 kg? Would you notice diffraction effects as you walk through a doorway? Approximately how long would it take you to walk through the doorway?

**59.** **Simple Harmonic Oscillator**. Suppose that a particle of mass $m$ is trapped not in a square well, but in one whose potential energy is that of a simple harmonic oscillator: $U(x) = \frac{1}{2}Cx^2$. That is, if the particle is displaced from $x = 0$, a restoring force $F = -Cx$ acts on it, where $C$ is constant. (*a*) Sketch this potential energy. (*b*) Show that $\psi = Ae^{-Bx^2}$ is a solution to the Schrödinger equation and that the energy of this state is $E = \frac{1}{2}\hbar\omega$, where $\omega = \sqrt{C/m}$ (as classically, Eq. 14–5) and $B = m\omega/2\hbar$. [*Note*: This is the ground state, and this energy $\frac{1}{2}\hbar\omega$ is the zero-point energy for a harmonic oscillator. The energies of higher states are $E_n = \left(n + \frac{1}{2}\right)\hbar\omega$, where $n$ is an integer.]

**60.** A small ball of mass $3.0 \times 10^{-6}$ kg is dropped on a table from a height of 2.0 m. After each bounce the ball rises to 65% of its height before the bounce because of its inelastic collision with the table. Estimate how many bounces occur before the uncertainty principle plays a role in the problem. [*Hint*: Determine when the uncertainty in the ball's speed is comparable to its speed of impact on the table.]

**61.** An atomic spectrum contains a line with a wavelength centered at 488 nm. Careful measurements show the line is really spread out between 487 and 489 nm. Estimate the lifetime of the excited state that produced this line.

**62.** A 1500-kg car is traveling with a speed of $(22 \pm 0.22)$ m/s. With what maximum precision can its position be determined?

**63.** By how much does the tunneling current through the tip of an STM change if the tip rises 0.020 nm from some initial height above a sodium surface with a work function $W_0 = 2.28$ eV? [*Hint*: Let the work function (see Section 37–2) equal the energy needed to raise the electron to the top of the barrier.]

**64.** An electron is trapped in the ground state of an infinite potential well of width $\ell = 0.10$ nm. The probability that the electron will be found in the central 1% of the well was estimated in Example 38–7 by $|\psi|^2\,\Delta x$. Determine how large $\Delta x$ could be to cause less than a 10% error in such an estimate.

*65. Consider a particle of mass $m$ and energy $E$ traveling to the right where it encounters a narrow potential barrier of height $U_0$ and width $\ell$ as shown in Fig. 38–21. It can be shown that:

(i) for $E < U_0$, the transmission probability is

$$T = \left[1 + \frac{(e^{G\ell} - e^{-G\ell})^2}{16(E/U_0)(1 - E/U_0)}\right]^{-1}$$

where

$$G = \sqrt{\frac{2m(U_0 - E)}{\hbar^2}}$$

and the reflection probability is $R = 1 - T$;

(ii) for $E > U_0$, the transmission probability is

$$T = \left[1 + \frac{\sin^2(G'\ell)}{4(E/U_0)(E/U_0 - 1)}\right]^{-1}$$

where

$$G' = \sqrt{\frac{2m(E - U_0)}{\hbar^2}}$$

and $R = 1 - T$. Consider that the particle is an electron and it is incident on a rectangular barrier of height $U_0 = 10\,\text{eV}$ and width $\ell = 1.0 \times 10^{-10}\,\text{m}$. (*a*) Calculate $T$ and $R$ for the electron from $E/U_0 = 0$ to 10, in steps of 0.1. Make a single graph showing the two curves of $T$ and $R$ as a function of $E/U_0$. (*b*) From the graph determine the energies $(E/U_0)$ at which the electron will have transmission probabilities of 10%, 20%, 50%, and 80%.

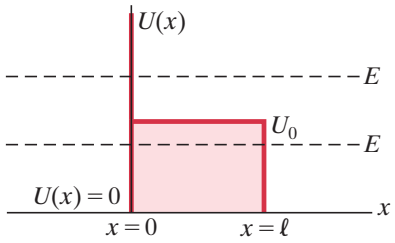

**FIGURE 38–21** Problem 63.

66. Show that all three formulations of the uncertainty principle given in this Chapter (position-momentum, energy-time, and angular momentum-angular position) are dimensionally correct.

67. A red ruby laser produces light of wavelength 704.1 nm. If the wavelength is assumed to be known to 0.1 nm, approximately what is the duration of the shortest pulse that a red ruby laser can produce? What is the length of that pulse in nm?

68. A 15.0-gram marble is in a hollow tube that is sealed closed on both ends approximating an infinite square well. If the tube is 7.5 cm long, what is the minimum speed the marble can have?

69. Imagine a line whose length equals the diameter of the smallest orbit in the Bohr model. If we are told only that an electron is located somewhere on this line, then the electron's position can be specified as $x = 0 \pm r_1$, where the origin is at the line's center and $r_1$ is the Bohr radius. Such an electron can never be observed at rest, but instead at a minimum will have a speed somewhere in the range from $v = 0 - \Delta v$ to $0 + \Delta v$. Determine $\Delta v$.

70. Consider a particle that can exist anywhere in space with a wave function given by $\psi(x) = b^{-\frac{1}{2}}|x/b|^{\frac{1}{2}}\, e^{-(x/b)^2/2}$, where $b = 1.0\,\text{nm}$. (*a*) Check that the wave function is normalized. (*b*) What is the most probable position for the particle in the region $x > 0$? (*c*) What is the probability of finding the particle between $x = 0\,\text{nm}$ and $x = 0.25\,\text{nm}$?

71. A 5.0-gram pencil, 18 cm long, is balanced on its point. Classically, this is a configuration of (unstable) equilibrium, so the pencil could remain there forever if it were perfectly placed. A quantum mechanical analysis shows that the pencil must fall. (*a*) Why is this the case? (*b*) Estimate (within a factor of 2) how long it will take the pencil to hit the table if it is initially positioned as well as possible. [*Hint*: Use the uncertainty principle in its angular form to obtain an expression for the initial angle $\phi_0 \approx \Delta\phi$.]

## ANSWERS TO EXERCISES

**A:** (*c*).
**B:** $2.1 \times 10^{-24}\,\text{kg}\cdot\text{m/s}$, $2.3 \times 10^{6}\,\text{m/s}$.
**C:** (*e*).
**D:** (*e*).
**E:** (*a*).

A neon tube is a thin glass tube, moldable into various shapes, filled with neon (or other) gas that glows with a particular color when a current at high voltage passes through it. Gas atoms, excited to upper energy levels, jump down to lower energy levels and emit light (photons) whose wavelengths (color) are characteristic of the type of gas.

In this Chapter we study what quantum mechanics tells us about atoms, their wave functions and energy levels, including the effect of the exclusion principle for atoms with more than one electron. We also discuss interesting applications such as lasers and holography.

## CHAPTER-OPENING QUESTIONS—Guess now!

**1.** Thousands of hydrogen atoms are all in their ground state. Which statement below is true?

**(a)** All of the atoms have the electron in a circular orbit at the Bohr radius.
**(b)** All of the atoms have the electron in the same orbit, but it's not the same orbit for the ground state in the Bohr model.
**(c)** The electron is not in an actual orbit, but the distance between the nucleus and the electron is the same in all of the atoms.
**(d)** If the distance from the nucleus to the electron could be measured, it would be found at different locations in different atoms. The most probable distance would be the Bohr radius.

**2.** The state of an electron in an atom can be specified by a set of quantum numbers. Which of the following statements are valid?

**(a)** No two electrons in the universe can be identical to each other.
**(b)** All electrons in the universe are identical.
**(c)** No two electrons in an atom can occupy the same quantum state.
**(d)** There cannot be more than one electron in a given electron orbit.
**(e)** Electrons must be excluded from the nucleus because only positive charges are allowed in the nucleus to give rise to stable electronic orbits according to Bohr's model.

At the beginning of Chapter 38 we discussed the limitations of the Bohr model of atomic structure and why a new theory was needed. Although the Bohr model had great success in predicting the wavelengths of light emitted and absorbed by the hydrogen atom, it could not do so for more complex atoms.

PSE5_CH39_v1.9_23-Jun-20

Nor did it explain *fine structure*, the splitting of emission lines into two or more closely spaced lines. And, as a theory, it was an uneasy mixture of classical and quantum ideas.

Quantum mechanics came to the rescue in 1925 and 1926, and in this Chapter we examine the quantum-mechanical theory of atomic structure, which is far more complete than the old Bohr model.

## 39–1 Quantum-Mechanical View of Atoms

Although the Bohr model has been discarded as an accurate description of nature, nonetheless, quantum mechanics reaffirms certain aspects of the older theory, such as that electrons in an atom exist only in discrete states of definite energy, and that a photon of light is emitted (or absorbed) when an electron makes a transition from one state to another. But quantum mechanics is a much deeper theory, and has provided us with a very different view of the atom. According to quantum mechanics, electrons do not exist in well-defined circular orbits as in the Bohr model. Rather, the electron (because of its wave nature) can be thought of as spread out in space as a "**cloud**." The size and shape of the electron cloud can be calculated for a given state of an atom. For the ground state in the hydrogen atom, the solution of the Schrödinger equation, as we will discuss in more detail in Section 39–3, gives

$$\psi(r) = \frac{1}{\sqrt{\pi r_0^3}} e^{-\frac{r}{r_0}}.$$

Here $\psi(r)$ is the wave function as a function of position, and it depends only on the radial distance $r$ from the center, and not on angular position $\theta$ or $\phi$ (like latitude and longitude on Earth). The constant $r_0$ happens to be equal to the first Bohr radius. Thus the electron cloud, whose density is $|\psi|^2$, for the ground state of hydrogen is spherically symmetric as shown in Fig. 39–1. The electron cloud at its higher densities roughly indicates the "size" of an atom. But just as a cloud may not have a distinct border, atoms do not have a precise boundary or a well-defined size. Not all electron clouds have a spherical shape, as we shall see later in this Chapter. But note that $\psi(r)$, while becoming extremely small for large $r$ (see the equation above), does not equal zero in any finite region. So quantum mechanics suggests that an atom is not mostly empty space.

The electron cloud can be interpreted from either the particle or the wave viewpoint. Remember that by a particle we mean something that is localized in space—it has a definite position at any given instant. By contrast, a wave is spread out in space. The electron cloud, spread out in space as in Fig. 39–1, is a result of the wave nature of electrons. Electron clouds can also be interpreted as **probability distributions** (or **probability density**) for a particle. As we saw in Section 38–3, we cannot predict the path an electron will follow (thinking of it as a particle). After one measurement of its position we cannot predict exactly where it will be at a later time. We can only calculate the probability that it will be found at different points. If you were to make 500 different measurements of the position of an electron in a hydrogen atom, the majority of the results would show the electron at points where the probability is high (darker area in Fig. 39–1). Only occasionally would the electron be found where the probability is low. The electron cloud on probability distribution becomes small (or thin) at places, especially far away, but never becomes zero. So quantum mechanics suggests that an atom is *not* mostly empty space, and that there is no truly empty space in the universe.

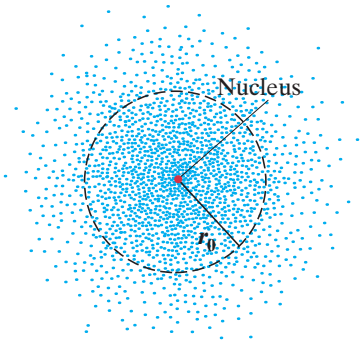

**FIGURE 39–1** Electron cloud or "probability distribution" $|\psi|^2$ for the ground state of the hydrogen atom, as seen from afar. The dots represent a hypothetical detection of an electron at each point: dots closer together represent more probable presence of an electron (denser cloud). The (dashed) circle represents the Bohr radius $r_0$.

## 39–2 Hydrogen Atom: Schrödinger Equation and Quantum Numbers

The hydrogen atom is the simplest of all atoms, consisting of a single electron of charge $-e$ moving around a central nucleus (a single proton) of charge $+e$. It is with hydrogen that a study of atomic structure must begin.

The Schrödinger equation (see Eq. 38–5) includes a term containing the potential energy. For the hydrogen (H) atom, the potential energy is due to the Coulomb force between electron and proton:

$$U = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r}$$

where $r$ is the radial distance from the proton (situated at $r = 0$) to the electron. See Fig. 39–2. The (time-independent) Schrödinger equation, which must now be written in three dimensions, is then

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2}\right) - \frac{1}{4\pi\epsilon_0}\frac{e^2}{r}\psi = E\psi, \qquad \textbf{(39–1)}$$

where $\partial^2\psi/\partial x^2$, $\partial^2\psi/\partial y^2$, and $\partial^2\psi/\partial z^2$ are partial derivatives with respect to $x$, $y$, and $z$. (As always, $\hbar = h/2\pi$.) To solve the Schrödinger equation for the H atom, it is usual to write it in terms of spherical coordinates $(r, \theta, \phi)$. We will not, however, actually go through the process of solving it. Instead, we look at the properties of the solutions, and (in the next Section) at the wave functions themselves.

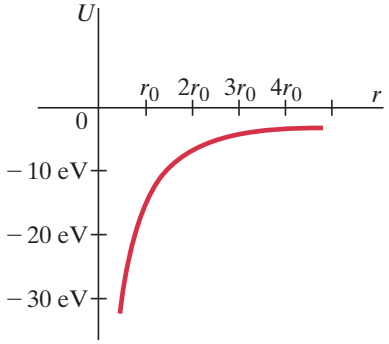

**FIGURE 39–2** Potential energy $U(r)$ for the hydrogen atom. The radial distance $r$ of the electron from the nucleus is given in terms of the Bohr radius $r_0$.

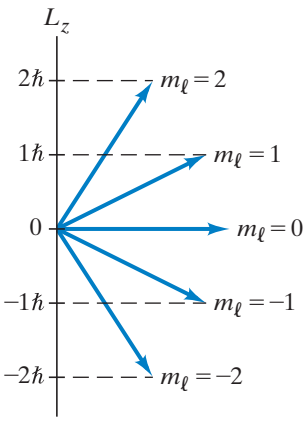
Recall from Chapter 38 that the solutions of the Schrödinger equation in one dimension for the infinite square well were characterized by a single quantum number, which we called $n$, which arises from applying the boundary conditions. In the three-dimensional H atom, the solutions of the Schrödinger equation are characterized by three quantum numbers corresponding to boundary conditions applied in the three dimensions. However, four different quantum numbers are actually needed to specify each state in the H atom, the fourth coming from a relativistic treatment. We now discuss each of these quantum numbers. Much of our analysis here will also apply to more complex atoms, which we discuss starting in Section 39–4.

Quantum mechanics predicts the same energy levels (Fig. 37–26) for the hydrogen atom as does the Bohr model. That is,

$$E_n = -\frac{13.6\,\text{eV}}{n^2} \qquad n = 1, 2, 3, \cdots, \qquad \textbf{(39–2)}$$

where $n$ is an integer. In the simple Bohr model, there was only one quantum number, $n$. In quantum mechanics, four different quantum numbers are needed to specify each state in the atom:

**(1)** The quantum number, $n$, from the Bohr model is found also in quantum mechanics and is called the **principal quantum number**. It can have any integer value from 1 to $\infty$. The total energy of a state in the hydrogen atom depends on $n$, as we saw above.



**(2)** The **orbital quantum number**, $\ell$, is related to the magnitude of the angular momentum of the electron; $\ell$ can take on integer values from 0 to $(n - 1)$. For the ground state, $n = 1$, $\ell$ can only be zero.† For $n = 3$, $\ell$ can be 0, 1, or 2. The actual magnitude of the angular momentum $L$ is related to the quantum number $\ell$ by

$$L = \sqrt{\ell(\ell + 1)}\,\hbar. \qquad \textbf{(39–3)}$$

The value of $\ell$ has almost no effect on the total energy in the hydrogen atom; only $n$ does to any appreciable extent (but see *fine structure* below). In atoms with two or more electrons, the energy does depend on $\ell$ as well as $n$, as we shall see.

**(3)** The **magnetic quantum number**, $m_\ell$, is related to the *direction* of the electron's angular momentum, and it can take on integer values ranging from $-\ell$ to $+\ell$. For example, if $\ell = 2$, then $m_\ell$ can be $-2, -1, 0, +1$, or $+2$. Since angular momentum is a vector, it is not surprising that both its magnitude and its direction would be quantized. For $\ell = 2$, the five different directions allowed can be represented by the diagram of Fig. 39–3.

**FIGURE 39–3** Quantization of angular momentum direction for $\ell = 2$. (Magnitude of $\vec{\mathbf{L}}$ is $L = \sqrt{6}\hbar$.)

†This replaces Bohr model, which assigned $\ell = 1$ to the ground state (Eq. 37–10).

PSE5_CH39_v1.9_23-Jun-20

This limitation on the direction of $\vec{\mathbf{L}}$ is often called **space quantization**. In quantum mechanics, the direction of the angular momentum is usually specified by giving its component along the $z$ axis (this choice is arbitrary). Then $L_z$ is related to $m_\ell$ by the equation

$$L_z = m_\ell \hbar. \tag{39–4}$$

The values of $L_x$ and $L_y$ are not definite, however. The name for $m_\ell$ derives not from theory (which relates it to $L_z$), but from experiment. It was found that when a gas-discharge tube was placed in a magnetic field, the spectral lines were split into several very closely spaced lines. This splitting, known as the **Zeeman effect**, implies that the energy levels must be split (Fig. 39–4), and thus that the energy of a state depends not only on $n$ but also on $m_\ell$ when a magnetic field is applied—hence the name "magnetic quantum number."

**(4)** Finally, there is the **spin quantum number**, $m_s$, which for an electron can have only two values, $m_s = +\frac{1}{2}$ and $m_s = -\frac{1}{2}$. The existence of this quantum number did not come out of Schrödinger's original theory, as did $n$, $\ell$, and $m_\ell$. Instead, a subsequent modification by P. A. M. Dirac (1902–1984) explained its presence as a relativistic effect. The first hint that $m_s$ was needed, however, came from experiment. A careful study of the spectral lines of hydrogen showed that each actually consisted of two (or more) very closely spaced lines even in the absence of an external magnetic field. It was at first hypothesized that this tiny splitting of energy levels, called **fine structure**, was due to angular momentum associated with a spinning of the electron. That is, the electron might spin on its axis as well as orbit the nucleus, just as the Earth spins on its axis as it orbits the Sun. The interaction between the tiny current of the spinning electron could then interact with the magnetic field due to the orbiting charge and cause the small observed splitting of energy levels. (The energy thus depends slightly on $m_\ell$ and $m_s$. Fine structure is said to be due to a **spin-orbit interaction**.) Today we consider the picture of a spinning electron as not legitimate. We cannot even view an electron as a localized object, much less a spinning one. What is important is that the electron can have two different states due to some intrinsic property that behaves like an angular momentum, and we still call this property "spin." The electron is said to have a spin quantum number $s = \frac{1}{2}$, which produces a spin angular momentum

$$S = \sqrt{s(s+1)}\,\hbar = \frac{\sqrt{3}}{2}\hbar.$$

The $z$ component is

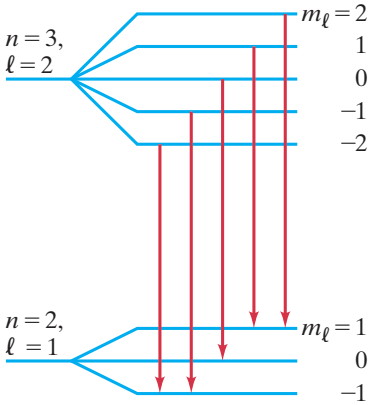
$$S_z = m_s \hbar$$

where the two possible values of $m_s\left(+\frac{1}{2} \text{ and } -\frac{1}{2}\right)$ are often said to be "spin up" and "spin down," referring to the two possible directions of the spin angular momentum. See Fig. 39–5. A state with spin down $\left(m_s = -\frac{1}{2}\right)$ has slightly lower energy than a state with spin up. (Note that we include $m_s$, but not $s$, in our list of quantum numbers since $s$ is the same for all electrons.)

The possible values of the four quantum numbers for an electron in the hydrogen atom are summarized in Table 39–1.

**TABLE 39–1 Quantum Numbers for an Electron**

| Name | Symbol | Possible Values |
|---|---|---|
| Principal | $n$ | $1, 2, 3, \cdots, \infty$. |
| Orbital | $\ell$ | For a given $n$: $\ell$ can be $0, 1, 2, \cdots, n-1$. |
| Magnetic | $m_\ell$ | For given $n$ and $\ell$: $m_\ell$ can be $\ell, \ell-1, \cdots, 0, \cdots, -\ell$. |
| Spin | $m_s$ | For each set of $n$, $\ell$, and $m_\ell$: $m_s$ can be $+\frac{1}{2}$ or $-\frac{1}{2}$. |



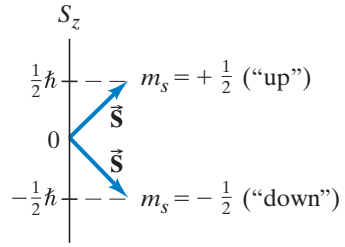


**FIGURE 39–4** Energy levels (not to scale). When a magnetic field is applied, an $n = 3$, $\ell = 2$ energy level is split into five separate levels, corresponding to the five values of $m_\ell (2, 1, 0, -1, -2)$. An $n = 2$, $\ell = 1$ level is split into three levels $(m_\ell = 1, 0, -1)$. Transitions can occur between levels (not all transitions are shown), with photons of several slightly different frequencies being given off (the Zeeman effect).

**FIGURE 39–5** The spin angular momentum $S$ can take on only two directions, $m_s = +\frac{1}{2}$ or $-\frac{1}{2}$, called "spin up" and "spin down."

PSE5_CH39_v1.9_23-Jun-20

**CONCEPTUAL EXAMPLE 39–1** **Possible states for $n = 3$.** How many different states are possible for an electron with principal quantum number $n = 3$?

**RESPONSE** For $n = 3$, $\ell$ can have the values $\ell = 2, 1, 0$. For $\ell = 2$, $m_\ell$ can be $2, 1, 0, -1, -2$, which is five different possibilities. For each of these, $m_s$ can be either up or down $\left(+\frac{1}{2} \text{ or } -\frac{1}{2}\right)$; so for $\ell = 2$, there are $2 \times 5 = 10$ states. For $\ell = 1$, $m_\ell$ can be $1, 0, -1$, and since $m_s$ can be $+\frac{1}{2}$ or $-\frac{1}{2}$ for each of these, we have 6 more possible states. Finally, for $\ell = 0$, $m_\ell$ can only be 0, and there are only 2 states corresponding to $m_s = +\frac{1}{2}$ and $-\frac{1}{2}$. The total number of states is $10 + 6 + 2 = 18$, as detailed in the following Table:

| $n$ | $\ell$ | $m_\ell$ | $m_s$ | $n$ | $\ell$ | $m_\ell$ | $m_s$ |
|---|---|---|---|---|---|---|---|
| 3 | 2 | 2 | $\frac{1}{2}$ | 3 | 1 | 1 | $\frac{1}{2}$ |
| 3 | 2 | 2 | $-\frac{1}{2}$ | 3 | 1 | 1 | $-\frac{1}{2}$ |
| 3 | 2 | 1 | $\frac{1}{2}$ | 3 | 1 | 0 | $\frac{1}{2}$ |
| 3 | 2 | 1 | $-\frac{1}{2}$ | 3 | 1 | 0 | $-\frac{1}{2}$ |
| 3 | 2 | 0 | $\frac{1}{2}$ | 3 | 1 | −1 | $\frac{1}{2}$ |
| 3 | 2 | 0 | $-\frac{1}{2}$ | 3 | 1 | −1 | $-\frac{1}{2}$ |
| 3 | 2 | −1 | $\frac{1}{2}$ | 3 | 0 | 0 | $\frac{1}{2}$ |
| 3 | 2 | −1 | $-\frac{1}{2}$ | 3 | 0 | 0 | $-\frac{1}{2}$ |
| 3 | 2 | −2 | $\frac{1}{2}$ | | | | |
| 3 | 2 | −2 | $-\frac{1}{2}$ | | | | |

**EXERCISE A** An electron has $n = 4$, $\ell = 2$. Which of the following values of $m_\ell$ are possible: 4, 3, 2, 1, 0, −1, −2, −3, −4?

**EXAMPLE 39–2** ***E* and *L* for $n = 3$.** Determine (*a*) the energy and (*b*) the orbital angular momentum for an electron in each of the hydrogen atom states with $n = 3$ (see also Example 39–1).

**APPROACH** The energy of a state depends only on $n$, except for the very small corrections mentioned above, which we will ignore. Energy is calculated as in the Bohr model, $E_n = -13.6\,\text{eV}/n^2$. For angular momentum we use Eq. 39–3.

**SOLUTION** (*a*) Since $n = 3$ for all these states, they all have the same energy,

$$E_3 = -\frac{13.6\,\text{eV}}{(3)^2} = -1.51\,\text{eV}.$$

(*b*) For $\ell = 0$, Eq. 39–3 gives

$$L = \sqrt{\ell(\ell + 1)}\,\hbar = 0.$$

For $\ell = 1$,

$$L = \sqrt{1(1 + 1)}\,\hbar = \sqrt{2}\hbar = 1.49 \times 10^{-34}\,\text{J} \cdot \text{s}.$$

For $\ell = 2$, $L = \sqrt{2(2 + 1)}\,\hbar = \sqrt{6}\hbar$.

**NOTE** Atomic angular momenta are generally given as a multiple of $\hbar$ $\left(\sqrt{2}\hbar$ or $\sqrt{6}\hbar$ in this case$\right)$, rather than in SI units.

**EXERCISE B** What is the magnitude of the orbital angular momentum for orbital quantum number $\ell = 3$? (*a*) $3\hbar$; (*b*) $3.5\hbar$; (*c*) $4\hbar$; (*d*) $12\hbar$.

**EXERCISE C** What are the energy and angular momentum of the electron in a hydrogen atom with $n = 6$ and $\ell = 4$?

## Selection Rules: Allowed and Forbidden Transitions

Another prediction of quantum mechanics is that when a photon is emitted or absorbed, transitions can occur only between states with values of $\ell$ that differ by exactly one unit:

$$\Delta\ell = \pm 1.$$

According to this **selection rule**, an electron in an $\ell = 2$ state can jump only to a state with $\ell = 1$ or $\ell = 3$. It cannot jump to a state with $\ell = 2$ or $\ell = 0$. A transition such as $\ell = 2$ to $\ell = 0$ is called a **forbidden transition**. Actually, such a transition is not absolutely forbidden and can occur, but only with very low probability compared to **allowed transitions**—those that satisfy the selection rule $\Delta\ell = \pm 1$. Experimentally, transitions with $\Delta\ell = \pm 1$ show spectral lines that are bright compared to forbidden transitions which are very dim and often hard to detect.

Since the orbital angular momentum of an H atom must change by one unit when it emits a photon, conservation of angular momentum tells us that the photon must carry off angular momentum. Indeed, experimental evidence of many sorts shows that the photon can be assigned a spin angular momentum of $1\,\hbar$.

## 39–3 Hydrogen Atom Wave Functions

The solution of the Schrödinger equation for the ground state of hydrogen (the state with lowest energy) has an energy $E_1 = -13.6\,\text{eV}$, as we have seen. The wave function for the ground state depends only on $r$ and so is spherically symmetric. As already mentioned in Section 39–1, its form is

$$\psi_{100} = \frac{1}{\sqrt{\pi r_0^3}} e^{-\frac{r}{r_0}} \qquad \textbf{(39–5a)}$$

where $r_0 = h^2\epsilon_0/\pi m e^2 = 0.0529\,\text{nm}$ is the Bohr radius (Section 37–11). The subscript 100 on $\psi$ represents the quantum numbers $n, \ell, m_\ell$:

$$\psi_{n\ell m_\ell}.$$

For the ground state, $n = 1$, $\ell = 0$, $m_\ell = 0$, and there is only one wave function that serves for both $m_s = +\frac{1}{2}$ and $m_s = -\frac{1}{2}$ (the value of $m_s$ does not affect the spatial dependence of the wave function for any state, since spin is an *internal* or *intrinsic* property of the electron). The probability density for the ground state is

$$|\psi_{100}|^2 = \frac{1}{\pi r_0^3} e^{-\frac{2r}{r_0}} \qquad \textbf{(39–5b)}$$

which falls off exponentially with $r$. Note that $\psi_{100}$, like all other wave functions we discuss, has been normalized:

$$\int_{\text{all space}} |\psi_{100}|^2\, dV = 1.$$

The quantity $|\psi|^2\, dV$ gives the probability of finding the electron in a volume $dV$ about a given point. It is often more useful to specify the **radial probability distribution**, $P_\text{r}$, which is defined so that $P_\text{r}\, dr$ is the probability of finding the electron at a radial distance between $r$ and $r + dr$ from the nucleus. That is, $P_\text{r}\, dr$ specifies the probability of finding the electron within a thin shell of thickness $dr$ of inner radius $r$ and outer radius $r + dr$, regardless of direction (see Fig. 39–6). The volume of this shell is the product of its surface area, $4\pi r^2$, and its thickness, $dr$:

$$dV = 4\pi r^2\, dr.$$

Hence

$$|\psi|^2\, dV = |\psi|^2 4\pi r^2\, dr$$

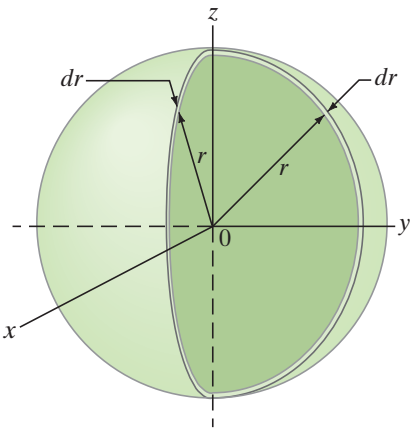
and the radial probability distribution is

$$P_\text{r} = 4\pi r^2 |\psi|^2. \qquad \textbf{(39–6)}$$

For the ground state of hydrogen, $P_\text{r}$ becomes

$$P_\text{r} = 4\frac{r^2}{r_0^3} e^{-\frac{2r}{r_0}} \qquad \textbf{(39–7)}$$

and is plotted in Fig. 39–7. The peak of the curve is the "most probable" value of $r$ and occurs for $r = r_0$, the Bohr radius, which we show in the following Example.



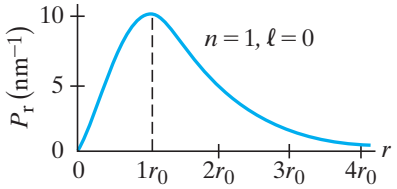


**FIGURE 39–6** A spherical shell of thickness $dr$, inner radius $r$, and outer radius $r + dr$. Its volume is $dV = 4\pi r^2\, dr$.

**FIGURE 39–7** The radial probability distribution $P_\text{r}$ for the ground state of hydrogen, $n = 1$, $\ell = 0$. The peak occurs at $r = r_0$, the Bohr radius.

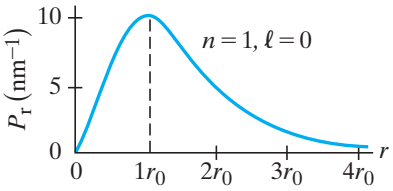

**FIGURE 39–7** (Repeated.) The radial probability distribution $P_r$ for the ground state of hydrogen, $n = 1$, $\ell = 0$. The peak occurs at $r = r_0$, the Bohr radius.

**EXAMPLE 39–3** **Most probable electron radius in hydrogen.** Determine the most probable distance $r$ from the nucleus at which to find the electron in the ground state of hydrogen.

**APPROACH** The peak of the curve in Fig. 39–7 corresponds to the most probable value of $r$. At this point the curve has zero slope, so we take the derivative of Eq. 39–7, set it equal to zero, and solve for $r$.

**SOLUTION** We find

$$\frac{d}{dr}\left(4\frac{r^2}{r_0^3}e^{-\frac{2r}{r_0}}\right) = 0$$

$$\left(8\frac{r}{r_0^3} - \frac{8r^2}{r_0^4}\right)e^{-\frac{2r}{r_0}} = 0.$$

Since $e^{-\frac{2r}{r_0}}$ goes to zero only at $r = \infty$, it is the term in parentheses that must be zero:

$$8\frac{r}{r_0^3} - 8\frac{r^2}{r_0^4} = 0.$$

Therefore,

$$\frac{r}{r_0^3} = \frac{r^2}{r_0^4}$$

or

$$r = r_0.$$

The most probable radial distance of the electron from the nucleus according to quantum mechanics is at the Bohr radius, an interesting coincidence.

**EXERCISE D** Return to the first Chapter-Opening Question, page 1158, and answer it again now. Try to explain why you may have answered differently the first time.

**EXAMPLE 39–4** **Calculating probability.** Determine the probability of finding the electron in the ground state of hydrogen within two Bohr radii of the nucleus.

**APPROACH** We need to integrate $P_r$ from $r = 0$ out to $r = 2r_0$.

**SOLUTION** We want to find

$$P = \int_{r=0}^{2r_0} |\psi|^2\, dV = \int_0^{2r_0} 4\frac{r^2}{r_0^3}e^{-\frac{2r}{r_0}}\, dr.$$

We first make the substitution

$$x = 2\frac{r}{r_0}$$

and then integrate by parts $\left(\int u\, dv = uv - \int v\, du\right)$ letting $u = x^2$ and $dv = e^{-x}\, dx$ (and note that $dx = 2\, dr/r_0$, and the upper limit is $x = 2(2r_0)/r_0 = 4$):

$$P = \tfrac{1}{2}\int_{x=0}^{4} x^2 e^{-x}\, dx = \tfrac{1}{2}\left[-x^2e^{-x} + \int 2xe^{-x}\, dx\right]\Bigg|_0^4.$$

The second term we also integrate by parts with $u = 2x$ and $dv = e^{-x}\, dx$:

$$P = \tfrac{1}{2}\left[-x^2e^{-x} - 2xe^{-x} + 2\int e^{-x}\, dx\right]\Bigg|_0^4$$

$$= \left(-\tfrac{1}{2}x^2 - x - 1\right)e^{-x}\Bigg|_0^4.$$

We evaluate this at $x = 0$ and at $x = 4$:

$$P = (-8 - 4 - 1)e^{-4} + e^0 = 0.76$$

or 76%. Thus the electron would be found 76% of the time within 2 Bohr radii of the nucleus and 24% of the time farther away.

**NOTE** This result depends on our wave function being properly normalized, which it is, as is readily shown by letting $r \to \infty$ and integrating over all space: $\int_0^\infty |\psi|^2\, dV = 1$; that is, let the upper limit in the equation above be $\infty$.

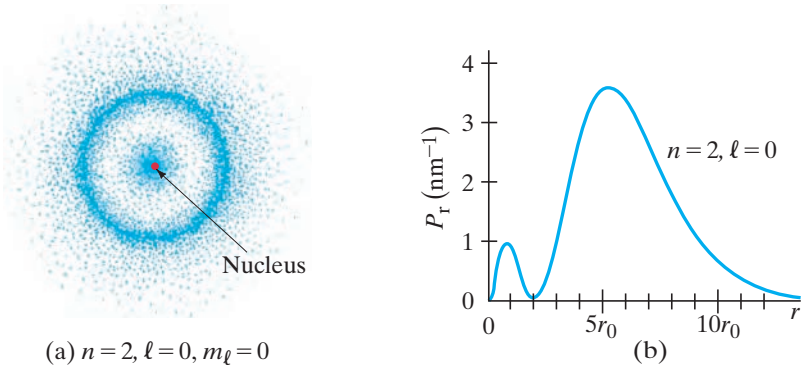

**FIGURE 39–8** (a) Electron cloud, or probability distribution, for $n = 2$, $\ell = 0$ state in hydrogen. (b) The radial probability distribution $P_r$ for the $n = 2$, $\ell = 0$ state in hydrogen.

The first excited state in hydrogen has $n = 2$. For $\ell = 0$, the solution of the Schrödinger equation (Eq. 39–1) is a wave function that is again spherically symmetric:

$$\psi_{200} = \frac{1}{\sqrt{32\pi r_0^3}}\left(2 - \frac{r}{r_0}\right)e^{-\frac{r}{2r_0}}. \qquad \textbf{(39–8)}$$

Figure 39–8a shows the probability distribution $|\psi_{200}|^2$ and Fig. 39–8b shows[†] a plot of the radial probability distribution

$$P_r = 4\pi r^2|\psi|^2 = \frac{1}{8}\frac{r^2}{r_0^3}\left(2 - \frac{r}{r_0}\right)^2 e^{-\frac{r}{r_0}}.$$

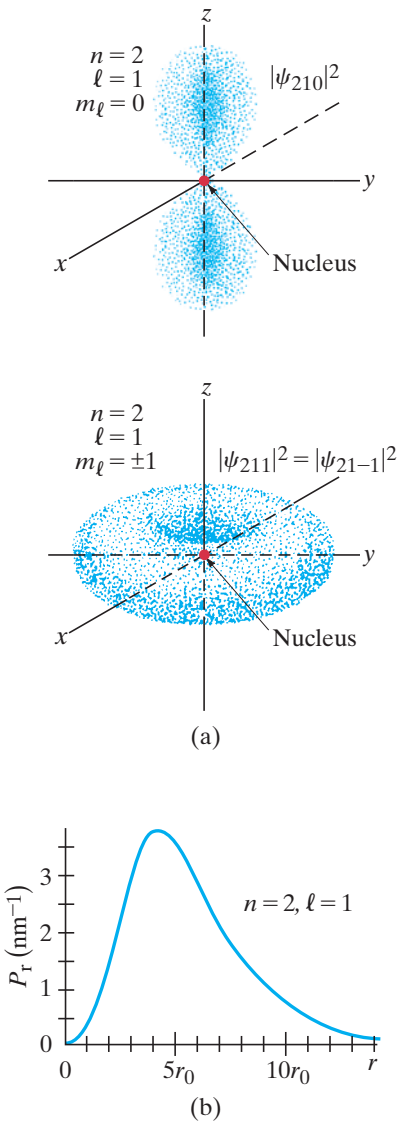
There are two peaks in this curve; the second, at $r \approx 5r_0$, is higher and corresponds to the most probable value for $r$ in the $n = 2$, $\ell = 0$ state. We see that the electron tends to be somewhat farther from the nucleus in the $n = 2$, $\ell = 0$ state than in the $n = 1$, $\ell = 0$ state. (Compare to the Bohr model that gave $r_2 = 4r_0$.)

For the state with $n = 2$, $\ell = 1$, there are three possible wave functions, corresponding to $m_\ell = +1$, 0, or $-1$:

$$\begin{aligned}\psi_{210} &= \frac{z}{\sqrt{32\pi r_0^5}}e^{-\frac{r}{2r_0}} \\ \psi_{211} &= \frac{x + iy}{\sqrt{64\pi r_0^5}}e^{-\frac{r}{2r_0}} \\ \psi_{21-1} &= \frac{x - iy}{\sqrt{64\pi r_0^5}}e^{-\frac{r}{2r_0}}\end{aligned} \qquad \textbf{(39–9)}$$

where $i$ is the imaginary number $i = \sqrt{-1}$. These wave functions are *not* spherically symmetric. The probability distributions, $|\psi|^2$, are shown in Fig. 39–9a, where we can see their directional orientation.

You may wonder how such non-spherically symmetric wave functions arise when the potential energy in the Schrödinger equation has spherical symmetry. Indeed, how could an electron select one of these states? In the absence of any external influence, such as a magnetic field in a particular direction, all three of these states are equally likely, and they all have the same energy. Thus an electron can be considered to spend one-third of its time in each of these states. The net effect, then, is the sum of these three wave functions squared:



$$|\psi_{210}|^2 + |\psi_{211}|^2 + |\psi_{21-1}|^2,$$

which is spherically symmetric, since $x^2 + y^2 + z^2 = r^2$. The radial probability distribution for this sum is shown in Fig. 39–9b.

Although the spatial distributions of the electron can be calculated for the various states, it is difficult to measure them experimentally. Indeed, most of the experimental information about atoms has come from a careful examination of the emission spectra under various conditions as in Figs. 37–20 and 35–22.

[†]Just as for a particle in a deep square well potential (see Figs. 38–9 and 38–10), the higher the energy, the more nodes there are in $\psi$ and $|\psi|^2$ also for the H atom.

**FIGURE 39–9** (a) The probability distribution for the three states with $n = 2$, $\ell = 1$. (b) Radial probability distribution for the sum of the three states with $n = 2$, $\ell = 1$, and $m_\ell = +1$, 0, or $-1$.

### Orbitals

Chemists refer to atomic states, and especially the shape in space of their probability distributions, as **orbitals**. Each atomic orbital is characterized by its quantum numbers $n$, $\ell$, and $m_\ell$, and can hold one or two electrons $\left(m_s = +\frac{1}{2} \text{ or } m_s = -\frac{1}{2}\right)$; $s$-orbitals $(\ell = 0)$ are spherically symmetric, Figs. 39–1 and 39–8a; $p$-orbitals $(\ell = 1)$ can be dumbbell shaped with lobes, Fig. 39–9a; or donut shaped if combining $m_\ell = +1$ and $m_\ell = -1$, Fig. 39–9b.

## 39–4 Multielectron Atoms; the Exclusion Principle

We have discussed the hydrogen atom in detail because it is the simplest to deal with. Now we briefly discuss more complex atoms, those that contain more than one electron. Their energy levels can be determined experimentally from an analysis of their emission spectra. The energy levels are *not* the same as in the H atom, because the electrons interact with each other as well as with the nucleus. Each electron in a complex atom still occupies a particular state characterized by the same quantum numbers $n$, $\ell$, $m_\ell$, and $m_s$. For atoms with more than one electron, the energy levels depend on both $n$ and $\ell$.

The number of electrons in a neutral atom is called its **atomic number**, $Z$; $Z$ is also the number of positive charges (protons) in the nucleus, and determines what kind of atom it is. That is, $Z$ determines the fundamental properties that distinguish one type of atom from another.

Quantum mechanics in the years after 1925 proved successful also in dealing with complex atoms. The mathematics becomes very difficult, however, since in multi-electron atoms, each electron is not only attracted to the nucleus but is also repelled by the other electrons.

To understand the possible arrangements of electrons in an atom, a new principle was needed. It was introduced by Wolfgang Pauli (1900–1958; Fig. 38–2) and is called the **Pauli exclusion principle**. It states:

**No two electrons in an atom can occupy the same quantum state.**

Thus, no two electrons in an atom can have exactly the same set of the quantum numbers $n$, $\ell$, $m_\ell$, and $m_s$. The Pauli exclusion principle forms the basis not only for understanding atoms, but also for understanding molecules and bonding, and other phenomena as well.

Let us now look at the structure of some of the simpler atoms when they are in the ground state. After hydrogen, the next simplest atom is *helium* with two electrons. Both electrons can have $n = 1$, because one can have spin up $\left(m_s = +\frac{1}{2}\right)$ and the other spin down $\left(m_s = -\frac{1}{2}\right)$, thus satisfying the exclusion principle. Since $n = 1$, then $\ell$ and $m_\ell$ must be zero (Table 39–1, page 1161). Thus the two electrons have the quantum numbers indicated at the top of Table 39–2.

Lithium has three electrons, two of which can have $n = 1$. But the third cannot have $n = 1$ without violating the exclusion principle. Hence the third electron must have $n = 2$. It happens that the $n = 2$, $\ell = 0$ level has a lower energy than $n = 2$, $\ell = 1$. So the electrons in the ground state have the quantum numbers indicated in Table 39–2. The quantum numbers of the third electron could also be, say, $\left(n, \ell, m_\ell, m_s\right) = \left(3, 1, -1, \frac{1}{2}\right)$. But the atom in this case would be in an excited state because it would have greater energy. It would not be long before it jumped to the ground state with the emission of a photon. At room temperature, unless extra energy is supplied (as in a discharge tube), the vast majority of atoms are in the ground state.

We can continue in this way to describe the quantum numbers of each electron in the ground state of larger and larger atoms. The quantum numbers for sodium, with its eleven electrons, are shown in Table 39–2.

**TABLE 39–2 Ground-State Quantum Numbers**

| $n$ | $\ell$ | $m_\ell$ | $m_s$ |
|---|---|---|---|
| **Helium, $Z = 2$** | | | |
| 1 | 0 | 0 | $\frac{1}{2}$ |
| 1 | 0 | 0 | $-\frac{1}{2}$ |
| **Lithium, $Z = 3$** | | | |
| 1 | 0 | 0 | $\frac{1}{2}$ |
| 1 | 0 | 0 | $-\frac{1}{2}$ |
| 2 | 0 | 0 | $\frac{1}{2}$ |
| **Sodium, $Z = 11$** | | | |
| 1 | 0 | 0 | $\frac{1}{2}$ |
| 1 | 0 | 0 | $-\frac{1}{2}$ |
| 2 | 0 | 0 | $\frac{1}{2}$ |
| 2 | 0 | 0 | $-\frac{1}{2}$ |
| 2 | 1 | 1 | $\frac{1}{2}$ |
| 2 | 1 | 1 | $-\frac{1}{2}$ |
| 2 | 1 | 0 | $\frac{1}{2}$ |
| 2 | 1 | 0 | $-\frac{1}{2}$ |
| 2 | 1 | −1 | $\frac{1}{2}$ |
| 2 | 1 | −1 | $-\frac{1}{2}$ |
| 3 | 0 | 0 | $\frac{1}{2}$ |

**EXERCISE E** Construct a Table of the ground-state quantum numbers for beryllium, $Z = 4$ (like those in Table 39–2).

PSE5_CH39_v1.9_23-Jun-20

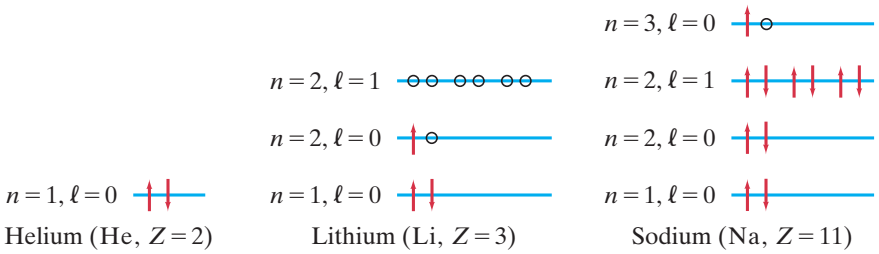


**FIGURE 39–10** Energy level diagram (not to scale) showing occupied states (arrows) and unoccupied states (○) for the ground states of He, Li, and Na. Note that we have shown the $n = 2$, $\ell = 1$ level of Li even though it is empty.

Figure 39–10 shows a simple energy level diagram where occupied states are shown as up or down arrows $\left(m_s = +\frac{1}{2} \text{ or } -\frac{1}{2}\right)$, and possible empty states are shown as a small circle.

The ground-state configuration for all atoms is given in the **Periodic Table**, which is displayed inside the back cover of this book, and discussed in the next Section.

The *exclusion principle* applies to identical particles whose spin quantum number is a half-integer $\left(\frac{1}{2}, \frac{3}{2}, \text{ and so on}\right)$, including electrons, protons, and neutrons; such particles are called **fermions**, after Enrico Fermi who derived a statistical theory describing them. A basic assumption is that all electrons are **identical**, indistinguishable one from another. Similarly, all protons are identical, all neutrons are identical, and so on. The exclusion principle does not apply to particles with integer spin (0, 1, 2, and so on), such as the photon and $\pi$ meson, all of which are referred to as **bosons** (after Satyendranath Bose, who derived a statistical theory for them).

**EXERCISE F** Return to the second Chapter-Opening Question, page 1158, and answer it again now. Try to explain why you may have answered differently the first time.

# 39–5 Periodic Table of Elements

More than a century ago, Dmitri Mendeleev (1834–1907) arranged the (then) known elements into what we now call the **Periodic Table** of the elements. The atoms were arranged according to increasing mass, but also so that elements with similar chemical properties would fall in the same column. Today's version is shown inside the back cover of this book. Each square contains the atomic number $Z$, the symbol for the element, and the atomic mass (in atomic mass units). Finally, the lower left corner shows the configuration of the ground state of the atom. This requires some explanation. Electrons with the same value of $n$ are referred to as being in the same **shell**. Electrons with $n = 1$ are in one shell (the K shell), those with $n = 2$ are in a second shell (the L shell), those with $n = 3$ are in the third (M) shell, and so on. Electrons with the same values of $n$ and $\ell$ are referred to as being in the same **subshell**. Letters are often used to specify the value of $\ell$ as shown in Table 39–3. That is, $\ell = 0$ is the $s$ subshell; $\ell = 1$ is the $p$ subshell; $\ell = 2$ is the $d$ subshell; beginning with $\ell = 3$, the letters follow the alphabet, $f, g, h, i$, and so on. (The first letters $s, p, d$, and $f$ were originally abbreviations of "sharp," "principal," "diffuse," and "fundamental," terms referring to the experimentally observed spectra.)

The Pauli exclusion principle limits the number of electrons possible in each shell and subshell. For any value of $\ell$, there are $2\ell + 1$ possible $m_\ell$ values ($m_\ell$ can be any integer from 1 to $\ell$, from $-1$ to $-\ell$, or zero), and two possible $m_s$ values. There can be, therefore, at most $2(2\ell + 1)$ electrons in any $\ell$ subshell. For example, for $\ell = 2$, five $m_\ell$ values are possible $(2, 1, 0, -1, -2)$, and for each of these, $m_s$ can be $+\frac{1}{2}$ or $-\frac{1}{2}$ for a total of $2(5) = 10$ states. Table 39–3 lists the maximum number of electrons that can occupy each subshell.

Because the energy levels depend almost entirely on the values of $n$ and $\ell$, it is customary to specify the electron configuration simply by giving the $n$ value and the appropriate letter for $\ell$, with the number of electrons in each subshell given as a superscript.

**TABLE 39–3 Value of $\ell$**

| Value of $\ell$ | Letter Symbol | Maximum Number of Electrons in Subshell |
|---|---|---|
| 0 | $s$ | 2 |
| 1 | $p$ | 6 |
| 2 | $d$ | 10 |
| 3 | $f$ | 14 |
| 4 | $g$ | 18 |
| 5 | $h$ | 22 |
| ⋮ | ⋮ | ⋮ |

**TABLE 39–4 Electron Configuration of Some Elements**

| $Z$ (Number of Electrons) | Element[†] | Ground State Configuration (outer electrons) |
|---|---|---|
| 1 | H | $1s^1$ |
| 2 | He | $1s^2$ |
| 3 | Li | $2s^1$ |
| 4 | Be | $2s^2$ |
| 5 | B | $2s^2 2p^1$ |
| 6 | C | $2s^2 2p^2$ |
| 7 | N | $2s^2 2p^3$ |
| 8 | O | $2s^2 2p^4$ |
| 9 | F | $2s^2 2p^5$ |
| 10 | Ne | $2s^2 2p^6$ |
| 11 | Na | $3s^1$ |
| 12 | Mg | $3s^2$ |
| 13 | Al | $3s^2 3p^1$ |
| 14 | Si | $3s^2 3p^2$ |
| 15 | P | $3s^2 3p^3$ |
| 16 | S | $3s^2 3p^4$ |
| 17 | Cl | $3s^2 3p^5$ |
| 18 | Ar | $3s^2 3p^6$ |
| 19 | K | $4s^1$ |
| 20 | Ca | $4s^2$ |
| 21 | Sc | $3d^1 4s^2$ |
| 22 | Ti | $3d^2 4s^2$ |
| 23 | V | $3d^3 4s^2$ |
| 24 | Cr | $3d^5 4s^1$ |
| 25 | Mn | $3d^5 4s^2$ |
| 26 | Fe | $3d^6 4s^2$ |

[†]Names of elements can be found in Appendix F.

**⚠ CAUTION**

*Subshells are not always filled in "order"*

The ground-state configuration of sodium, for example, is written as $1s^2 2s^2 2p^6 3s^1$. This is simplified in the Periodic Table by specifying the configuration only of the outermost electrons and any other nonfilled subshells (see Table 39–4 here, and the Periodic Table inside the back cover).

**CONCEPTUAL EXAMPLE 39–5 Electron configurations.** Which of the following electron configurations are possible, and which are not: (*a*) $1s^2 2s^2 2p^6 3s^3$; (*b*) $1s^2 2s^2 2p^6 3s^2 3p^5 4s^2$; (*c*) $1s^2 2s^2 2p^6 2d^1$?

**RESPONSE** (*a*) This is not allowed, because too many electrons (three) are shown in the *s* subshell of the M $(n = 3)$ shell. The *s* subshell has $m_\ell = 0$, with two slots only, for "spin up" and "spin down" electrons.

(*b*) This is allowed, but it is an excited state. One of the electrons from the 3*p* subshell has jumped up to the 4*s* subshell. Since there are 19 electrons, the element is potassium.

(*c*) This is not allowed, because there is no *d* $(\ell = 2)$ subshell in the $n = 2$ shell (Table 39–1). The outermost electron will have to be (at least) in the $n = 3$ shell.

**EXERCISE G** Write the complete ground-state configuration for gallium, with its 31 electrons.

The grouping of atoms in the Periodic Table is according to increasing atomic number, $Z$. There is also a strong regularity according to chemical properties. Although this is treated in chemistry textbooks, we discuss it here briefly because it is a result of quantum mechanics. See the Periodic Table inside the back cover.

All the **noble gases** (in column VIII of the Periodic Table) have completely filled shells or subshells. That is, their outermost subshell is completely full, and the electron distribution is spherically symmetric. With such full spherical symmetry, other electrons are not attracted nor are electrons readily lost (ionization energy is high). This is why the noble gases are chemically inert (more on this when we discuss molecules and bonding in Chapter 40). Column VII contains the **halogens**, which lack one electron from a filled shell. Because of the shapes of the orbits (see Section 40–1), an additional electron can be accepted from another atom, and hence these elements are quite reactive. They have a *valence* of $-1$, meaning that when an extra electron is acquired, the resulting ion has a net charge of $-1e$. Column I of the Periodic Table contains the **alkali metals**, all of which have a single outer *s* electron. This electron spends most of its time outside the inner filled shells and subshells which shield it from most of the nuclear charge. Indeed, it is relatively far from the nucleus and is attracted to it by a net charge of only about $+1e$, because of the shielding effect of the other electrons. Hence this outer electron is easily removed and can spend much of its time around another atom, forming a molecule. This is why the alkali metals are chemically very reactive and have a valence of $+1$. The other columns of the Periodic Table can be treated similarly.

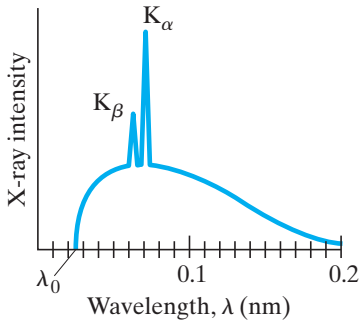
The presence of the **transition elements** in the center of the Periodic Table, as well as the lanthanides (rare earths) and actinides below, is a result of incomplete inner shells. For the lowest $Z$ elements, the subshells are filled in a simple order: first 1*s*, then 2*s*, followed by 2*p*, 3*s*, and 3*p*. You might expect that 3*d* $(n = 3, \ell = 2)$ would be filled next, but it isn't. Instead, the 4*s* level actually has a slightly lower energy than the 3*d* (due to electrons interacting with each other), so it fills first (K and Ca). Only then does the 3*d* shell start to fill up, beginning with Sc, as can be seen in Table 39–4. (The 4*s* and 3*d* levels are close, so some elements have only one 4*s* electron, such as Cr.) Most of the chemical properties of these transition elements are governed by the relatively loosely held 4*s* electrons, and hence they usually have valences of $+1$ or $+2$. A similar effect is responsible for the *lanthanides* and *actinides*, which are shown at the bottom of the Periodic Table for convenience. All have very similar chemical properties, which are determined by their two outer 6*s* or 7*s* electrons, whereas the different numbers of electrons in the unfilled inner shells have little effect.

PSE5_CH39_v1.9_23-Jun-20

# 39–6 X-Ray Spectra and Atomic Number

The line spectra of atoms in the visible, UV, and IR regions of the EM spectrum are mainly due to transitions between states of the outer electrons. Much of the positive charge of the nucleus is shielded from these electrons by the negative charge on the inner electrons. But the innermost electrons in the $n = 1$ shell "see" the full charge of the nucleus. Since the energy of a level is proportional to $Z^2$ (see Eq. 37–14), for an atom with $Z = 50$, we would expect wavelengths about $50^2 = 2500$ times shorter than those found in the Lyman series of hydrogen (around 100 nm), or $(100\,\text{nm})/(2500) \approx 10^{-2}$ to $10^{-1}$ nm. Such short wavelengths lie in the X-ray region of the spectrum.

X-rays are produced when electrons accelerated by a high voltage strike the metal target inside an X-ray tube (Section 35–10). If we look at the spectrum of wavelengths emitted by an X-ray tube, we see that the spectrum consists of two parts: a continuous spectrum with a cutoff at some $\lambda_0$ which depends only on the voltage across the tube, and a series of peaks superimposed. A typical example is shown in Fig. 39–11. The smooth curve and the cutoff wavelength $\lambda_0$ move to the left as the voltage across the tube increases. The sharp lines or peaks (labeled $K_\alpha$ and $K_\beta$ in Fig. 39–11), however, remain at the same wavelength when the voltage is changed, although they are located at different wavelengths when different target materials are used. This observation suggests that the peaks are characteristic of the target material used. Indeed, we can explain the peaks by imagining that the electrons accelerated by the high voltage of the tube can reach sufficient energies that when they collide with the atoms of the target, they can knock out one of the very tightly held inner electrons. Then we explain these **characteristic X-rays** (the peaks in Fig. 39–11) as photons emitted when an electron in an upper state drops down to fill the vacated lower state. The K lines result from transitions *into* the K shell $(n = 1)$. The $K_\alpha$ line consists of photons emitted in a transition that originates from the $n = 2$ (L) shell and drops to the $n = 1$ (K) shell. On the other hand, the $K_\beta$ line reflects a transition from the $n = 3$ (M) shell down to the K shell. An L line is due to a transition into the L shell, and so on.



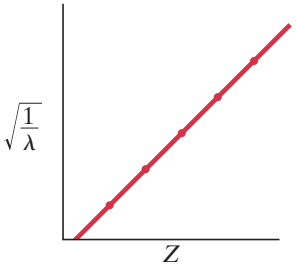


**FIGURE 39–11** Spectrum of X-rays emitted from a molybdenum target in an X-ray tube operated at 50 kV.

Measurement of the characteristic X-ray spectra has allowed a determination of the inner energy levels of atoms. It has also allowed the determination of $Z$ values for many atoms, because (as we have seen) the wavelength of the shortest characteristic X-rays emitted will be inversely proportional to $Z^2$. Actually, for an electron jumping from, say, the $n = 2$ to the $n = 1$ level ($K_\alpha$ line), the wavelength is inversely proportional to $(Z - 1)^2$ because the nucleus is shielded by the one electron that still remains in the 1$s$ level. In 1914, H. G. J. Moseley (1887–1915) found that a plot of $\sqrt{1/\lambda}$ vs. $Z$ produced a straight line, Fig. 39–12 where $\lambda$ is the wavelength of the $K_\alpha$ line. The $Z$ values of a number of elements were determined by fitting them to such a **Moseley plot**. The work of Moseley put the concept of atomic number on a firm experimental basis.

**FIGURE 39–12** Plot of $\sqrt{1/\lambda}$ vs. $Z$ for $K_\alpha$ X-ray lines.

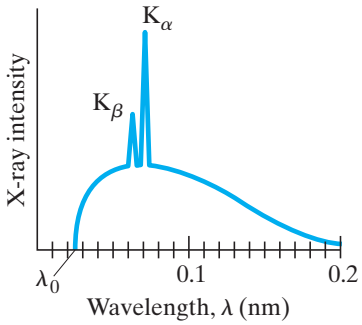

**FIGURE 39–11** (Repeated.) Spectrum of X-rays emitted from a molybdenum target in an X-ray tube operated at 50 kV.

**EXAMPLE 39–6** **X-ray wavelength.** Estimate the wavelength for an $n = 2$ to $n = 1$ transition in molybdenum $(Z = 42)$. What is the energy of such a photon?

**APPROACH** We use the Bohr formula, Eq. 37–15 for $1/\lambda$, with $Z^2$ replaced by $(Z-1)^2 = (41)^2$.

**SOLUTION** Equation 37–15 gives

$$\frac{1}{\lambda} = \left(\frac{e^4 m}{8\epsilon_0^2 h^3 c}\right)(Z-1)^2\left(\frac{1}{n'^2} - \frac{1}{n^2}\right)$$

where $n = 2$ and $n' = 1$. We substitute in values:

$$\frac{1}{\lambda} = (1.097 \times 10^7\,\text{m}^{-1})(41)^2\left(\frac{1}{1} - \frac{1}{4}\right) = 1.38 \times 10^{10}\,\text{m}^{-1}.$$

So

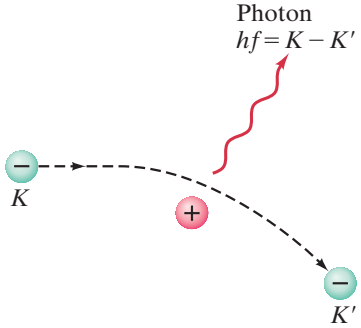
$$\lambda = \frac{1}{1.38 \times 10^{10}\,\text{m}^{-1}} = 0.072\,\text{nm}.$$

This is close to the measured value (Fig. 39–11) of 0.071 nm. Each of these photons would have energy (in eV) of:

$$E = hf = \frac{hc}{\lambda} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.00 \times 10^8\,\text{m/s})}{(7.2 \times 10^{-11}\,\text{m})(1.60 \times 10^{-19}\,\text{J/eV})} = 17\,\text{keV}.$$

The denominator includes the conversion factor from joules to eV.

**EXAMPLE 39–7** **Determining atomic number.** High-energy electrons are used to bombard an unknown material. The strongest peak is found for X-rays emitted with an energy of 7.5 keV. Guess what the material is.



**APPROACH** The highest intensity X-rays are generally for the $K_\alpha$ line (see Fig. 39–11) which occurs when the high-energy electrons knock out K shell electrons (the innermost orbit, $n = 1$) and their place is taken by electrons from the L shell $(n = 2)$. We use the Bohr model, and assume the electrons of the unknown atoms $(Z)$ "see" a nuclear charge of $Z - 1$ (screened by one electron).

**SOLUTION** The hydrogen transition $n = 2$ to $n = 1$ would yield $E_H = 13.6\,\text{eV} - 3.4\,\text{eV} = 10.2\,\text{eV}$ (see Fig. 37–26 or Example 37–13). Energy of our unknown $E_Z$ is proportional to $Z^2$ (Eq. 37–14), or rather $(Z-1)^2$ because the nucleus is shielded by the one electron in a 1*s* state (see above), so we can use ratios:

$$\frac{E_Z}{E_H} = \frac{(Z-1)^2}{1^2} = \frac{7500\,\text{eV}}{10.2\,\text{eV}} = 735,$$

so $Z - 1 = \sqrt{735} = 27$, and $Z = 28$, which makes it cobalt.

**FIGURE 39–13** Bremsstrahlung photon produced by an electron decelerated by interaction with a target atom.

Now we briefly analyze the continuous part of an X-ray spectrum (Fig. 39–11) based on the photon theory of light. When electrons strike the target, they collide with atoms of the material and give up most of their energy as heat (about 99%, so X-ray tubes must be cooled). Electrons can also give up energy by emitting a photon of light: an electron decelerated by interaction with atoms of the target (Fig. 39–13) emits radiation because of its deceleration (Chapter 31), and in this case it is called **bremsstrahlung** (German for "braking radiation"). Because energy is conserved, the energy of the emitted photon, $hf$, equals the loss of kinetic energy of the electron, $\Delta K = K - K'$, so

$$hf = \Delta K.$$

An electron may lose all or a part of its energy in such a collision. The continuous X-ray spectrum (Fig. 39–11) is explained as being due to such bremsstrahlung collisions in which varying amounts of energy are lost by the electrons. The shortest-wavelength X-ray (the highest frequency) must be due to an electron that gives up *all* its kinetic energy to produce one photon in a single collision.

PSE5_CH39_v1.9_23-Jun-20

Since the initial kinetic energy of an electron is equal to the energy given it by the accelerating voltage, $V$, then $K = eV$. In a single collision in which the electron is brought to rest ($\text{KE}' = 0$), then $\Delta K = eV$ and

$$hf_0 = eV.$$

We set $f_0 = c/\lambda_0$ where $\lambda_0$ is the cutoff wavelength (Fig. 39–11) and find

$$\lambda_0 = \frac{hc}{eV}. \qquad \textbf{(39–10)}$$

This prediction for $\lambda_0$ corresponds precisely with that observed experimentally. This result is further evidence that X-rays are a form of electromagnetic radiation (light)[†] and that the photon theory of light is valid.

**EXAMPLE 39–8** **Cutoff wavelength.** What is the shortest-wavelength X-ray photon emitted in an X-ray tube subjected to 50 kV?

**APPROACH** The electrons striking the target will have a kinetic energy of 50 keV. The shortest-wavelength photons are due to collisions in which all of an electron's kinetic energy is given to the photon so $K = eV = hf_0$.

**SOLUTION** From Eq. 39–10,

$$\lambda_0 = \frac{hc}{eV} = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^8\,\text{m/s})}{(1.6 \times 10^{-19}\,\text{C})(5.0 \times 10^4\,\text{V})} = 2.5 \times 10^{-11}\,\text{m},$$

or 0.025 nm.

**NOTE** This result agrees well with experiment, Fig. 39–11.

# *39–7 Magnetic Dipole Moment; Total Angular Momentum

## * Magnetic Dipole Moment and the Bohr Magneton

An electron orbiting the nucleus of an atom can be considered as a current loop, classically, and thus might be expected to have a **magnetic dipole moment** as discussed in Chapter 27. Indeed, in Example 27–12 we did a classical calculation of the magnetic dipole moment of the electron in the ground state of hydrogen based, essentially, on the Bohr model, and found it to give

$$\mu = IA = \tfrac{1}{2}evr.$$

Here $v$ is the orbital velocity of the electron, and for a particle moving in a circle of radius $r$, its angular momentum is

$$L = mvr.$$

So we can write

$$\mu = \frac{1}{2}\frac{e}{m}L.$$

The direction of the angular momentum $\vec{\mathbf{L}}$ is perpendicular to the plane of the current loop. So is the direction of the magnetic dipole moment vector $\vec{\boldsymbol{\mu}}$, although in the opposite direction since the electron's charge is negative. Hence we can write the vector equation

$$\vec{\boldsymbol{\mu}} = -\frac{1}{2}\frac{e}{m}\vec{\mathbf{L}}. \qquad \textbf{(39–11)}$$

This rough semiclassical derivation was based on the Bohr model. The same result (Eq. 39–11) is obtained using quantum mechanics. Since $\vec{\mathbf{L}}$ is quantized in quantum mechanics, the magnetic dipole moment, too, must be quantized.

[†]If X-rays were not photons but rather neutral particles with mass $m$, Eq. 39–10 would not be valid.

The magnitude of the dipole moment is given by (see Eq. 39–3)

$$\mu = \frac{e\hbar}{2m}\sqrt{\ell(\ell+1)}.$$

When a magnetic dipole moment is in a magnetic field $\vec{\mathbf{B}}$, it experiences a torque as we saw in Section 27–5, and the potential energy $U$ of such a system depends on $\vec{\mathbf{B}}$ and the orientation of $\vec{\boldsymbol{\mu}}$ relative to $\vec{\mathbf{B}}$ (Eq. 27–12):

$$U = -\vec{\boldsymbol{\mu}} \cdot \vec{\mathbf{B}}.$$

If the magnetic field $\vec{\mathbf{B}}$ is in the $z$ direction, then

$$U = -\mu_z B_z$$

and from Eq. 39–4 $(L_z = m_\ell \hbar)$ and Eq. 39–11, we have

$$\mu_z = -\frac{e\hbar}{2m} m_\ell.$$

(Be careful here not to confuse the electron mass $m$ with the magnetic quantum number, $m_\ell$.) It is useful to define the quantity

$$\mu_B = \frac{e\hbar}{2m} \qquad \textbf{(39–12)}$$

which is called the **Bohr magneton** and has the value $\mu_B = 9.27 \times 10^{-24}\,\text{J/T}$ (joule/tesla). Then we can write

$$\mu_z = -\mu_B m_\ell, \qquad \textbf{(39–13)}$$

where $m_\ell$ has integer values from 0 to $\pm\ell$ (see Table 39–1). An atom placed in a magnetic field would have its energy split into levels that differ by $\Delta U = \mu_B B$; this is the *Zeeman effect*, and was shown in Fig. 39–4.

## *Stern-Gerlach Experiment and the *g*-Factor for Electron Spin

The first evidence for the splitting of atomic energy levels, known as *space quantization* (Section 39–2), came in 1922 in a famous experiment known as the **Stern-Gerlach experiment**. Silver atoms (and later others) were heated in an oven from which they escaped as shown in Fig. 39–14. The atoms were made to pass

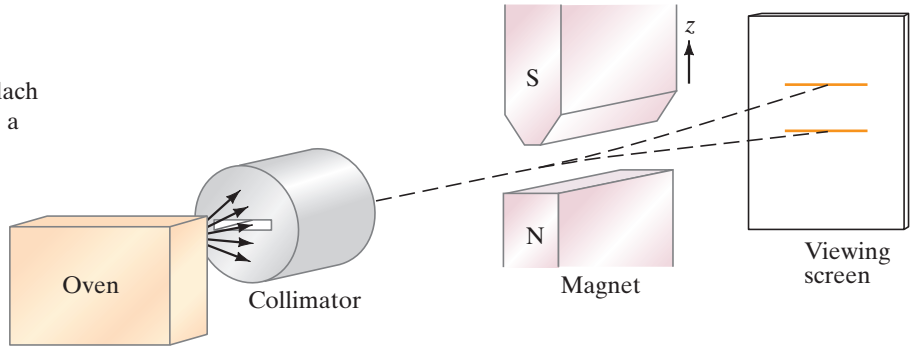


**FIGURE 39–14** The Stern-Gerlach experiment, which is done inside a vacuum chamber.

through a collimator, which eliminated all but a narrow beam. The beam then passed into a *nonhomogeneous* magnetic field. The field was deliberately made nonhomogeneous so that it would exert a force on atomic magnetic moments: remember that the potential energy (in this case $-\vec{\boldsymbol{\mu}} \cdot \vec{\mathbf{B}}$) must change in space if there is to be a force $(F_x = -dU/dx,$ etc., Section 8–2). If $\vec{\mathbf{B}}$ has a gradient along the $z$ axis, as in Fig. 39–14, then the force is along $z$:

$$F_z = -\frac{dU}{dz} = \mu_z \frac{dB_z}{dz}.$$

Thus the silver atoms would be deflected up or down depending on the value of $\mu$ for each atom. Classically, we would expect to see a continuous distribution on the viewing screen, since we would expect the atoms to have randomly oriented magnetic moments. But Stern and Gerlach saw instead two distinct lines for silver (and for other atoms sometimes more than two lines). These observations were the first evidence for space quantization, though not fully explained until a few years later.

PSE5_CH39_v1.9_23-Jun-20

If the lines were due to orbital angular momentum, there should have been an odd number of them, corresponding to the possible values of $m_\ell$ (since $\mu_z = -\mu_B m_\ell$). For $\ell = 0$, there is only one possibility, $m_\ell = 0$. For $\ell = 1$, $m_\ell$ can be 1, 0, or $-1$, and we would expect three lines, and so on. Why there are only two lines was eventually explained by the concept of electron spin. With a spin of $\frac{1}{2}$, the electron spin can have only two orientations in space, as we saw in Fig. 39–5. Hence a magnetic dipole moment associated with spin would have only two positions. Thus, the two states for silver seen in the Stern-Gerlach experiment must be due to the spin of its one valence electron. Silver atoms must thus have zero orbital angular momentum but a total spin of $\frac{1}{2}$ due to this one valence electron. (Of silver's 47 electrons, the spins of the first 46 cancel.) For the H atom in its ground state, again only two lines were seen on the screen of Fig. 39–14: due to the spin $\frac{1}{2}$ of its electron since the orbital angular momentum is zero.

The Stern-Gerlach deflection is proportional to the magnetic dipole moment, $\mu_z$, and for a spin $\frac{1}{2}$ particle we expect $\mu_z = -\mu_B m_s = -\left(\frac{1}{2}\right)(e\hbar/2m)$ as for the case of orbital angular momentum, Eq. 39–13. Instead, $\mu_z$ for spin was found to be about twice as large:

$$\mu_z = -g\mu_B m_s, \qquad \text{[electron spin]} \quad \textbf{(39–14)}$$

where $g$, called the ***g*-factor** or **gyromagnetic ratio**, has been measured to be slightly larger than 2: $g = 2.0023\cdots$ for a free electron. This unexpected factor of (about) 2 clearly indicates that spin cannot be viewed as a classical angular momentum. It is a purely quantum-mechanical effect. Equation 39–14 is the same as Eq. 39–13 for orbital angular momentum with $m_s$ replacing $m_\ell$. But for the orbital case, $g = 1$.

## *Total Angular Momentum $\vec{\mathbf{J}}$

An atom can have both orbital and spin angular momenta. For example, in the $2p$ state of hydrogen $\ell = 1$ and $s = \frac{1}{2}$. In the $4d$ state, $\ell = 2$ and $s = \frac{1}{2}$. The **total angular momentum** is the vector sum of the orbital angular momentum $\vec{\mathbf{L}}$ and the spin $\vec{\mathbf{S}}$:

$$\vec{\mathbf{J}} = \vec{\mathbf{L}} + \vec{\mathbf{S}}.$$

According to quantum mechanics, the magnitude of the total angular momentum $\vec{\mathbf{J}}$ is quantized:

$$J = \sqrt{j(j+1)}\,\hbar. \qquad \textbf{(39–15)}$$

For the single electron in the H atom, quantum mechanics gives the result that $j$ can be

$$j = \ell + s = \ell + \tfrac{1}{2}$$

or

$$j = \ell - s = \ell - \tfrac{1}{2}$$

but never less than zero, just as for $\ell$ and $s$. For the $1s$ state, $\ell = 0$ and $j = \frac{1}{2}$ is the only possibility. For $p$ states, say the $2p$ state, $\ell = 1$ and $j$ can be either $\frac{3}{2}$ or $\frac{1}{2}$. The $z$ component for $j$ is quantized in the usual way:

$$m_j = j, j-1, \cdots, -j.$$

For a $2p$ state with $j = \frac{1}{2}$, $m_j$ can be $\frac{1}{2}$ or $-\frac{1}{2}$; for $j = \frac{3}{2}$, $m_j$ can be $\frac{3}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2}$, for a total of four states. Note that the state of a single electron can be specified by giving $n, \ell, m_\ell, m_s$, or by giving $n, j, \ell, m_j$ (only one of these descriptions at a time).

**EXERCISE H** What are the possibilities for $j$ in the $3d$ state of hydrogen? (*a*) $\frac{3}{2}, \frac{1}{2}$; (*b*) $\frac{5}{2}, \frac{3}{2}, \frac{1}{2}$; (*c*) $\frac{7}{2}, \frac{5}{2}, \frac{3}{2}, \frac{1}{2}$; (*d*) $\frac{5}{2}, \frac{3}{2}$; (*e*) $\frac{7}{2}, \frac{5}{2}$.

The interaction of magnetic fields with atoms, as in the Zeeman effect and the Stern-Gerlach experiment, involves the *total* angular momentum. Thus the Stern-Gerlach experiment on H atoms in the ground state shows two lines (for $m_j = +\frac{1}{2}$ and $-\frac{1}{2}$), but for the first excited state it shows four lines corresponding to the four possible $m_j$ values $\left(\frac{3}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2}\right)$.

## *Spectroscopic Notation

We can specify the state of an atom, including the total angular momentum quantum number $j$, using the following **spectroscopic notation**. For a single electron state we can write

$$nL_j,$$

where the value of $L$ (the orbital quantum number) is specified using the same letters as in Table 39–3, but in upper case:

$$\begin{aligned} L &= 0 \quad 1 \quad 2 \quad 3 \quad 4 \quad \cdots \\ \text{letter} &= \text{S} \quad \text{P} \quad \text{D} \quad \text{F} \quad \text{G} \quad \cdots . \end{aligned}$$

So the $2P_{3/2}$ state has $n = 2$, $\ell = 1$, $j = \frac{3}{2}$, whereas $1S_{1/2}$ specifies the ground state in hydrogen.

## *Fine Structure; Spin-Orbit Interaction

A magnetic effect also produces the *fine structure* splitting mentioned in Section 39–2, but it occurs in the absence of any external field. Instead, it is due to a magnetic field produced by the atom itself. We can see how it occurs by putting ourselves in the reference frame of the electron, in which case we see the nucleus revolving about us as a moving charge or electric current that produces a magnetic field, $B_n$. The electron has an intrinsic magnetic dipole moment $\mu_s$ (Eq. 39–14) and hence its energy will be altered by an amount (Eq. 27–12)

$$\Delta U = -\vec{\boldsymbol{\mu}}_s \cdot \vec{\mathbf{B}}_n.$$

Since $\mu_s$ takes on quantized values according to the values of $m_s$, the energy of a single electron state will split into two closely spaced energy levels (for $m_s = +\frac{1}{2}$ and $-\frac{1}{2}$). This tiny splitting of energy levels produces a tiny splitting in spectral lines. For example, in the H atom, the $2P \rightarrow 1S$ transition is split into two lines corresponding to $2P_{1/2} \rightarrow 1S_{1/2}$ and $2P_{3/2} \rightarrow 1S_{1/2}$. The difference in energy between these two is only about $5 \times 10^{-5}\,\text{eV}$, which is very small compared to the $2P \rightarrow 1S$ transition energy of $13.6\,\text{eV} - 3.4\,\text{eV} = 10.2\,\text{eV}$.

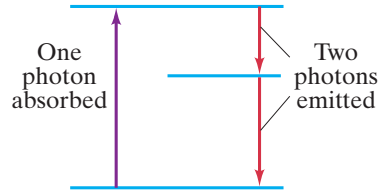
The magnetic field $\vec{\mathbf{B}}_n$ produced by the orbital motion is proportional to the orbital angular momentum $\vec{\mathbf{L}}$, and since $\vec{\boldsymbol{\mu}}_s$ is proportional to the spin $\vec{\mathbf{S}}$, then $\Delta U = -\vec{\boldsymbol{\mu}}_s \cdot \vec{\mathbf{B}}_n$ can be written

$$\Delta U \propto \vec{\mathbf{L}} \cdot \vec{\mathbf{S}}.$$

This interaction, which produces the fine structure, is thus called the **spin-orbit interaction**. Its magnitude is related to a dimensionless constant known as the **fine structure constant**,

$$\alpha = \frac{e^2}{2\epsilon_0 hc} \approx \frac{1}{137},$$

which also appears elsewhere in atomic physics



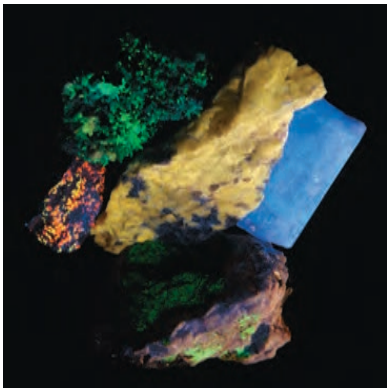


**FIGURE 39–15** Fluorescence.

**FIGURE 39–16** When UV light (a range of wavelengths) illuminates these various "fluorescent" rocks, they fluoresce in the visible region of the spectrum.

# 39–8 Fluorescence and Phosphorescence

When an atom is excited from one energy state to a higher one by the absorption of a photon, it may return to the lower level in a series of two (or more) transitions if there is at least one energy level in between (Fig. 39–15). The photons emitted will consequently have lower energy and frequency than the absorbed photon. When the absorbed photon is in the UV and the emitted photons are in the visible region of the spectrum, this phenomenon is called **fluorescence** (Fig. 39–16).

The wavelength for which fluorescence will occur depends on the energy levels of the particular atoms. Because the frequencies are different for different substances, and because many substances fluoresce readily, fluorescence is a powerful tool for identification of compounds. It is also used for assaying—determining how much of a substance is present—and for following substances along a natural *metabolic pathway* in biological organisms. For detection of a given compound, the stimulating light must be monochromatic,

and solvents or other materials present must not fluoresce in the same region of the spectrum. Sometimes the observation of fluorescent light being emitted is sufficient to detect a compound. In other cases, spectrometers are used to measure the wavelengths and intensities of the emitted light.

**Fluorescent lightbulbs** work in a two-step process. The applied voltage accelerates electrons that strike atoms of the gas in the tube and cause them to be excited. When the excited atoms jump down to their normal levels, they emit UV photons which strike a fluorescent coating on the inside of the tube. The light we see is a result of this material fluorescing in response to the UV light striking it.

Materials such as those used for luminous watch dials, and other glow-in-the-dark products, are said to be **phosphorescent**. When an atom is raised to a normal excited state, it drops back down within about $10^{-8}$ s. In phosphorescent substances, atoms can be excited by photon absorption to energy levels, called **metastable**, which are states that last much longer because to jump down is a "forbidden" transition as discussed in Section 39–2. Metastable states can last even a few seconds or longer. In a collection of such atoms, many of the atoms will descend to the lower state fairly soon, but many will remain in the excited state for over an hour. Hence light will be emitted even after long periods. When you put a luminous watch dial close to a bright lamp, many atoms are excited to metastable states, and you can see the glow for a long time afterward.

## 39–9 Lasers

A **laser** is a device that can produce a very narrow intense beam of monochromatic coherent light. (By *coherent*, we mean that across any cross section of the beam, all parts have the same phase.) The emitted beam is a nearly perfect plane wave. An ordinary light source, on the other hand, emits light in all directions (so the intensity decreases rapidly with distance), and the emitted light is incoherent (the different parts of a beam are not in phase with each other). The excited atoms that emit the light in an ordinary lightbulb act independently, so each photon emitted can be considered as a short wave train lasting about $10^{-8}$ s. Different wave trains bear no phase relation to one another. Just the opposite is true of lasers.

The action of a laser is based on quantum theory. We have seen that a photon can be absorbed by an atom if (and only if) the photon energy $hf$ corresponds to the energy difference between an occupied energy level of the atom and an available excited state, Fig. 39–17a. If the atom is already in the excited state, it may jump down spontaneously (i.e., no stimulus) to the lower state with the emission of a photon. However, if a photon with this same energy strikes the excited atom, it can stimulate the atom to make the transition sooner to the lower state, Fig. 39–17b. This phenomenon is called **stimulated emission**: not only do we still have the original photon, but also a second one of the same frequency as a result of the atom's transition. These two photons are exactly *in phase*, and they are moving in the same direction. This is how coherent light is produced in a laser. The name "laser" is an acronym for **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation.

The natural population in energy states of atoms in thermal equilibrium at any temperature $T$ (in K) is given by the **Boltzmann distribution** (or **Boltzmann factor**):

$$N_n = Ce^{-\frac{E_n}{kT}}, \qquad \textbf{(39–16a)}$$

where $N_n$ is the number of atoms in the state with energy $E_n$. For two states $n$ and $n'$, the ratio of the number of atoms in the two states is

$$\frac{N_n}{N_{n'}} = e^{-\left(\frac{E_n - E_{n'}}{kT}\right)}. \qquad \textbf{(39–16b)}$$

Thus most atoms are in the ground state unless the temperature is very high. In the two-level system of Fig. 39–17, most atoms are normally in the lower state, so the majority of incident photons will be absorbed. In order to obtain the coherent light from stimulated emission, two conditions must be satisfied.

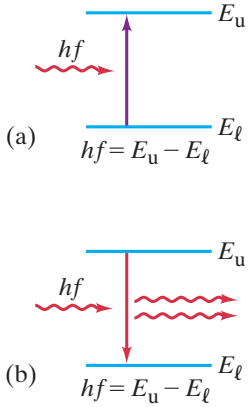

**FIGURE 39–17** (a) Absorption of a photon. (b) Stimulated emission. $E_u$ and $E_\ell$ refer to "upper" and "lower" energy states.

**FIGURE 39–18** Two energy levels for a collection of atoms. Each dot represents the energy state of one atom. (a) A normal situation; (b) an inverted population.

**⚠ CAUTION**

*Laser: photons have same frequency and direction, and are in phase*

First, the atoms must be excited to the higher state, so that an **inverted population** is produced, one in which more atoms are in the upper state than in the lower one (Fig. 39–18). Then *emission* of photons will dominate over absorption. Hence the system will not be in thermal equilibrium. And second, the higher state must be a **metastable state**—a state in which the electrons remain longer than usual[†] so that the transition to the lower state occurs by stimulated emission rather than spontaneously. (How inverted populations are created will be discussed shortly.)

Figure 39–19 is a schematic diagram of a laser: the "lasing" material is placed in a long narrow tube at the ends of which are two mirrors, one of which is partially transparent (transmitting perhaps 1 or 2%). Some of the excited atoms drop down fairly soon after being excited. One of these is the blue atom shown on the far left in Fig. 39–19. If the emitted photon strikes another atom in the excited state, it stimulates this atom to emit a photon of the *same* frequency, moving in the *same* direction, and *in phase* with it. These two photons then move on to strike other atoms causing more stimulated emission. As the process continues, the number of photons multiplies. When the photons strike the end mirrors, most are reflected back, and as they move in the opposite direction, they continue to stimulate more atoms to emit photons. As the photons move back and forth between the mirrors, a small percentage passes through the partially transparent mirror at one end. These photons make up the narrow coherent external laser beam.

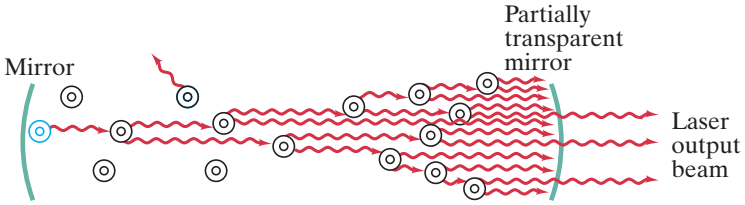

**FIGURE 39–19** Laser diagram, showing excited atoms stimulated to emit light.

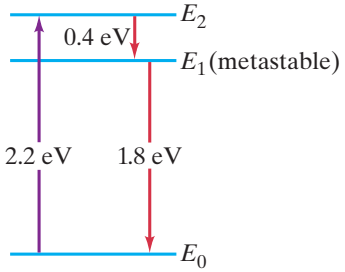
Inside the tube, some spontaneously emitted photons will be emitted at an angle to the axis, and these will merely go out the side of the tube and not affect the narrow width of the main beam.



In a well-designed laser, the spreading of the beam is limited only by diffraction, so the angular spread is $\approx \lambda/D$ (see Eq. 35–1 or 35–10), where $D$ is the diameter of the end mirror. The diffraction spreading can be incredibly small. The light energy, instead of spreading out in space as it does for an ordinary light source, can be a pencil-thin beam.

## Creating an Inverted Population

The excitation of the atoms in a laser can be done in several ways to produce the necessary inverted population. In a **ruby laser**, the lasing material is a ruby rod consisting of $Al_2O_3$ with a small percentage of aluminum (Al) atoms replaced by chromium (Cr) atoms. The Cr atoms are the ones involved in lasing. In a process called **optical pumping**, the atoms are excited by strong flashes of light of wavelength 550 nm, which corresponds to a photon energy of 2.2 eV. As shown in Fig. 39–20, the atoms are excited from state $E_0$ to state $E_2$. The atoms quickly decay either back to $E_0$ or to the intermediate state $E_1$, which is metastable with a lifetime of about $3 \times 10^{-3}$ s (compared to $10^{-8}$ s for ordinary levels). With strong pumping action, more atoms can be found in the $E_1$ state than are in the $E_0$ state. Thus we have the inverted population needed for lasing. As soon as a few atoms in the $E_1$ state jump down to $E_0$, they emit photons that produce stimulated emission of the other atoms, and the lasing action begins. A ruby laser thus emits a beam whose photons have energy 1.8 eV and a wavelength of 694.3 nm (or "ruby-red" light).

In a **helium–neon laser** (He–Ne), the lasing material is a gas, a mixture of about 85% He and 15% Ne. The atoms are excited by applying a high voltage to the tube so that an electric discharge takes place within the gas. In the process,

**FIGURE 39–20** Energy levels of chromium in a ruby crystal. Photons of energy 2.2 eV "pump" atoms from $E_0$ to $E_2$, which then decay to metastable state $E_1$. Lasing action occurs by stimulated emission of photons in transition from $E_1$ to $E_0$.

[†]An excited atom may land in such a state and can jump to a lower state only by a so-called forbidden transition (Section 39–2), which is why its lifetime is longer than normal.

some of the He atoms are raised to the metastable state $E_1$ shown in Fig. 39–21, which corresponds to a jump of 20.61 eV, almost exactly equal to an excited state in neon, 20.66 eV. The He atoms do not quickly return to the ground state by spontaneous emission, but instead often give their excess energy to a Ne atom when they collide—see Fig. 39–21. In such a collision, the He drops to the ground state and the Ne atom is excited to the state $E'_3$ (the prime refers to neon states). The slight difference in energy (0.05 eV) is supplied by the kinetic energy of the moving atoms. In this manner, the $E'_3$ state in Ne—which is metastable—becomes more populated than the $E'_2$ level. This inverted population between $E'_3$ and $E'_2$ is what is needed for lasing.

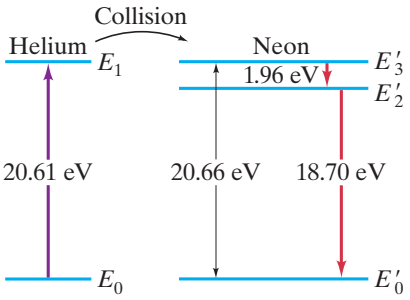


**FIGURE 39–21** Energy levels for He and Ne. He is excited in the electric discharge to the $E_1$ state. This energy is transferred to the $E'_3$ level of the Ne by collision. $E'_3$ is metastable and decays to $E'_2$ by stimulated emission.

Very common now are **semiconductor diode lasers**, also called **pn junction lasers**, which utilize an inverted population of electrons between the conduction band and the lower-energy valence band (Sections 40–7 to 40–9). When an electron jumps down, a photon can be emitted, which in turn can stimulate another electron to make the transition and emit another photon, in phase. The needed mirrors (as in Fig. 39–19) are made by the polished ends of the *pn* crystal. Semiconductor lasers are used in CD and DVD players (see below), and in many other applications.

Other types of laser include: *chemical lasers*, in which the energy input comes from the chemical reaction of highly reactive gases; *dye lasers*, whose frequency is tunable; $CO_2$ *gas lasers*, capable of high-power output in the infrared; and *rare-earth solid-state lasers* such as the high-power Nd:YAG laser.

The excitation of the atoms in a laser can be done continuously or in pulses. In a **pulsed laser**, the atoms are excited by periodic inputs of energy. In a **continuous laser**, the energy input is continuous: as atoms are stimulated to jump down to the lower level, they are soon excited back up to the upper level so the output is a continuous laser beam.

No laser is a source of energy. Energy must be put in, and the laser converts a part of it into an intense narrow beam output.

**CAUTION**
*Laser not an energy source*

## *Applications

The unique feature of light from a laser, that it is a coherent narrow beam, has found many applications. In everyday life, lasers are used as bar-code readers (at store checkout stands) and in compact disc (CD) and digital video disc (DVD) players. The laser beam reflects off the stripes and spaces of a bar code, or off the tiny pits of a CD or DVD as shown in Fig. 39–22a. The recorded information on a CD or DVD is a series of pits and spaces representing 0s and 1s (or "off" and "on") of a binary code (Section 23–9) that is decoded electronically before being sent to the audio or video system. The laser of a CD player starts reading at the inside of the disc which rotates at about 500 rpm at the start. As the disc rotates, the laser follows the spiral track (Fig. 39–22b), and as the laser moves outward the disc must slow down because each successive circumference $(C = 2\pi r)$ is slightly longer as $r$ increases; when the laser reaches the outer edge, the disc is rotating about 200 rpm. A 1-hour CD has a track roughly 5 km long; the track width is about 1600 nm $(= 1.6\ \mu\text{m})$ and the distance between pits is about 800 nm. DVDs contain much more information. Standard DVDs use a thinner track $(0.7\ \mu\text{m})$ and shorter pit length (400 nm).

**PHYSICS APPLIED**
*DVD and CD players, bar codes*

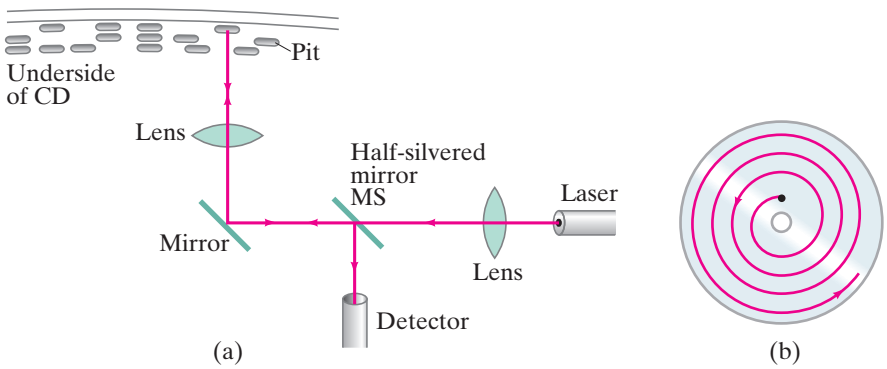

**FIGURE 39–22** (a) Reading a CD (or DVD). The fine beam of a laser, focused even more finely with lenses, is directed at the undersurface of a rotating compact disc. The beam is reflected back from the areas between pits but reflects much less from pits. The reflected light is detected as shown, reflected by a half-reflecting mirror MS. The strong and weak reflections correspond to the 0s and 1s of the binary code representing the audio or video signal. (b) A laser follows the CD track which starts near the center and spirals outward.

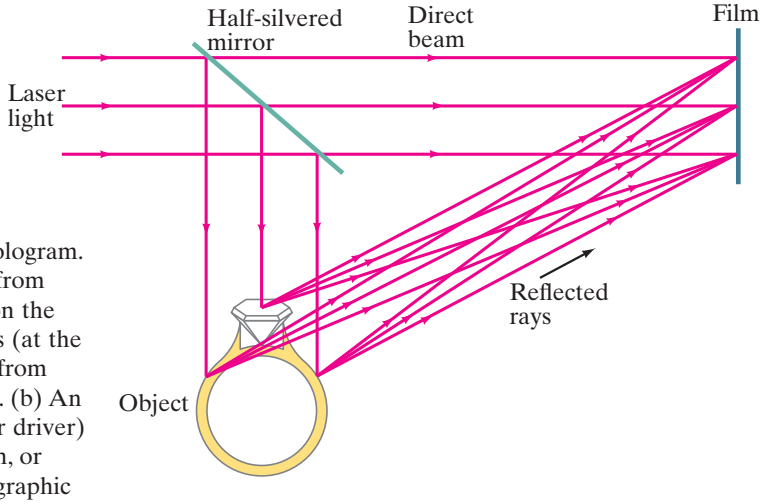
Blu-ray discs use a "blue" laser with a short wavelength (405 nm) and narrower beam, allowing a narrower track ($0.3\ \mu m$) that can store much more data for high definition. DVDs can also have two layers, one below the other. When the laser focuses on the second layer, the light passes through the semitransparent surface layer. The second layer may start reading at the outer edge instead of inside. DVDs can also have a single or double layer on *both* surfaces of the disc.

**PHYSICS APPLIED**
*Medical and other uses of lasers*

Lasers are a useful surgical tool. The narrow intense beam can be used to destroy tissue in a localized area, or to break up gallstones and kidney stones. Because of the heat produced, a laser beam can be used to "weld" broken tissue, such as a detached retina, Fig. 39–23, or to mold the cornea of the eye (by vaporizing tiny bits of material) to correct myopia and other eye defects (LASIK surgery). The laser beam can be carried by an optical fiber (Section 32–7) to the surgical point, sometimes as an additional fiber-optic path on an endoscope (again Section 32–7). An example is the removal of plaque clogging human arteries. Lasers have been used to destroy tiny organelles within a living cell by researchers studying how the absence of that organelle affects the behavior of the cell. Laser beams are used to destroy cancerous and precancerous cells; and the heat seals off capillaries and lymph vessels, thus "cauterizing" the wound to prevent spread of the disease.

**FIGURE 39–23** Laser being used in eye surgery.



The intense heat produced in a small area by a laser beam is used for welding and machining metals and for drilling tiny holes in hard materials. Because a laser beam is coherent, monochromatic, narrow, and essentially parallel, lenses can be used to focus the light into even smaller areas. The precise straightness of a laser beam is also useful to surveyors for lining up equipment accurately, especially in inaccessible places.

The U.S. Navy is said to have a laser that is strong enough to shoot down small unmanned aircraft such as drones, and to disable small attack boats.

## *39–10 Holography

**PHYSICS APPLIED**
*Holography*

One of the most interesting applications of laser light is the production of three-dimensional images called **holograms** (see Fig. 39–24). In an ordinary photograph, the film simply records the intensity of light reaching it at each point. When the photograph or transparency is viewed, light reflecting from it or passing through it gives us a two-dimensional picture. In holography, the images are formed by interference, without lenses. A laser hologram is typically made on photographic emulsion (film). A broadened laser beam is split into two parts by a half-silvered mirror, Fig. 39–24a. One part goes directly to the film; the rest passes to the object to be photographed, from which it is reflected to the film. Light from every point on the surface of the object reaches each point on the film, and the interference of the two beams allows the film to record both the intensity and relative phase of the light at each point.

(a)

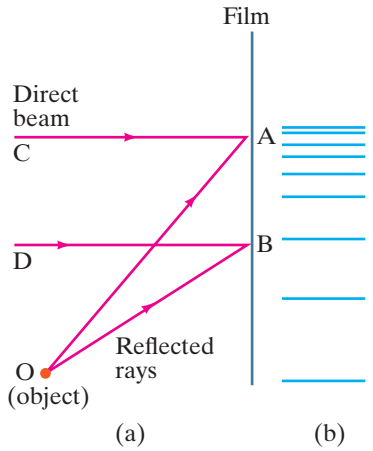
(b)

**FIGURE 39–24**
(a) Making a hologram. Light reflected from various points on the object interferes (at the film) with light from the direct beam. (b) An athlete (race-car driver) puts his hand on, or through, a holographic image of himself.

It is crucial that the incident light be coherent—that is, in phase at all points—which is why a laser is used. After the film is developed, it is placed again in a laser beam and a three-dimensional image of the object is created. You can walk around such an image and see it from different sides as if it were the original object. Yet, if you try to touch it with your hand (Fig. 39–24b), there will be nothing material there.

The details of how the image is formed are quite complicated. But we can get the basic idea by considering one single point on the object. In Fig. 39–25a the rays OA and OB have reflected from one point on our object. The rays CA and DB come directly from the source and interfere with OA and OB at points A and B on the film. A set of interference fringes is produced as shown in Fig. 39–25b. The spacing between the fringes changes from top to bottom as shown. Why this happens is explained in Fig. 39–26. Thus the hologram of a single point object would have the fringe pattern shown in Fig. 39–25b. The film in this case looks like a diffraction grating with variable spacing. Hence, when coherent laser light is passed back through the developed film to reconstruct the image, the diffracted rays in the first order maxima occur at slightly different angles because the spacing changes. (Remember Eq. 35–13, $\sin\theta = \lambda/d$: where the spacing $d$ is greater, the angle $\theta$ is less.) Hence, the rays diffracted upward (in first order) seem to diverge from a single point, Fig. 39–27. This is a virtual image of the original object, which can be seen with the eye. Rays diffracted in first order *downward* converge to make a real image, which can be seen and also photographed. (Note that the straight-through undiffracted rays are of no interest.) Of course real objects consist of many points, so a hologram will be a complex interference pattern which, when laser light is incident on it, will reproduce an image of the object. Each image point will be at the correct (three-dimensional) position with respect to other points, so the image accurately represents the original object. And it can be viewed from different angles as if viewing the original object. Holograms can be made in which a viewer can walk entirely around the image (360°) and see all sides of it.

**Volume** or **white-light holograms** do not require a laser to see the image, but can be viewed with ordinary white light (preferably a nearly point source, such as the Sun or a clear bulb with a small bright filament). Such holograms must be made, however, with a laser. They are made not on thin film, but on a *thick* emulsion. The interference pattern in the film emulsion can be thought of as an array of bands or ribbons where constructive interference occurred. This array, and the reconstruction of the image, can be compared to Bragg scattering of X-rays from the atoms in a crystal (see Section 35–10). White light can reconstruct the image because the Bragg condition $(m\lambda = 2d\sin\theta)$ selects out the appropriate single wavelength. If the hologram is originally produced by lasers emitting the three additive primary colors (red, green, and blue), the three-dimensional image can be seen in full color when viewed with white light.



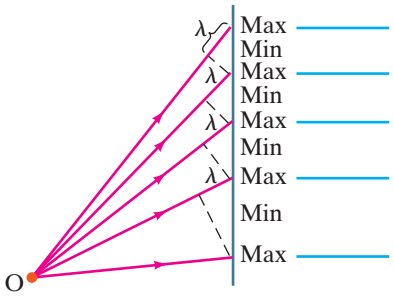


**FIGURE 39–25** (a) Light from point O on the object interferes with light of the direct beam (rays CA and DB). (b) Interference fringes produced.

**FIGURE 39–26** Each of the rays shown leaving point O is one wavelength shorter than the one above it. If the top ray is in phase with the direct beam (not shown), which has the same phase at all points on the screen, each of the rays shown produces a constructive interference fringe. From this diagram it can be seen that the fringe spacing increases toward the bottom.

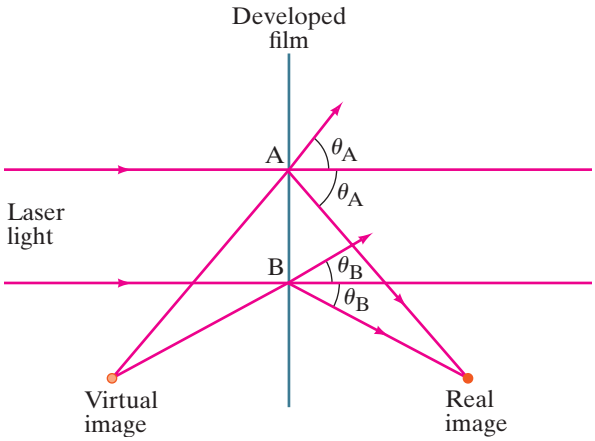

**FIGURE 39–27** Reconstructing the image of one point on the object. Laser beam strikes the developed film, which is like a diffraction grating of variable spacing. Rays corresponding to the first diffraction maxima are shown emerging. The angle $\theta_A > \theta_B$ because the spacing at B is greater than at A $(\sin\theta = \lambda/d)$. Hence real and virtual images of the point are reproduced as shown.

# Summary

In the quantum-mechanical view of the atom, the electrons do not have well-defined orbits, but instead exist as a "cloud." Electron clouds can be interpreted as an electron wave spread out in space, or as a **probability distribution** for electrons considered as particles.

For the simplest atom, hydrogen, the Schrödinger equation contains the potential energy

$$U = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r}.$$

The solutions give the same values of energy as the old Bohr model.

According to quantum mechanics, the state of an electron in an atom is specified by four **quantum numbers**: $n$, $\ell$, $m_\ell$, and $m_s$:

1. $n$, the **principal quantum number**, can take on any integer value $(1, 2, 3, \cdots)$ and corresponds to the quantum number of the old Bohr model;
2. $\ell$, the **orbital quantum number**, can take on integer values from 0 up to $n - 1$;
3. $m_\ell$, the **magnetic quantum number**, can take on integer values from $-\ell$ to $+\ell$;
4. $m_s$, the **spin quantum number**, can be $+\frac{1}{2}$ or $-\frac{1}{2}$.

The energy levels in the hydrogen atom depend on $n$, whereas in other atoms they depend on $n$ and $\ell$.

The orbital angular momentum of an atom has magnitude $L = \sqrt{\ell(\ell+1)}\,\hbar$ and $z$ component $L_z = m_\ell\hbar$. Spin angular momentum has magnitude $S = \sqrt{s(s+1)}\,\hbar$ and $z$ component $S_z = m_s\hbar$ where $s = \frac{1}{2}$ and $m_s = \pm\frac{1}{2}$.

When an external magnetic field is applied, the spectral lines are split (the **Zeeman effect**), indicating that the energy depends also on $m_\ell$ in this case.

Even in the absence of a magnetic field, precise measurements of spectral lines show a tiny splitting of the lines called **fine structure**, whose explanation is that the energy depends very slightly on $m_\ell$ and $m_s$.

Transitions between states that obey the **selection rule** $\Delta\ell = \pm 1$ are far more probable than other so-called **forbidden transitions**.

The ground-state wave function in hydrogen has spherical symmetry, as do other $\ell = 0$ states. States with $\ell > 0$ have some directionality in space.

The **probability density** (or probability distribution), $|\psi|^2$, and the **radial probability density**, $P_r = 4\pi r^2|\psi|^2$, are both useful to illustrate the spatial extent of the electron cloud.

The arrangement of electrons in multi-electron atoms is governed by the Pauli **exclusion principle**, which states that no two electrons can occupy the same quantum state—that is, they cannot have the same set of quantum numbers $n$, $\ell$, $m_\ell$, and $m_s$.

As a result, electrons in multi-electron atoms are grouped into **shells** (according to the value of $n$) and **subshells** (according to $\ell$).

Electron configurations are specified using the numerical values of $n$, and using letters for $\ell$: $s$, $p$, $d$, $f$, etc., for $\ell = 0, 1, 2, 3,$ and so on, plus a superscript for the number of electrons in that subshell. Thus, the ground state of hydrogen is $1s^1$, whereas that for oxygen is $1s^2 2s^2 2p^4$.

In the **Periodic Table**, the elements are arranged in horizontal rows according to increasing **atomic number** (= number of electrons in the neutral atom). The shell structure gives rise to a periodicity in the properties of the elements, so that each vertical column can contain elements with similar chemical properties.

X-rays, which are a form of electromagnetic radiation of very short wavelength, are produced when high-speed electrons strike a target. The spectrum of X-rays so produced consists of two parts, a *continuous* spectrum produced when the electrons are decelerated by atoms of the target, and *peaks* representing photons emitted by atoms of the target after being excited by collision with the high-speed electrons. Measurement of these peaks allows determination of inner energy levels of atoms and determination of atomic number $Z$.

[*An atom has a **magnetic dipole moment** $\vec{\boldsymbol{\mu}}$ related to its orbital angular momentum $\vec{\mathbf{L}}$, which produces a potential energy when in a magnetic field, $U = -\boldsymbol{\mu}\cdot\vec{\mathbf{B}}$. Electron spin also yields a magnetic moment, but the energy in a magnetic field is a factor $g = 2.0023\cdots$ times larger than expected, as determined in Stern-Gerlach experiments.]

[*Atoms have a total angular momentum $\vec{\mathbf{J}} = \vec{\mathbf{L}} + \vec{\mathbf{S}}$ which is quantized as for $L$ and $S$, namely $J = \sqrt{j(j+1)}\,\hbar$, where $j$ is a half-integer equal to $\ell \pm \frac{1}{2}$ in hydrogen.]

**Fluorescence** occurs when absorbed UV photons are followed by emission of visible light, due to the special arrangement of energy levels of atoms of the material. **Phosphorescent** materials have **metastable** states (long-lived) that emit light seconds or minutes after absorption of light.

**Lasers** produce a narrow beam of monochromatic coherent light (light waves *in phase*).

[***Holograms** are images with a 3-dimensional quality, formed by interference of laser light.]

# Questions

1. (*a*) List two aspects of the Bohr model that the quantum-mechanical theory of the atom retained. (*b*) Give one major difference between the Bohr model and the quantum-mechanical theory of the atom.
2. The probability density $|\psi|^2$ is a maximum at the center of the H atom $(r = 0)$ for the ground state, whereas the radial probability density $P_r = 4\pi r^2|\psi|^2$ is zero at this point. Explain why.
3. Which model of the hydrogen atom, the Bohr model or the quantum-mechanical model, predicts that the electron spends more time near the nucleus? Explain.
4. The size of atoms varies by only a factor of three or so, from largest to smallest, yet the number of electrons varies from one to over 100. Explain.
5. Excited hydrogen and excited helium atoms both radiate light as they jump down to the $n = 1$, $\ell = 0$, $m_\ell = 0$ state. Why do the two elements have very different emission spectra?
6. In Fig. 39–4, why do the upper and lower levels have different energy splittings in a magnetic field?
7. The 589-nm yellow line in sodium is actually two very closely spaced lines. This splitting is due to an "internal" Zeeman effect. Can you explain this? [*Hint*: Put yourself in the reference frame of the electron.]

**8.** Which of the following electron configurations are not allowed: (*a*) $1s^2 2s^2 2p^8 3s^1$; (*b*) $1s^2 2s^2 2p^4 3s^2 4p^2$; (*c*) $1s^2 2s^2 2p^6 3s^2 3p^5 4s^2 4d^5 4f^1$? If not allowed, explain why.

**9.** Give the complete electron configuration for a uranium atom (careful scrutiny across the Periodic Table on the inside back cover will provide useful hints).

**10.** For noble gases, the halogens, and the alkali metals, explain the atomic structure that is common to each group and how that structure explains a common property of the group.

**11.** In what column of the Periodic Table would you expect to find the atom with each of the following configurations?

(*a*) $1s^2 2s^2 2p^6 3s^2$; (*b*) $1s^2 2s^2 2p^5$; (*c*) $1s^2 2s^2 2p^6 3s^2 3p^6$; (*d*) $1s^2 2s^2 2p^6 3s^2 3p^6 4s^1$.

**12.** On what factors does the periodicity of the Periodic Table depend? Consider the exclusion principle, quantization of angular momentum, spin, and any others you can think of.

**13.** How would the Periodic Table look if there were no electron spin but otherwise quantum mechanics were valid? Consider the first 20 elements or so.

**14.** The ionization energy for neon $(Z = 10)$ is 21.6 eV and that for sodium $(Z = 11)$ is 5.1 eV. Explain the large difference.

**15.** Why do chlorine and iodine exhibit similar properties?

**16.** Explain why potassium and sodium exhibit similar properties.

**16'.** Briefly explain why noble gases are non-reactive and why alkali metals are highly reactive.

**17.** Why are the chemical properties of the rare earths so similar? [*Hint*: Examine the Periodic Table.]

**18.** Why do we not expect perfect agreement between measured values of characteristic X-ray line wavelengths and those calculated using the Bohr model, as in Example 39–6?

**19.** Why does the Bohr model, which does not work at all well for normal transitions involving the outer electrons for He and more complex atoms, nevertheless predict reasonably well the atomic X-ray spectra for transitions deep inside the atom?

**20.** Why does the cutoff wavelength in Fig. 39–11 imply a photon nature for light?

**21.** How would you figure out which lines in an X-ray spectrum correspond to $K_\alpha$, $K_\beta$, L, etc., transitions?

**22.** Why do the characteristic X-ray spectra vary in a systematic way with $Z$, whereas the visible spectra (Fig. 35–22) do not?

**23.** Why do we expect electron transitions deep within an atom to produce shorter wavelengths than transitions by outer electrons?

***24.** Why is the direction of the magnetic dipole moment of an electron opposite to that of its orbital angular momentum?

***25.** Why is a nonhomogeneous field used in the Stern-Gerlach experiment?

**26.** Compare spontaneous emission to stimulated emission.

**27.** Does the intensity of light from a laser fall off as the inverse square of the distance? Explain.

**28.** How does laser light differ from ordinary light? How is it the same?

**29.** Explain how a 0.0005-W laser beam, photographed at a distance, can seem much stronger than a 1000-W street lamp at the same distance.

# MisConceptual Questions

**1.** An atom has the electron configuration $1s^2 2s^2 2p^6 3s^2 3p^6 4s^1$. How many electrons does this atom have?
(*a*) 15. (*b*) 19. (*c*) 30. (*d*) 46.

**2.** For the electron configuration of MisConceptual Question 1, what orbital quantum numbers do the electrons have?
(*a*) 0.
(*b*) 0 and 1.
(*c*) 0 and 1 and 2.
(*d*) 0 and 1 and 2 and 3.
(*e*) 0 and 1 and 2 and 3 and 4.

**3.** What is meant by the ground state of an atom?
(*a*) All of the quantum numbers have their lowest values $(n = 1,\ \ell = m_\ell = 0)$.
(*b*) The principal quantum number of the electrons in the outer shell is 1.
(*c*) All of the electrons are in the lowest energy state, consistent with the exclusion principle.
(*d*) The electrons are in the lowest state allowed by the uncertainty principle.

**4.** The Pauli exclusion principle applies to all electrons
(*a*) in the same shell, but not electrons in different shells.
(*b*) in the same container of atoms.
(*c*) in the same column of the Periodic Table.
(*d*) in incomplete shells.
(*e*) in the same atom.

**5.** Which of the following is required by the Pauli exclusion principle?
(*a*) No electron in an atom can have the same set of quantum numbers as any other electron in that atom.
(*b*) Each electron in an atom must have the same $n$ value.
(*c*) Each electron in an atom must have different $m_\ell$ values.
(*d*) Only two electrons can be in any particular shell of an atom.
(*e*) No two electrons in a collection of atoms can have the exact same set of quantum numbers.

**6.** Under what condition(s) can the exact location and velocity of an electron be measured at the same time?
(*a*) The electron is in the ground state of the atom.
(*b*) The electron is in an excited state of the atom.
(*c*) The electron is free (not bound to an atom).
(*d*) Both (*a*) and (*b*).
(*e*) Never.

**7.** Which of the following is *not* always a property of lasers?
(*a*) All of the photons in laser light have the same phase.
(*b*) All laser photons have nearly identical frequencies.
(*c*) Laser light moves as a beam, spreading out very slowly.
(*d*) Laser light is always brighter than other sources of light.
(*e*) Lasers depend on an inverted population of atoms where more atoms occupy a higher energy state than some lower energy state.

**8.** The letters $s, p, d, f, g, \ldots$
(*a*) summarize all the quantum numbers for electrons in atoms.
(*b*) are an alternative notation for the principal quantum number.
(*c*) apply only to the electron in hydrogen.
(*d*) denote orbitals characterized by the $\ell$ value of an electron.

**9.** Which statement below is correct?
(*a*) Forbidden transitions do not occur.
(*b*) Forbidden transitions only occur in lasers.
(*c*) Forbidden transitions occur but with much lower probability than allowed transitions.
(*d*) Forbidden transitions occur in multi-electron atoms but not in hydrogen.

**10.** How does the energy difference between adjacent states in a hydrogen atom change as the principal quantum number increases?
(*a*) The energy difference increases with increasing values of the principal quantum number.
(*b*) The energy difference remains constant with increasing values of the principal quantum number.
(*c*) The energy difference decreases with increasing values of the principal quantum number.
(*d*) The energy difference varies with increasing values of the principal quantum number.

# Problems

## 39–2 Hydrogen Atom Quantum Numbers

**1.** (I) For $n = 6$, what values can $\ell$ have?

**2.** (I) For $n = 7$, $\ell = 3$, what are the possible values of $m_\ell$ and $m_s$?

**3.** (I) How many different states are possible for an electron whose principal quantum number is $n = 4$? Write down the quantum numbers for each state.

**4.** (I) If a hydrogen atom has $m_\ell = -5$, what are the possible values of $n$, $\ell$, and $m_s$?

**5.** (I) A hydrogen atom has $\ell = 4$. What are the possible values for $n$, $m_\ell$, and $m_s$?

**6.** (I) Calculate the magnitude of the angular momentum of an electron in the $n = 5$, $\ell = 4$ state of hydrogen.

**7.** (II) A hydrogen atom is in the 8*g* state. Determine (*a*) the principal quantum number, (*b*) the energy of the state, (*c*) the orbital angular momentum and its quantum number $\ell$, and (*d*) the possible values for the magnetic quantum number.

**8.** (II) (*a*) Show that the number of different states possible for a given value of $\ell$ is equal to $2(2\ell + 1)$. (*b*) What is this number for $\ell = 0, 1, 2, 3, 4, 5,$ and 6?

**9.** (II) Show that the number of different electron states possible for a given value of $n$ is $2n^2$. (See Problem 8.)

**10.** (II) An excited H atom is in a 5*d* state. (*a*) Name all the states $(n, \ell)$ to which the atom is "allowed" to make a transition with the emission of a photon. (*b*) How many different wavelengths are there (ignoring fine structure)?

**10'.** (II) Show that there can be 18 electrons in a "*g*" shell.

**11.** (II) The magnitude of the orbital angular momentum in an excited state of hydrogen is $6.84 \times 10^{-34}\ \text{J}\cdot\text{s}$ and the $z$ component is $2.11 \times 10^{-34}\ \text{J}\cdot\text{s}$. What are all the possible values of $n$, $\ell$, and $m_\ell$ for this state?

## 39–3 Hydrogen Atom Wave Functions

**12.** (II) Show that the ground-state wave function, Eq. 39–5, is normalized. [*Hint*: See Example 39–4.]

**13.** (II) For the ground state of hydrogen, what is the value of (*a*) $\psi$, (*b*) $|\psi|^2$, and (*c*) $P_r$, at $r = 1.5\, r_0$?

**14.** (II) For the $n = 2$, $\ell = 0$ state of hydrogen, what is the value of (*a*) $\psi$, (*b*) $|\psi|^2$, and (*c*) $P_r$, at $r = 4r_0$?

**15.** (II) By what factor is it more likely to find the electron in the ground state of hydrogen at the Bohr radius $(r_0)$ than at twice the Bohr radius $(2r_0)$?

**16.** (II) (*a*) Show that the probability of finding the electron in the ground state of hydrogen at less than one Bohr radius from the nucleus is 32%. (*b*) What is the probability of finding a 1*s* electron between $r = r_0$ and $r = 2r_0$?

**17.** (III) Determine the radius $r$ of a sphere centered on the nucleus within which the probability of finding the electron for the ground state of hydrogen is (*a*) 50%, (*b*) 90%, (*c*) 99%.

**18.** (II) (*a*) Estimate the probability of finding an electron, in the ground state of hydrogen, within the nucleus assuming it to be a sphere of radius $r = 1.1$ fm. (*b*) Repeat the estimate assuming the electron is replaced with a muon, which is very similar to an electron (Chapter 43) except that its mass is 207 times greater.

**19.** (II) Show that the mean value of $r$ for an electron in the ground state of hydrogen is $\bar{r} = \frac{3}{2} r_0$, by calculating

$$\bar{r} = \int_{\text{all space}} r|\psi_{100}|^2\, dV = \int_0^\infty r|\psi_{100}|^2 4\pi r^2\, dr.$$

**20.** (II) Show that $\psi_{200}$ as given by Eq. 39–8 is normalized.

**21.** (II) Determine the average radial probability distribution $P_r$ for the $n = 2$, $\ell = 1$ state in hydrogen by calculating

$$P_r = 4\pi r^2\left[\tfrac{1}{3}|\psi_{210}|^2 + \tfrac{1}{3}|\psi_{211}|^2 + \tfrac{1}{3}|\psi_{21-1}|^2\right].$$

**22.** (II) Use the result of Problem 21 to show that the most probable distance $r$ from the nucleus for an electron in the 2*p* state of hydrogen is $r = 4r_0$, which is just the second Bohr radius (Eq. 37–11, Fig. 37–25).

**23.** (II) For the ground state of hydrogen, what is the probability of finding the electron within a spherical shell of inner radius $0.99r_0$ and outer radius $1.01r_0$?

**24.** (III) For the $n = 2$, $\ell = 0$ state of hydrogen, what is the probability of finding the electron within a spherical shell of inner radius $4.00\, r_0$ and outer radius $5.00\, r_0$? [*Hint*: You might integrate by parts.]

**25.** (III) Show that $\psi_{100}$ (Eq. 39–5a) satisfies the Schrödinger equation (Eq. 39–1) with the Coulomb potential, for energy $E = -me^4/8\epsilon_0^2 h^2$.

**26.** (III) Show that the probability of finding the electron within 1 Bohr radius of the nucleus in the hydrogen atom is (*a*) 3.4% for the $n = 2$, $\ell = 0$ state, and (*b*) 0.37% for the $n = 2$, $\ell = 1$ state. (See Problem 21.)

**27.** (III) The wave function for the $n = 3$, $\ell = 0$ state in hydrogen is

$$\psi_{300} = \frac{1}{\sqrt{27\pi r_0^3}}\left(1 - \frac{2r}{3r_0} + \frac{2r^2}{27r_0^2}\right)e^{-\frac{r}{3r_0}}.$$

(*a*) Determine the radial probability distribution $P_r$ for this state, and (*b*) draw the curve for it on a graph. (*c*) Estimate from the graph the most probable distance from the nucleus for an electron in this state.

## 39–4 and 39–5 Complex Atoms

**28.** (I) List the quantum numbers for each electron in the ground state of carbon $(Z = 6)$.

**29.** (I) List the quantum numbers for each electron in the ground state of (*a*) oxygen $(Z = 8)$, (*b*) aluminum $(Z = 13)$.

**30.** (I) How many electrons can be in the $n = 6$, $\ell = 4$ subshell?

**31.** (II) An electron has $m_\ell = 3$ and is in its lowest possible energy state. What are the values of $n$ and $\ell$ for this electron?

**32.** (II) If the principal quantum number $n$ were limited to the range from 1 to 6, how many elements would we find in nature?

**33.** (II) What is the full electron configuration for (*a*) cobalt (Co), (*b*) gold (Au), and (*c*) uranium (U)? [*Hint*: See the Periodic Table inside the back cover.]

**34.** (II) Estimate the binding energy of the third electron in lithium using the Bohr model. [*Hint*: This electron has $n = 2$ and "sees" a net charge of approximately $+1e$.] The measured value is 5.36 eV.

**35.** (II) Using the Bohr formula for the radius of an electron orbit, estimate the average distance from the nucleus for an electron in the innermost $(n = 1)$ orbit in uranium $(Z = 92)$. Approximately how much energy would be required to remove this innermost electron?

**36.** (II) Let us apply the exclusion principle to an infinitely high square well (Section 38–8). Let there be five electrons confined to this rigid box whose width is $\ell$. Find the lowest energy state of this system, by placing the electrons in the lowest available levels, consistent with the Pauli exclusion principle.

**37.** (II) Show that the total angular momentum is zero for a filled subshell.

## 39–6 X-rays

**38.** (I) If the shortest-wavelength bremsstrahlung X-rays emitted from an X-ray tube have $\lambda = 0.023$ nm, what is the voltage across the tube?

**39.** (I) For the spectrum of X-rays emitted from the molybdenum target of Fig. 39–11, determine the maximum and minimum energies of the photons.

**40.** (I) Show that the cutoff wavelength $\lambda_0$ in an X-ray spectrum is given by

$$\lambda_0 = \frac{1240}{V}\ \text{nm},$$

where $V$ is the X-ray tube voltage in volts.

**41.** (II) Estimate the wavelength for an $n = 2$ to $n = 1$ transition in iron $(Z = 26)$.

**42.** (II) Use the approach of Example 39–6 to estimate the X-ray wavelength emitted when a cobalt atom $(Z = 27)$ makes a transition from $n = 2$ to $n = 1$.

**43.** (II) A mixture of iron and an unknown material is bombarded with electrons. The wavelength of the $K_\alpha$ lines are 194 pm for iron and 229 pm for the unknown. What is the unknown material?

**44.** (II) Use the Bohr model to estimate the wavelength for an $n = 3$ to $n = 1$ transition in molybdenum $(Z = 42)$. The measured value is 0.063 nm. Why do we not expect perfect agreement?

**45.** (III) Use conservation of energy and momentum to show that a moving electron cannot give off an X-ray photon unless there is a third object present, such as an atom or nucleus.

## *39–7 Magnetic Dipole Moment; $\vec{J}$

***46.** (I) Verify that the Bohr magneton has the value $\mu_B = 9.27 \times 10^{-24}$ J/T (see Eq. 39–12).

***47.** (I) If the quantum state of an electron is specified by $(n, \ell, m_\ell, m_s)$, estimate the energy difference between the states $(1, 0, 0, -\frac{1}{2})$ and $(1, 0, 0, +\frac{1}{2})$ of an electron in the 1*s* state of helium in an external magnetic field of 3.5 T.

***48.** (II) Silver atoms $(\text{spin} = \frac{1}{2})$ are placed in a 2.0-T magnetic field which splits the ground state into two close levels. (*a*) What is the difference in energy between these two levels, and (*b*) what wavelength photon could cause a transition from the lower level to the upper one? (*c*) How would your answer differ if the atoms were hydrogen?

***49.** (II) In a Stern-Gerlach experiment, Ag atoms exit the oven with an average speed of 780 m/s and pass through a magnetic field gradient $dB/dz = 1.8 \times 10^3$ T/m for a distance of 4.0 cm. (*a*) What is the separation of the two beams as they emerge from the magnet? (*b*) What would the separation be if the *g*-factor were 1 for electron spin?

***50.** (II) For an electron in a 5*g* state, what are all the possible values of $j$, $m_j$, $J$, and $J_z$?

***51.** (II) What are the possible values of $j$ for an electron in (*a*) the 4*p*, (*b*) the 4*f*, and (*c*) the 3*d* state of hydrogen? (*d*) What is $J$ in each case?

***52.** (II) (*a*) Write down the quantum numbers for each electron in the gallium atom. (*b*) Which subshells are filled? (*c*) The last electron is in the 4*p* state; what are the possible values of the total angular momentum quantum number, $j$, for this electron? (*d*) Explain why the angular momentum of this last electron also represents the total angular momentum for the entire atom (ignoring any angular momentum of the nucleus). (*e*) How could you use a Stern-Gerlach experiment to determine which value of $j$ the atom has?

***53.** (III) The difference between the $2P_{3/2}$ and $2P_{1/2}$ energy levels in hydrogen is about $5 \times 10^{-5}$ eV, due to the spin-orbit interaction. (*a*) Taking the electron's (orbital) magnetic moment to be 1 Bohr magneton, estimate the internal magnetic field due to the electron's orbital motion. (*b*) Estimate the internal magnetic field using a simple model of the nucleus revolving in a circle about the electron.

## 39–9 Lasers

**54.** (II) A laser used to weld detached retinas puts out 23-ms-long pulses of 640-nm light which average 0.68-W output during a pulse. How much energy can be deposited per pulse and how many photons does each pulse contain? [*Hint*: See Example 37–4.]

**55.** (II) Estimate the angular spread of a laser beam due to diffraction if the beam emerges through a 3.6-mm-diameter mirror. Assume that $\lambda = 658\,\text{nm}$. What would be the diameter of this beam if it struck (*a*) a satellite 380 km above the Earth, (*b*) the Moon? [*Hint*: See Chapter 35.]

**56.** (II) A low-power laser used in a physics lab might have a power of 0.50 mW and a beam diameter of 3.0 mm. Calculate (*a*) the average light intensity of the laser beam, and (*b*) compare it to the intensity of a 100-W incandescent lightbulb that emits 2.2 W of visible light, that is viewed from a distance of 2.0 m.

**57.** (II) Calculate the wavelength of a He–Ne laser. See Fig 39–21.

**58.** (II) Suppose that the energy level system in Fig. 39–20 is not being pumped and is in thermal equilibrium. Determine the fraction of atoms in levels $E_2$ and $E_1$ relative to $E_0$ at $T = 300\,\text{K}$.

**59.** (II) To what temperature would the system in Fig. 39–20 have to be raised (see Problem 58) so that in thermal equilibrium the level $E_2$ would have half as many atoms as $E_0$? (Note that pumping mechanisms do not maintain thermal equilibrium.)

**60.** (II) Show that a population inversion for two levels (as in a pumped laser) corresponds to a negative Kelvin temperature in the Boltzmann distribution. Explain why such a situation does not contradict the idea that negative Kelvin temperatures cannot be reached in the normal sense of temperature.

# General Problems

**61.** The ionization (binding) energy of the outermost electron in boron is 8.26 eV. (*a*) Use the Bohr model to estimate the "effective charge," $Z_{\text{eff}}$, seen by this electron. (*b*) Estimate the average orbital radius.

**62.** How many electrons can there be in an "*h*" subshell?

**63.** What is the full electron configuration in the ground state for elements with $Z$ equal to (*a*) 24, (*b*) 35, (*c*) 40? [*Hint*: See the Periodic Table inside the back cover.]

**64.** What are the largest and smallest possible values for the angular momentum $L$ of an electron in the $n = 6$ shell?

**65.** Estimate (*a*) the quantum number $\ell$ for the orbital angular momentum of the Earth about the Sun, and (*b*) the number of possible orientations for the plane of Earth's orbit.

**66.** Use the Bohr model (especially Eq. 37–15) to show that the Moseley plot (Fig. 39–12) can be written

$$\sqrt{\frac{1}{\lambda}} = a(Z - b),$$

where $b \approx 1$, and evaluate $a$.

**67.** In the so-called **vector model** of the atom, space quantization of angular momentum (Fig. 39–3) is illustrated as shown in Fig. 39–28. The angular momentum vector of magnitude $L = \sqrt{\ell(\ell+1)}\,\hbar$ is thought of as precessing around the $z$ axis (like a spinning top or gyroscope) in such a way that the $z$ component of angular momentum, $L_z = m_\ell \hbar$, also stays constant. Calculate the possible values for the angle $\theta$ between $\vec{\mathbf{L}}$ and the $z$ axis (*a*) for $\ell = 1$, (*b*) $\ell = 2$, and (*c*) $\ell = 3$. (*d*) Determine the minimum value of $\theta$ for $\ell = 100$ and $\ell = 10^6$. Is this consistent with the correspondence principle?

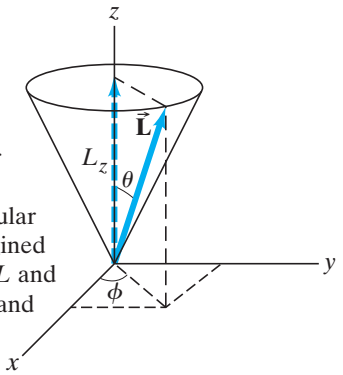

**FIGURE 39–28** The vector model for orbital angular momentum. The orbital angular momentum vector $\vec{\mathbf{L}}$ is imagined to precess about the $z$ axis; $L$ and $L_z$ remain constant, but $L_x$ and $L_y$ continually change. Problems 67 and 68.

**68.** The vector model (Problem 67) gives some insight into the uncertainty principle for angular momentum, which is

$$\Delta L_z \, \Delta\phi \geq \hbar$$

for the $z$ component. Here $\phi$ is the angular position measured in the plane perpendicular to the $z$ axis. Once $m_\ell$ for an atom is known, $L_z$ is known precisely, so $\Delta L_z = 0$. (*a*) What does this tell us about $\phi$? (*b*) What can you say about $L_x$ and $L_y$, which are not quantized (only $L$ and $L_z$ are)? (*c*) Show that although $L_x$ and $L_y$ are not quantized, nonetheless $(L_x^2 + L_y^2)^{1/2} = [\ell(\ell+1) - m_\ell^2]^{1/2}\hbar$ is.

**69.** Determine the most probable distance from the nucleus of an electron in the $n = 3$, $\ell = 0$ state of hydrogen.

**70.** Show that the diffractive spread of a laser beam, $\approx \lambda/D$ as described in Section 39–9, is precisely what you might expect from the uncertainty principle. [*Hint*: Since the beam's width is constrained by the dimension of the aperture $D$, the component of the light's momentum perpendicular to the laser axis is uncertain.]

**71.** (*a*) Show that the mean value for $1/r$ of an electron in the ground state of hydrogen equals $1/r_0$, and from this conclude that the mean value of the potential energy is

$$\overline{U} = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r_0}.$$

(*b*) Using $E = \overline{U} + \overline{K}$, find a relationship between the average kinetic energy and the average potential energy in the ground state. [*Hint*: For (*a*), see Problem 19 or Example 38–9.]

**72.** The angular momentum in the hydrogen atom is given both by the Bohr model and by quantum mechanics. Compare the results for $n = 2$.

**73.** For each of the following atomic transitions, state whether the transition is *allowed* or *forbidden*, and why: (*a*) $4p \rightarrow 3p$; (*b*) $3p \rightarrow 1s$; (*c*) $4d \rightarrow 3d$; (*d*) $4d \rightarrow 3s$; (*e*) $4s \rightarrow 2p$.

**74.** It is possible for atoms to be excited into states with very high values of the principal quantum number. Electrons in these so-called *Rydberg states* have very small ionization energies and huge orbital radii. This makes them particularly sensitive to external perturbation, as would be the case if the atom were in an electric field. Consider the $n = 45$ state of the hydrogen atom. Determine the binding energy, the radius of the orbit, and the effective cross-sectional area of this Rydberg state.

**75.** Suppose that the spectrum of an unknown element shows a series of lines with one out of every four matching a line from the Lyman series of hydrogen. Assuming that the unknown element is an ion with $Z$ protons and one electron, determine $Z$ and the element in question.

***76.** Suppose that the splitting of energy levels shown in Fig. 39–4 was produced by a 2.6-T magnetic field. (*a*) What is the separation in energy between adjacent $m_\ell$ levels for the same $\ell$? (*b*) How many different wavelengths will there be for $3d$ to $2p$ transitions, if $m_\ell$ can change only by $\pm 1$ or 0? (*c*) What is the wavelength for each of these transitions?

**77.** *Populations in the H atom*. Use the Boltzmann factor (Eq. 39–16) to estimate the fraction of H atoms in the $n = 2$ and $n = 3$ levels (relative to the ground state) for thermal equilibrium at (*a*) $T = 300\,\text{K}$ and (*b*) $T = 6000\,\text{K}$. [Note: Since there are eight states with $n = 2$ and only two with $n = 1$, multiply your result for $n = 2$ by $\frac{8}{2} = 4$; do similarly for $n = 3$.] (*c*) Given 1.0 g of hydrogen, estimate the number of atoms in each state at $T = 6000\,\text{K}$. (*d*) Estimate the number of $n = 3$ to $n = 1$ and $n = 2$ to $n = 1$ photons that will be emitted per second at $T = 6000\,\text{K}$. Assume that the lifetime of each excited state is $10^{-8}\,\text{s}$. [*Hint:* To evaluate a large exponent, you can use base-10 logarithms, Appendix A.]

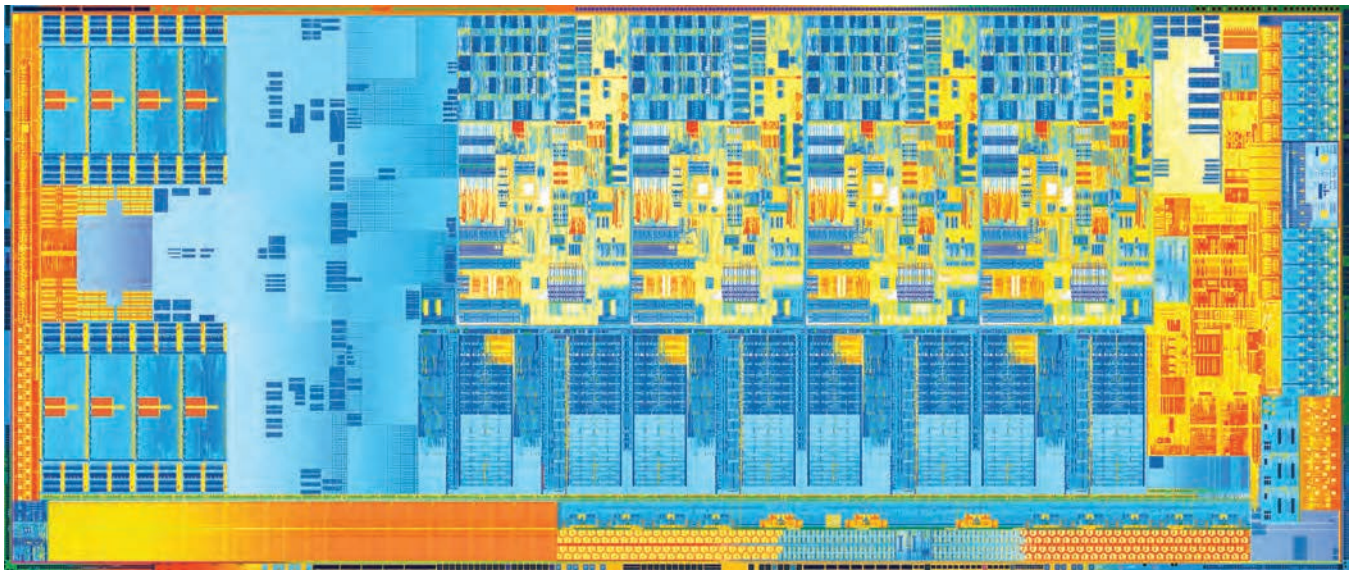
**78.** Photons of wavelength 0.154 nm are emitted from the surface of a certain metal when it is bombarded with high-energy radiation. If this photon wavelength corresponds to the $K_\alpha$ line, what is the element?

**79.** Imagine a line whose length equals the diameter of the smallest orbit in the Bohr model. If we are told only that an electron is located somewhere on this line, then the electron's positions can be specified as $x = 0 \pm r_1$, where the origin is at the line's center and $r_1$ is the Bohr radius. Such an electron can never be observed at rest, but instead at a minimum will have a speed somewhere in the range from $v = 0 - \Delta v$ to $0 + \Delta v$. Determine $\Delta v$.

**80.** The electron in a hydrogen atom is in a $4s$ state. (*a*) Write down all the lower energy states it can decay to in a single transition. (*b*) How many transitions must it make to get to the ground state? What state(s) could it go through?

Section 39–7 (II) Equation 39–11 can be obtained by a semiclassical derivation but can also be derived quantum mechanically. The semiclassical model has the electron moving in a circle. How fast would a $2p$ electron in H have to be moving to produce a magnetic moment equal to 1 Bohr magneton?

**81.** Refer to Figure 39–20 and determine the wavelength of a ruby laser.



**82.** Show that the three wave functions of the $n = 2$, $\ell = 1$ are orthogonal to each other by showing that the dot product for each pairing is zero for any point in space.

**83.** Show that the sum of the probabilities of the electron being in one of the $n = 2$, $\ell = 1$ states is spherically symmetric. Remember to use the complex conjugate in determining the absolute value of a complex number.

**84.** For the hydrogen atom, show that $|\psi_{210}|^2 + |\psi_{211}|^2 + |\psi_{21-1}|^2$ is spherically symmetric.

## ANSWERS TO EXERCISES

**A:** 2, 1, 0, −1, −2.
**B:** (*b*).
**C:** −0.38 eV, $\sqrt{20}\hbar$.
**D:** (*d*).
**E:** Add one line to Li in Table 39–2: 2, 0, 0, $-\frac{1}{2}$.
**F:** (*b*), (*c*).
**G:** $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^1$.
**H:** (*d*).

This computer processor chip contains more than 5 billion transistors, plus diodes, resistors, and other electronic elements, all in a space of about 1 $cm^2$ on a single silicon semiconductor crystal. It uses so-called 14-nm technology, meaning the "wires" (conducting lines) are about 14 nm wide ($\approx$ 30 atoms).

Before discussing semiconductors and their applications, we study the quantum theory description of bonding between atoms to form molecules, and how it explains molecular behavior. We then examine how atoms and molecules form solids, with emphasis on metals as well as on semiconductors and their use in electronics.

CHAPTER 40

# Molecules and Solids

## CONTENTS

40 – 1 Bonding in Molecules
40 – 2 Potential-Energy Diagrams for Molecules
40 – 3 Weak (van der Waals) Bonds
40 – 4 Molecular Spectra
40 – 5 Bonding in Solids
40 – 6 Free-Electron Theory of Metals; Fermi Energy
40 – 7 Band Theory of Solids
40 – 8 Semiconductors and Doping
40 – 9 Semiconductor Diodes, LEDs, OLEDs
40–10 Transistors: Bipolar and MOSFETs
*40–11 Integrated Circuits, 14-nm Technology

## CHAPTER-OPENING QUESTIONS—Guess now!

**1.** What holds a solid together?
- **(a)** Gravitational forces.
- **(b)** Magnetic forces.
- **(c)** Electric forces.
- **(d)** Glue.
- **(e)** Nuclear forces.

**2.** As a metal is heated, how does the rms speed ($v_{rms}$) of the electrons change? Assume a temperature change of about 30C° near room temperature.
- **(a)** $v_{rms}$ increases linearly with temperature.
- **(b)** $v_{rms}$ decreases linearly with temperature.
- **(c)** $v_{rms}$ increases exponentially with temperature.
- **(d)** $v_{rms}$ decreases exponentially with temperature.
- **(e)** $v_{rms}$ changes very little as the temperature is increased.

Since its development in the 1920s, quantum mechanics has had a profound influence on our lives, both intellectually and technologically. Even the way we view the world has changed, as we have seen in the last few Chapters. Now we discuss how quantum mechanics has given us an understanding of the structure of molecules and matter in bulk, as well as important applications including semiconductor devices and applications to molecular biology. Semiconductor devices, such as transistors, now may be only a few atoms thick, which is the realm of quantum mechanics.

PSE5_CH40_v1.7_23-Jun-20

# 40–1 Bonding in Molecules

One of the great successes of quantum mechanics was to give scientists, at last, an understanding of the nature of chemical bonds. Since it is based in physics, and because this understanding is so important in many fields, we discuss it here.

By a molecule, we mean a group of two or more atoms that are strongly held together so as to function as a single unit. When atoms make such an attachment, we say that a chemical **bond** has been formed. There are two main types of strong chemical bond: covalent and ionic. Many bonds are actually intermediate between these two types.

## Covalent Bonds

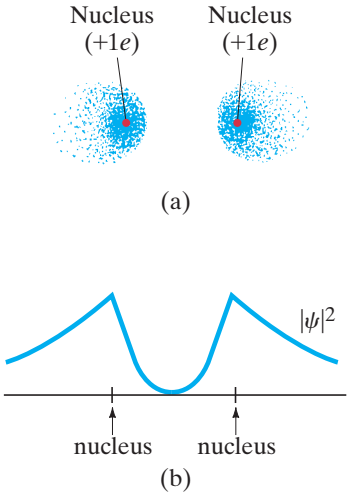
To understand how *covalent bonds* are formed, we take the simplest case, the bond that holds two hydrogen atoms together to form the hydrogen molecule, $H_2$. The mechanism is basically the same for other covalent bonds. As two H atoms approach each other, the electron clouds begin to overlap, and the electrons from each atom can "orbit" both nuclei. (This is sometimes called **sharing** electrons.) If both electrons are in the ground state $(n = 1)$ of their respective atoms, there are two possibilities: their spins can be parallel (both up or both down), in which case the total spin is $S = \frac{1}{2} + \frac{1}{2} = 1$; or their spins can be opposite ($m_s = +\frac{1}{2}$ for one, and $m_s = -\frac{1}{2}$ for the other), so that the total spin $S = +\frac{1}{2} + \left(-\frac{1}{2}\right) = 0$. We shall now see that a bond is formed only for the $S = 0$ state, when the spins are opposite.

First we consider the $S = 1$ state, for which the spins are the same. The two electrons cannot both be in the lowest energy state and be attached to the same atom, for then they would have identical quantum numbers in violation of the exclusion principle. The exclusion principle tells us that, because no two electrons can occupy the same quantum state, if two electrons have the same quantum numbers, they must be different in some other way—namely, by being in different places in space (for example, attached to different atoms). Thus, for $S = 1$, when the two atoms approach each other, the electrons will stay away from each other as shown by the probability distribution of Fig. 40–1. The electrons spend very little time between the two nuclei, so the positively charged nuclei repel each other and no bond is formed.

For the $S = 0$ state, on the other hand, the spins are opposite and the two electrons are consequently in different quantum states ($m_s$ is different, $+\frac{1}{2}$ for one, $-\frac{1}{2}$ for the other). Hence the two electrons can come close together, and the probability distribution looks like Fig. 40–2: the electrons can spend much of their time between the two nuclei. The two positively charged nuclei are attracted to the negatively charged electron cloud between them, and this is the attraction that holds the two hydrogen atoms together to form a hydrogen molecule. This is a **covalent bond**.

The probability distributions of Figs. 40–1 and 40–2 can perhaps be better understood on the basis of waves. What the exclusion principle requires is that when the spins are the same, there is destructive interference of the electron wave functions in the region between the two atoms. But when the spins are opposite, constructive interference occurs in the region between the two atoms, resulting in a large amount of negative charge there. Thus a covalent bond can be said to be the result of constructive interference of the electron wave functions in the space between the two atoms, and of the electrostatic attraction of the two positive nuclei for the negative charge concentration between them.

Why a bond is formed can also be understood from the energy point of view. When the two H atoms approach close to one another, if the spins of their electrons are opposite, the electrons can occupy the same space, as discussed above. This means that each electron can now move about in the space of two atoms instead of in the volume of only one. Because each electron now occupies more space, it is less well localized. From the uncertainty principle with $\Delta x$ larger, we see that $\Delta p$ and the minimum momentum can be less. With less momentum, each electron has less energy when the two atoms combine than when they are separate. That is, the molecule has less energy than the two separate atoms, and so is more stable.



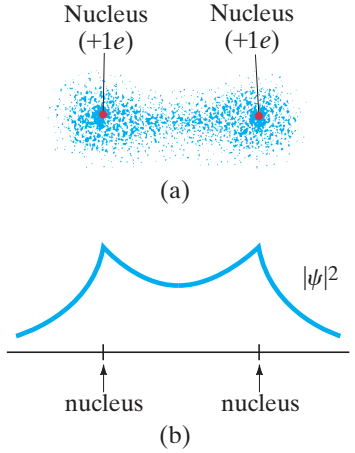


**FIGURE 40–1** Electron probability distribution (electron cloud) around two H atoms when the spins are the same $\left(S = \frac{1}{2} + \frac{1}{2} = 1\right)$: (a) electron cloud; (b) projection of $|\psi|^2$ along the line through the centers of the two atoms.

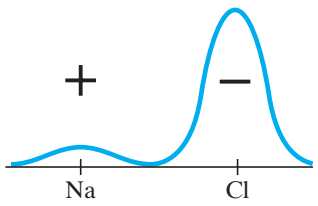
**FIGURE 40–2** Electron probability distribution (cloud) around two H atoms when the spins are opposite $(S = 0)$: (a) electron cloud; (b) projection of $|\psi|^2$ along the line through the centers of the atoms. In this case a bond is formed because the positive nuclei are attracted to the concentration of the electron cloud's negative charge between them. This is a hydrogen molecule, $H_2$.

An energy input is required to break the $H_2$ molecule into two separate H atoms, so the $H_2$ molecule is a stable entity. This is what we mean by a *bond*. The energy required to break a bond is called the **bond energy**, the **binding energy**, or the **dissociation energy**. For the hydrogen molecule, $H_2$, the bond energy is 4.5 eV.

## Ionic Bonds

An *ionic bond* is, in a sense, a special case of the covalent bond. Instead of the electrons being shared equally, they are shared unequally. For example, in sodium chloride (NaCl), the outer electron of the sodium spends nearly all its time around the chlorine (Fig. 40–3). The chlorine atom acquires a net negative charge as a result of the extra electron, whereas the sodium atom is left with a net positive charge. The electrostatic attraction between these two charged atoms holds them together. The resulting bond is called an **ionic bond** because it is created by the attraction between the two ions $(Na^+$ and $Cl^-)$. But to understand the ionic bond, we must understand why the extra electron from the sodium spends so much of its time around the chlorine. After all, the chlorine atom is neutral; why should it attract another electron?



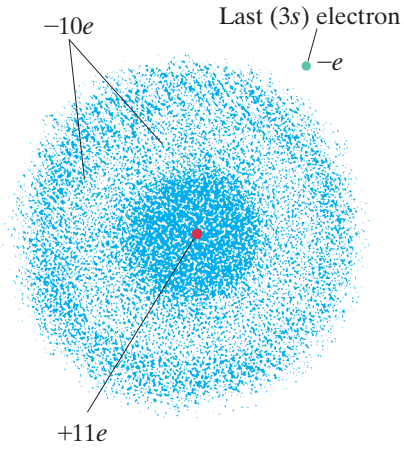


**FIGURE 40–3** Probability distribution $|\psi|^2$ for the outermost electron of Na in NaCl.

**FIGURE 40–4** In a neutral sodium atom, the 10 inner electrons shield the nucleus, so the single outer electron is attracted by a net charge of $+1e$.

The answer lies in the probability distributions of the electrons in the two neutral atoms. Sodium contains 11 electrons, 10 of which are in spherically symmetric closed shells (Fig. 40–4). The last electron spends most of its time beyond these closed shells. Because the closed shells have a total charge of $-10e$ and the nucleus has charge $+11e$, the outermost electron in sodium "feels" a net attraction due to $+1e$. It is not held very strongly. On the other hand, 12 of chlorine's 17 electrons form closed shells, or subshells (corresponding to $1s^2 2s^2 2p^6 3s^2$). These 12 electrons form a spherically symmetric shield around the nucleus. The other five electrons are in $3p$ states whose probability distributions are not spherically symmetric and have a form similar to those for the $2p$ states in hydrogen shown in Fig. 39–9. Four of these $3p$ electrons can have "doughnut-shaped" distributions symmetric about the $z$ axis, as shown in Fig. 40–5. The fifth can have a "barbell-shaped" distribution (as for $m_\ell = 0$ in Fig. 39–9), which in Fig. 40–5 is shown only in dashed outline because it is half empty. That is, the exclusion principle allows one more electron to be in this state (it will have spin opposite to that of the electron already there). If an extra electron—say from a Na atom—happens to be in the vicinity, it can be in this state, perhaps at point $x$ in Fig. 40–5. It could experience an attraction due to as much as $+5e$ because the $+17e$ of the nucleus is partly shielded at this point by the 12 inner electrons. Thus, the outer electron of a sodium atom will be more strongly attracted by the $+5e$ of the chlorine atom than by the $+1e$ of its own atom. This, combined with the strong attraction between the two ions when the extra electron stays with the $Cl^-$, produces the charge distribution of Fig. 40–3, and hence the ionic bond.

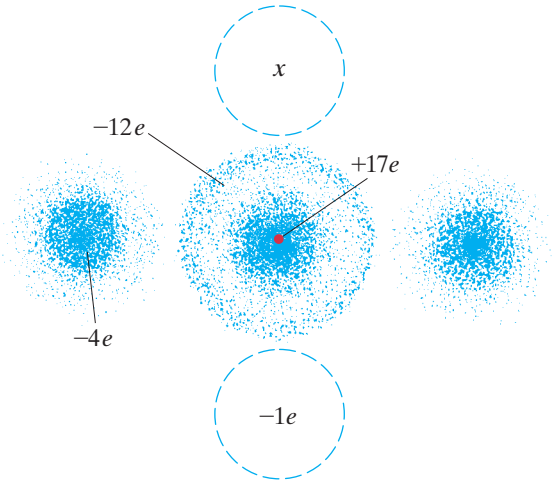

**FIGURE 40–5** Neutral chlorine atom. The $+17e$ of the nucleus is shielded by the 12 electrons in the inner shells and subshells. Four of the five $3p$ electrons are shown in doughnut-shaped clouds (seen in cross section at left and right), and the fifth is in the dashed-line cloud concentrated about the $z$ axis (vertical). An extra electron at $x$ will be attracted by a net charge that can be as much as $+5e$.

## Partial Ionic Character of Covalent Bonds

A pure covalent bond in which the electrons are shared equally occurs mainly in symmetrical molecules such as $H_2$, $O_2$, and $Cl_2$. When the atoms involved are different from each other, usually the shared electrons are more likely to be

PSE5_CH40_v1.7_23-Jun-20

in the vicinity of one atom than the other. The extreme case is an ionic bond. In intermediate cases the *covalent bond* is said to have a **partial ionic character**. The molecules themselves are **polar**—that is, one part (or parts) of the molecule has a net positive charge and other parts a net negative charge. An example is the water molecule, $H_2O$ (Fig. 40–6). Covalent bonds have shared electrons, which in $H_2O$ are more likely to be found around the oxygen atom than around the two hydrogens. The reason is similar to that discussed above in connection with ionic bonds. Oxygen has eight electrons $(1s^2 2s^2 2p^4)$, of which four form a spherically symmetric core and the other four could have, for example, a doughnut-shaped distribution. The barbell-shaped distribution on the $z$ axis (like that shown dashed in Fig. 40–5) could be empty, so electrons from hydrogen atoms can be attracted by a net charge of $+4e$. They are also attracted by the H nuclei, so they partly orbit the H atoms as well as the O atom. The net effect is that there is a net positive charge on each H atom (less than $+1e$), because the electrons spend only part of their time there. And, there is a net negative charge on the O atom.

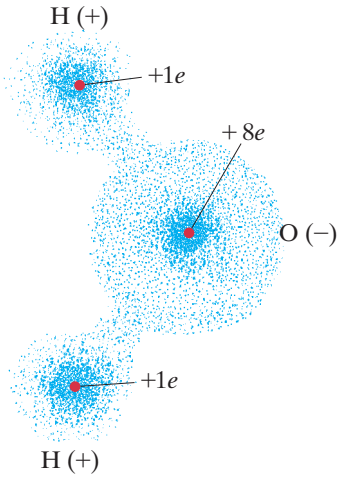

**FIGURE 40–6** The water molecule $H_2O$ is polar.

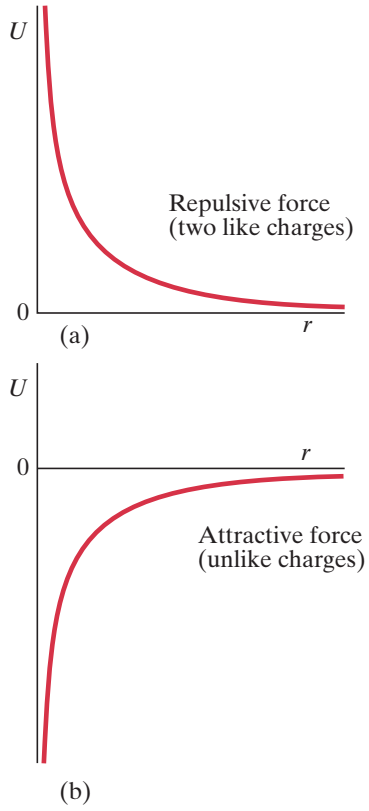
## 40–2 Potential-Energy Diagrams for Molecules



It is useful to analyze the interaction between two objects—say, between two atoms or molecules—with the use of a potential-energy diagram, which is a plot of the potential energy versus the separation distance.

For the simple case of two point charges, $q_1$ and $q_2$, the potential energy $U$ is given by (see Chapter 23)

$$U = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r},$$

where $r$ is the distance between the charges, and the constant $(1/4\pi\epsilon_0)$ is equal to $9.0 \times 10^9\ \mathrm{N \cdot m^2/C^2}$. If the two charges have the same sign, the potential energy $U$ is positive for all values of $r$, and a graph of $U$ versus $r$ in this case is shown in Fig. 40–7a. The force is repulsive (the charges have the *same* sign) and the curve rises as $r$ decreases; this makes sense because work is done to bring the charges together, thereby increasing their potential energy. If, on the other hand, the two charges are of the *opposite* sign, the potential energy is negative because the product $q_1 q_2$ is negative. The force is attractive in this case, and the graph of $U(\propto -1/r)$ versus $r$ looks like Fig. 40–7b. The potential energy becomes more *negative* as $r$ decreases.

**FIGURE 40–7** Potential energy $U$ as a function of separation $r$ for two point charges of (a) like sign and (b) opposite sign.

Now let us look at the potential-energy diagram for the formation of a covalent bond, such as for the hydrogen molecule, $H_2$. The potential energy $U$ of one H atom in the presence of the other is plotted in Fig. 40–8. Starting at large $r$, $U$ decreases as the atoms approach, because the electrons concentrate between the two nuclei (Fig. 40–2), so attraction occurs. However, at very short distances, the electrons would be "squeezed out"—there is no room for them between the two nuclei. Without the electrons between them, each nucleus would feel a repulsive force due to the other, so the curve rises as $r$ decreases further. There is an optimum separation of the atoms, $r_0$ in Fig. 40–8, at which the energy is lowest.

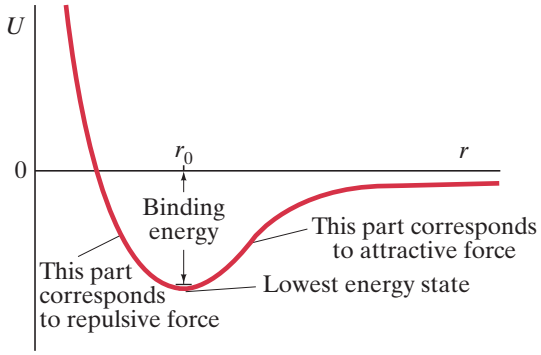


**FIGURE 40–8** Potential-energy diagram for $H_2$ molecule; $r$ is the separation of the two H atoms. The binding energy (the energy difference between $U = 0$ and the lowest energy state near the bottom of the well) is 4.5 eV, and $r_0 = 0.074$ nm.

This is the point of greatest stability for the hydrogen molecule, and $r_0$ is the average separation of atoms in the $H_2$ molecule. The depth of this "well" is the *binding energy*,[†] as shown. This is how much energy must be put into the system to separate the two atoms to infinity, where $U = 0$. For the $H_2$ molecule, the binding energy is about 4.5 eV and $r_0 = 0.074$ nm.

In molecules made of larger atoms, say, oxygen or nitrogen, repulsion also occurs at short distances, because the closed inner electron shells begin to overlap and the exclusion principle forbids their coming too close. The repulsive part of the curve rises even more steeply than $1/r$. A reasonable approximation to the potential energy, at least in the vicinity of $r_0$, is

$$U = -\frac{A}{r^m} + \frac{B}{r^n}, \tag{40–1}$$

where $A$ and $B$ are constants associated with the attractive and repulsive parts of the potential energy and the exponents $m$ and $n$ are small integers. For ionic and some covalent bonds, the attractive term can often be written with $m = 1$ (Coulomb potential).

For many bonds, the potential-energy curve has the shape shown in Fig. 40–9. There is still an optimum distance $r_0$ at which the molecule is stable. But when the atoms approach from a large distance, the force is initially repulsive rather than attractive. The atoms thus do not spontaneously form a bond. Some additional energy must be injected into the system to get it over the "hump" (or barrier) in the potential-energy diagram. This required energy is called the **activation energy**.

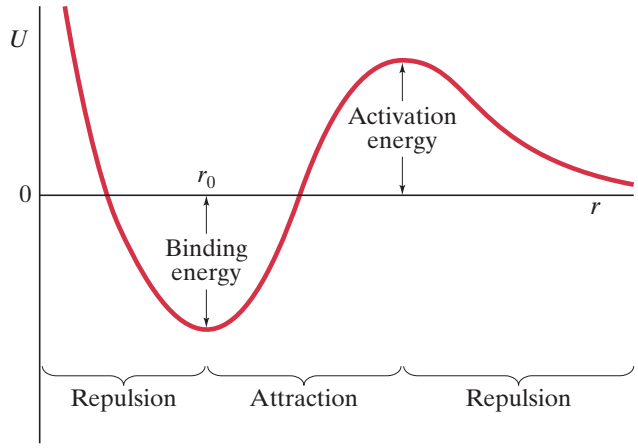

**FIGURE 40–9** Potential-energy diagram for a bond requiring an activation energy.

The curve of Fig. 40–9 is much more common than that of Fig. 40–8. The activation energy often reflects a need to break other bonds, before the one under discussion can be made. For example, to make water from $O_2$ and $H_2$, the $H_2$ and $O_2$ molecules must first be broken into H and O atoms by an input of energy; this is what the activation energy represents. Then the H and O atoms can combine to form $H_2O$ with the release of a great deal more energy than was put in initially. The initial activation energy can be provided by applying an electric spark to a mixture of $H_2$ and $O_2$, breaking a few of these molecules into H and O atoms. When the three atoms combine to form $H_2O$, a lot of energy is released—the ground state is near the bottom of the well (as in Fig. 40–8)—which provides the activation energy needed for further reactions, so additional $H_2$ and $O_2$ molecules are broken up and recombined to form $H_2O$.

The potential-energy diagrams for ionic bonds, such as NaCl, may be more like Fig. 40–8: the $Na^+$ and $Cl^-$ ions attract each other at distances a bit larger than some $r_0$, but at shorter distances the overlapping of inner electron shells gives rise to repulsion. The two atoms thus are most stable at some intermediate separation, $r_0$. For partially ionic bonds, there is usually an activation energy, Fig. 40–9.

[†]The binding energy corresponds not quite to the bottom of the potential energy curve, but to the lowest quantum energy state, slightly above the bottom, as shown in Fig. 40–8.

PSE5_CH40_v1.7_23-Jun-20

**EXAMPLE 40–1** **ESTIMATE** **Sodium chloride bond.** A potential-energy diagram for the NaCl ionic bond is shown in Fig. 40–10, where we have set $U = 0$ for free Na and Cl neutral atoms (which are represented on the right in Fig. 40–10). Measurements show that 5.14 eV are required to remove an electron from a neutral Na atom to produce the $Na^+$ ion; and 3.61 eV of energy is released when an electron is "grabbed" by a Cl atom to form the $Cl^-$ ion. Thus, forming $Na^+$ and $Cl^-$ ions from neutral Na and Cl atoms requires $5.14\,\text{eV} - 3.61\,\text{eV} = 1.53\,\text{eV}$ of energy, a form of activation energy. This is shown as the "bump" in Fig. 40–10. But note that the potential-energy diagram from here out to the right is not really a function of distance—it is drawn dashed to remind us that it only represents the energy difference between the ions and the neutral atoms (for which we have chosen $U = 0$). (*a*) Calculate the separation distance, $r_1$, at which the potential of the $Na^+$ and $Cl^-$ ions drops to zero (measured value is $r_1 = 0.94\,\text{nm}$). (*b*) Estimate the binding energy of the NaCl bond, which occurs at a separation $r_0 = 0.24\,\text{nm}$. Ignore the repulsion of the overlapping electron shells that occurs at this distance (and causes the rise of the potential-energy curve for $r < r_0$, Fig. 40–10).

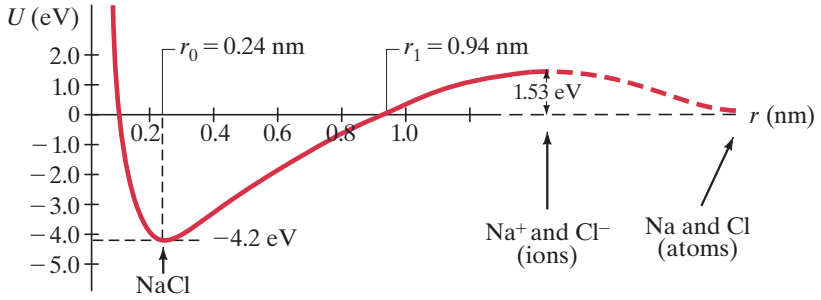

**FIGURE 40–10** Example 40–1. Potential-energy diagram for the NaCl bond. Beyond about $r = 1.2\,\text{nm}$, the diagram is schematic only, and represents the energy difference between ions and neutral atoms. $U = 0$ is chosen for the two separated atoms Na and Cl (not for the ions). [For the two ions, $Na^+$ and $Cl^-$, the zero of potential energy at $r = \infty$ corresponds to $U \approx 1.53\,\text{eV}$ on this diagram.]

**SOLUTION** (*a*) The potential energy of two point charges is given by Coulomb's law:

$$U' = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r},$$

where $q_1$ and $q_2$ are the charges on the two ions. (This equation for $U'$ differs from the $U$ shown in Fig 40–10 which is "shifted" to show the activation energy and to have $U = 0$ at $r = \infty$.) This formula works for our two ions if we set $U' = 0$ at $r = \infty$, which in the plot of Fig. 40–10 corresponds to $U = +1.53\,\text{eV}$ (Fig. 40–10 is drawn for $U = 0$ for the free *atoms*). The point $r_1$ in Fig. 40–10 corresponds to $U' = -1.53\,\text{eV}$ relative to the two free ions. We solve the $U'$ equation above for $r$, setting $q_1 = +e$ and $q_2 = -e$:

$$r_1 = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{U'} = \frac{(9.0\times10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)(-1.60\times10^{-19}\,\text{C})(+1.60\times10^{-19}\,\text{C})}{(-1.53\,\text{eV})(1.60\times10^{-19}\,\text{J/eV})} = 0.94\,\text{nm},$$

which is just the measured value.

(*b*) At $r_0 = 0.24\,\text{nm}$, the potential energy of the two ions (relative to $r = \infty$ for the two ions) is

$$U' = \frac{1}{4\pi\epsilon_0}\frac{q_1 q_2}{r} = \frac{(9.0\times10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)(-1.60\times10^{-19}\,\text{C})(+1.60\times10^{-19}\,\text{C})}{(0.24\times10^{-9}\,\text{m})(1.60\times10^{-19}\,\text{J/eV})} = -6.0\,\text{eV}.$$

Thus, we estimate that 6.0 eV of energy is given up when $Na^+$ and $Cl^-$ ions form a NaCl bond. Put another way, it takes 6.0 eV to break the NaCl bond and form the $Na^+$ and $Cl^-$ ions. To get the binding energy—the energy to separate the NaCl into Na and Cl *atoms*—we need to subtract out the 1.53 eV (the "bump" in Fig. 40–10) needed to ionize them:

$$\text{binding energy} = 6.0\,\text{eV} - 1.53\,\text{eV} = 4.5\,\text{eV}.$$

The measured value (shown on Fig. 40–10) is 4.2 eV. The difference can be attributed to the energy associated with the repulsion of the electron shells at this distance.

**PHYSICS APPLIED**
*ATP and energy in the cell*

Sometimes the potential energy of a bond looks like that of Fig. 40–11. In this case, the energy of the bonded molecule, at a separation $r_0$, is greater than when there is no bond $(r = \infty)$. That is, an energy *input* is required to make the bond (hence the binding energy is negative), and there is energy release when the bond is broken. Such a bond is stable only because there is the barrier of the activation energy. This type of bond is important in living cells, for it is in such bonds that energy can be stored efficiently in certain molecules, particularly ATP (adenosine triphosphate). The bond that connects the last phosphate group (designated Ⓟ in Fig. 40–11) to the rest of the molecule (ADP, meaning adenosine diphosphate, since it contains only two phosphates) has potential energy of the shape shown in Fig. 40–11. Energy is stored in this bond. When the bond is broken $(\text{ATP} \rightarrow \text{ADP} + \text{Ⓟ})$, energy is released and this energy can be used to make other chemical reactions "go."

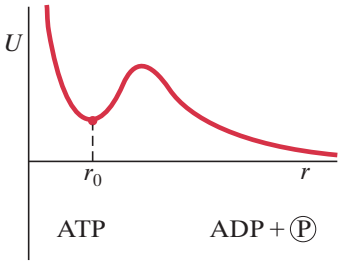

**FIGURE 40–11** Potential-energy diagram for the formation of ATP from ADP and phosphate (Ⓟ).

In living cells, many chemical reactions have activation energies that are often on the order of several eV. Such energy barriers are not easy to overcome in the cell. This is where enzymes come in. They act as *catalysts*, which means they act to lower the activation energy so that reactions can occur that otherwise would not. Enzymes act via the electrostatic force to distort the bonding electron clouds, so that the initial bonds are easily broken.

**EXAMPLE 40–2** **Bond length.** Suppose a diatomic molecule has a potential energy given by $U = -(1/4\pi\epsilon_0)(e^2/r) + B/r^6$ where $B = 1.0 \times 10^{-78}\,\text{J}\cdot\text{m}^6$ and $r$ is the distance between the centers of the two atoms. Determine the expected equilibrium separation of the two atoms (bond length of the molecule).

**APPROACH** The force between the two atoms is given by $F = -dU/dr$ (analogous to Eq. 8–7). The classical equilibrium separation is found by setting $F = 0$.

**SOLUTION**

$$F = -dU/dr = (1/4\pi\epsilon_0)(-e^2/r^2) - B(-6/r^7) = -(1/4\pi\epsilon_0)(e^2/r^2) + 6B/r^7 = 0.$$

Then

$$r^5 = 6B(4\pi\epsilon_0)/e^2 = 2.6 \times 10^{-50}\,\text{m}^5.$$

So $r = 1.2 \times 10^{-10}\,\text{m} = 0.12\,\text{nm}$.

**NOTE** This can be shown to be a stable equilibrium point by checking the sign of $d^2U/dr^2$, or by evaluating $F$ at positions slightly larger and smaller than the equilibrium position.

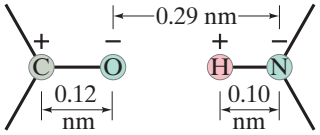
## 40–3 Weak (van der Waals) Bonds

Once a bond between two atoms or ions is made, energy must normally be supplied to break the bond and separate the atoms. As mentioned in Section 40–1, this energy is called the *bond energy* or *binding energy*. The binding energy for covalent and ionic bonds is typically 2 to 5 eV. These bonds,

PSE5_CH40_v1.7_23-Jun-20

which hold atoms together to *form* molecules, are often called **strong bonds** to distinguish them from so-called "weak bonds." The term **weak bond**, as we use it here, refers to attachments *between* molecules due to simple electrostatic attraction—such as *between* polar molecules (and not *within* a polar molecule, which is a strong bond). The strength of the attachment is much less than for the strong bonds. Binding energies are typically in the range 0.04 to 0.3 eV—hence their name "weak bonds."

Weak bonds are generally the result of attraction between dipoles (Sections 21–11, 23–6). For example, Fig. 40–12 shows two molecules, which have permanent dipole moments, attracting one another. Besides such **dipole–dipole bonds**, there can also be **dipole–induced dipole bonds**, in which a polar molecule with a permanent dipole moment can induce a dipole moment in an otherwise electrically balanced (nonpolar) molecule, just as a single charge can induce a separation of charge in a nearby object (see Fig. 21–7). There can even be an attraction between two nonpolar molecules, because their electrons are moving about: at any instant there may be a transient separation of charge, creating a brief dipole moment and weak attraction. All these weak bonds are referred to as **van der Waals bonds**, and the forces involved **van der Waals forces**. The potential energy has the general shape shown in Fig. 40–8, with the attractive van der Waals potential energy varying as $1/r^6$. The force decreases rapidly with increased distance.



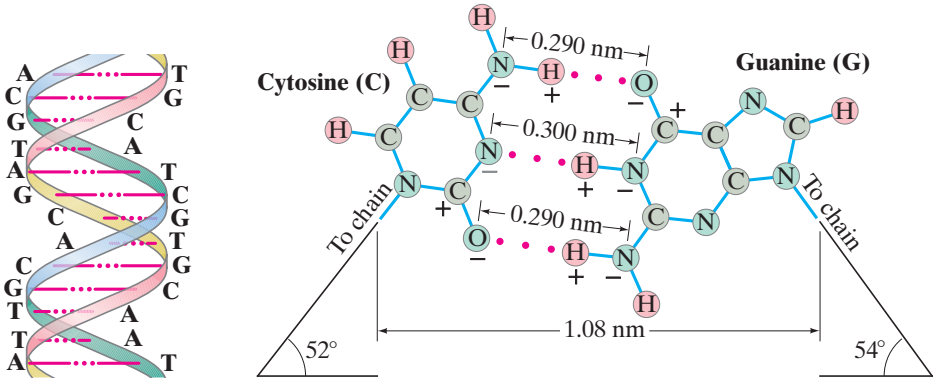


**FIGURE 40–12** The $C^+—O^-$ and $H^+—N^-$ dipoles attract each other. (These dipoles may be part of, for example, the nucleotide bases cytosine and guanine in DNA molecules. See Fig. 40–13.) The + and − charges typically have magnitudes of a fraction of $e$.

When one of the atoms in a dipole–dipole bond is hydrogen, as in Fig. 40–12, it is called a **hydrogen bond**. A hydrogen bond is generally the strongest of the weak bonds, because the hydrogen atom is the smallest atom and can be approached more closely. Hydrogen bonds also have a partial "covalent" character: that is, electrons between the two dipoles may be shared to a small extent, making a stronger, more lasting bond.

Weak bonds are important in liquids and solids when strong bonds are absent (see Section 40–5). They are also very important for understanding the activities of cells, such as the double helix shape of DNA (Fig. 40–13), and DNA replication (see Section 21–12). The average kinetic energy of molecules in a living cell at normal temperatures ($T \approx 300\,\text{K}$) is around $\frac{3}{2}kT \approx 0.04\,\text{eV}$ (kinetic theory, Eq. 18–4), about the magnitude of weak bonds. This means that a weak bond can readily be broken just by a molecular collision. Hence weak bonds are not very permanent—they are, instead, brief attachments. This helps them play particular roles in the cell. On the other hand, strong bonds—those that hold molecules together—are almost never broken simply by molecular collision because their binding energies are much too high ($\approx 2$ to $5\,\text{eV}$). Thus they are relatively permanent. They can be broken by chemical action (the making of even stronger bonds), and this usually happens in the cell with the aid of an enzyme, which is a protein molecule.

**PHYSICS APPLIED**
*DNA*

(a) (b)

**FIGURE 40–13** (a) Model of part of a DNA double helix. The red dots represent hydrogen bonds between the two strands. (b) "Close-up" view: cytosine (C) and guanine (G) molecules on separate strands of a DNA double helix are held together by the hydrogen bonds (red dots) involving an $H^+$ on one molecule attracted to an $N^-$ or $C^+—O^-$ of a molecule on the adjacent chain. See also Section 21–12 and Figs. 21–49 and 21–50.

**EXAMPLE 40–3** **Nucleotide energy.** Calculate the potential energy between a $C^+—O^-$ dipole of the nucleotide base cytosine and the nearby $H^+—N^-$ dipole of guanine, assuming that the two dipoles are lined up as shown in Fig. 40–12. Dipole moment $(= q\ell)$ measurements (see Table 23–2 and Fig. 40–12) give

$$q_H = -q_N = \frac{3.0 \times 10^{-30}\,\text{C}\cdot\text{m}}{0.10 \times 10^{-9}\,\text{m}} = 3.0 \times 10^{-20}\,\text{C} = 0.19e,$$

and

$$q_C = -q_O = \frac{8.0 \times 10^{-30}\,\text{C}\cdot\text{m}}{0.12 \times 10^{-9}\,\text{m}} = 6.7 \times 10^{-20}\,\text{C} = 0.42e.$$

**APPROACH** We want to find the potential energy of the two charges in one dipole due to the two charges in the other, because this will be equal to the work needed to pull the two dipoles infinitely far apart. The potential energy $U$ of a charge $q_1$ in the presence of a charge $q_2$ is $U = (1/4\pi\epsilon_0)(q_1 q_2/r_{12})$ where $1/4\pi\epsilon_0 = 9.0 \times 10^9\,\text{N}\cdot\text{m}^2/\text{C}^2$ and $r_{12}$ is the distance between the two charges.

**SOLUTION** The potential energy $U$ consists of four terms:

$$U = U_{CH} + U_{CN} + U_{OH} + U_{ON},$$

where $U_{CH}$ means the potential energy of C in the presence of H, and similarly for the other terms. We do not have terms corresponding to C and O, or N and H, because the two dipoles are assumed to be stable entities. Then, using the distances shown in Fig. 40–12, we get:

$$\begin{aligned} U &= \frac{1}{4\pi\epsilon_0}\left[\frac{q_C q_H}{r_{CH}} + \frac{q_C q_N}{r_{CN}} + \frac{q_O q_H}{r_{OH}} + \frac{q_O q_N}{r_{ON}}\right] \\ &= \frac{1}{4\pi\epsilon_0} q_C q_H\left(\frac{1}{r_{CH}} - \frac{1}{r_{CN}} - \frac{1}{r_{OH}} + \frac{1}{r_{ON}}\right) \\ &= (9.0 \times 10^9\,\text{N}\cdot\text{m}^2/\text{C}^2)(6.7)(3.0)\left(\frac{1}{0.31} - \frac{1}{0.41} - \frac{1}{0.19} + \frac{1}{0.29}\right)\frac{(10^{-20}\,\text{C})^2}{(10^{-9}\,\text{m})} \\ &= -1.86 \times 10^{-20}\,\text{J} = -0.12\,\text{eV}. \end{aligned}$$

The potential energy is negative, meaning 0.12 eV of work (or energy input) is required to separate the dipoles. That is, the binding energy of this "weak" or hydrogen bond is 0.12 eV. This is only an estimate, of course, since other charges in the vicinity would have an influence too. Note how small and wide this energy is compared to the 4.5 eV of an $H_2$ molecule (Fig. 40–8) or the 4.2 eV for the NaCl bond (end of Example 40–1).

## *Protein Synthesis

Weak bonds, especially hydrogen bonds, are crucial to the process of protein synthesis. Proteins serve as structural parts of the cell and as enzymes to catalyze chemical reactions needed for the growth and survival of the organism. A protein molecule consists of one or more chains of small molecules known as *amino acids*.[†] There are 20 different amino acids, and a single protein chain may contain hundreds of them in a specific order. The standard model for how amino acids are connected together in the correct order to form a protein molecule is shown schematically in Fig. 40–14.

**PHYSICS APPLIED**
*Protein synthesis*

It begins at the DNA double helix: each gene on a chromosome contains the information for producing one protein. The ordering of the four bases, A, C, G, and T, provides the "code," the **genetic code**, for the order of amino acids in the protein. First, the DNA double helix unwinds and a new molecule called *messenger*-RNA (m-RNA) is synthesized using one strand of the DNA as a "template." m-RNA is a chain molecule containing four different bases, like those of DNA (Section 21–12) except that thymine (T) is replaced by the similar uracil molecule (U). Near the top left in Fig. 40–14, a C has just been added to the growing m-RNA chain in much

[†]Typical amino acids have atomic masses of about 100, and are made up mainly of H, C, O, and N.

PSE5_CH40_v1.7_23-Jun-20

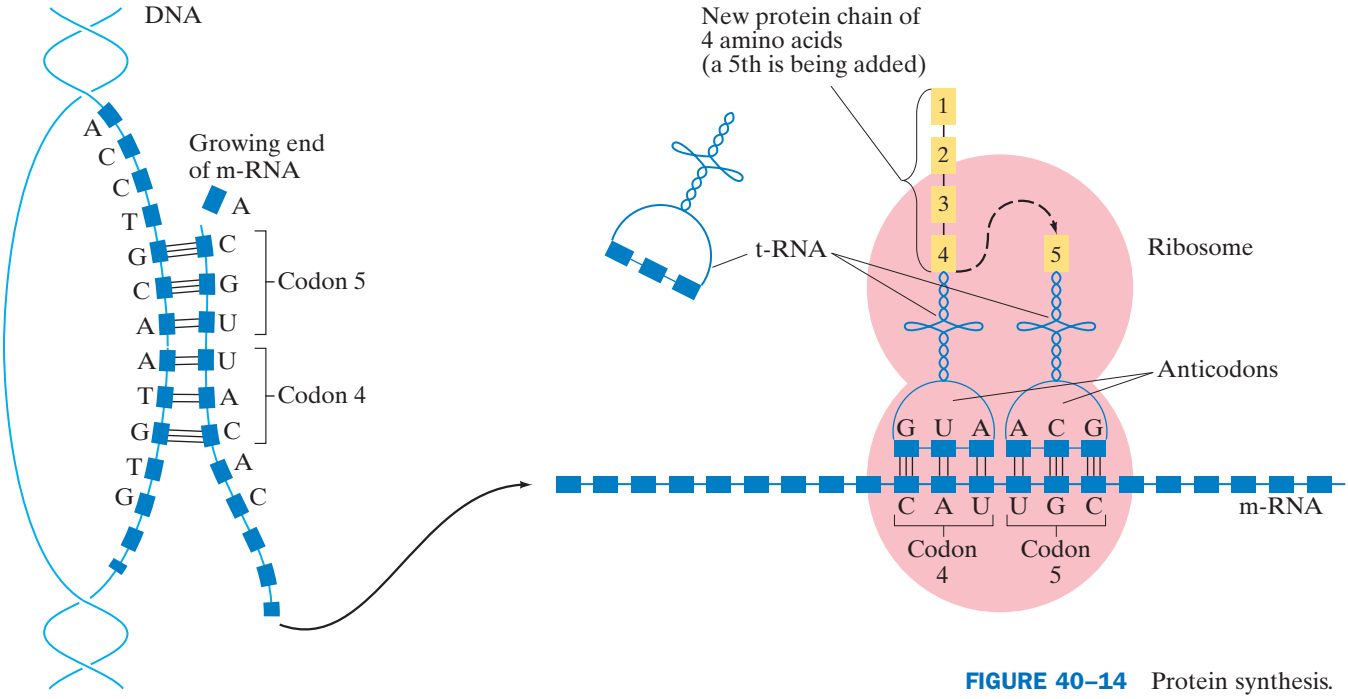

**FIGURE 40–14** Protein synthesis. The yellow rectangles represent amino acids. See text for details.

the same way that DNA replicates (Fig. 21–49); and an A, attracted and held close to the T on the DNA chain by the electrostatic force, will soon be attached to the C by an enzyme. The order of the bases, and thus the genetic information, is preserved in the m-RNA because the shapes of the molecules only allow the "proper" one to get close enough so the electrostatic force can act to form weak bonds.

Next, the m-RNA is buffeted about in the cell (kinetic theory, Chapter 18) until it gets close to a tiny organelle known as a *ribosome*, to which it can attach by electrostatic attraction (on the right in Fig. 40–14), because their shapes allow the charged parts to get close enough to form weak bonds (for which the force decreases greatly with increased separation). Also held by the electrostatic force to the ribosome are one or two *transfer*-RNA (t-RNA) molecules. These t-RNA molecules "translate" the genetic code of nucleotide bases into amino acids in the following way. There is a different t-RNA molecule for each amino acid and each combination of three bases. On one end of a t-RNA molecule is an amino acid. On the other end of the t-RNA molecule is the appropriate "anticodon," a set of three nucleotide bases that "code" for that amino acid. If all three bases of an anticodon match the three bases of the "codon" on the m-RNA (in the sense of G to C and A to U), the anticodon is attracted electrostatically to the m-RNA codon and that t-RNA molecule is held there briefly. The ribosome has two particular attachment sites which hold two t-RNA molecules while enzymes bond the two amino acids together to lengthen the amino acid chain (yellow in Fig. 40–14). As each amino acid is connected by an enzyme (four are already connected in Fig. 40–14, top right, and a fifth is about to be connected), the old t-RNA molecule is removed—perhaps by a random collision with some molecule in the cellular fluid. A new one soon becomes attracted as the ribosome moves along the m-RNA.

This process of protein synthesis is often presented as if it occurred in clockwork fashion—as if each molecule knew its role and went to its assigned place. But this is not the case. The forces of attraction between the electric charges of the molecules are rather weak and become significant only when the molecules can come close together and when several weak bonds can be made. Indeed, if the shapes are not just right, the electrostatic attraction is nearly zero, which is why there are few mistakes. The fact that weak bonds are weak is very important. If they were strong, collisions with other molecules would not allow a t-RNA molecule to be released from the ribosome, or the m-RNA to be released from the DNA. If they were not temporary encounters, metabolism would grind to a halt.

As each amino acid is added to the next, the protein molecule grows in length until it is complete. Even as it is being made, this chain is being buffeted about in the cell—we might think of a wiggling worm. But a protein molecule has electrically charged polar groups along its length. And as it takes on various shapes, the electric forces of attraction between different parts of the molecule will eventually lead to a particular shape of the protein which is quite stable. Each type of protein has its own special shape, depending on the location of charged atoms. In the last analysis, the final shape depends on the order of the amino acids.

# 40–4 Molecular Spectra

When atoms combine to form molecules, the probability distributions of the outer electrons overlap and this interaction alters the energy levels. Nonetheless, molecules can undergo transitions between electron energy levels just as atoms do. For example, the $H_2$ molecule can absorb a photon of just the right frequency to excite one of its ground-state electrons to an excited state. The excited electron can then return to the ground state, emitting a photon. The energy of photons emitted by molecules can be of the same order of magnitude as for atoms, typically 1 to 10 eV, or less.

Additional energy levels become possible for molecules (but not for atoms) because the molecule as a whole can rotate, and the atoms of the molecule can vibrate relative to each other. The energy levels for both rotational and vibrational levels are quantized, and are generally spaced much more closely $(10^{-3}$ to $10^{-1}$ eV) than the electronic levels. Each atomic energy level thus becomes a set of closely spaced levels corresponding to the vibrational and rotational motions, Fig. 40–15. Transitions from one level to another appear as many very closely spaced lines. In fact, the lines are not always distinguishable, and these spectra are called **band spectra**. Each type of molecule has its own characteristic spectrum, which can be used for identification and for determination of structure. We now look in more detail at rotational and vibrational states in molecules.

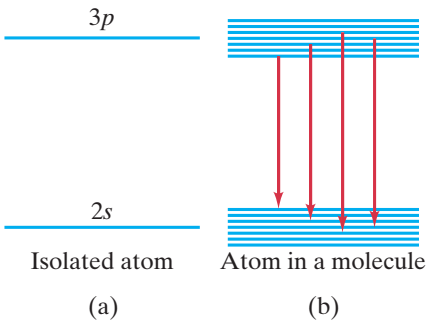

**FIGURE 40–15** (a) The individual energy levels of an isolated atom become (b) bands of closely spaced levels in molecules, as well as in solids and liquids.

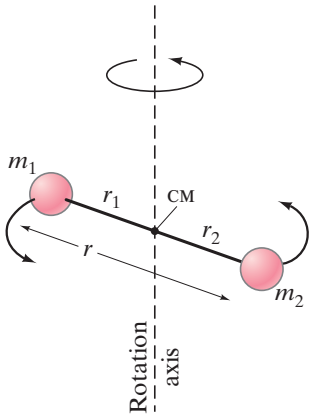
## Rotational Energy Levels in Molecules

We consider only diatomic molecules, although the analysis can be extended to polyatomic molecules. When a diatomic molecule rotates about its center of mass as shown in Fig. 40–16, its kinetic energy of rotation (see Section 10–8) is

$$E_{\text{rot}} = \frac{1}{2} I\omega^2 = \frac{(I\omega)^2}{2I},$$



where $I\omega$ is the angular momentum (Section 11–1). Quantum mechanics predicts quantization of angular momentum just as in atoms (see Eq. 39–3):

$$I\omega = \sqrt{\ell(\ell+1)}\,\hbar, \qquad \ell = 0, 1, 2, \cdots,$$

where $\ell$ is an integer called the **rotational angular momentum quantum number**. Thus the rotational energy is quantized:

$$E_{\text{rot}} = \frac{(I\omega)^2}{2I} = \ell(\ell+1)\frac{\hbar^2}{2I}. \qquad \ell = 0, 1, 2, \cdots. \qquad \textbf{(40–2)}$$

**FIGURE 40–16** Diatomic molecule rotating about a vertical axis.

Transitions between rotational energy levels are subject to the **selection rule** (as in Section 39–2):

$$\Delta\ell = \pm 1.$$

The energy of a photon emitted or absorbed for a transition between rotational states with angular momentum quantum number $\ell$ and $\ell - 1$ will be

$$\Delta E_{\text{rot}} = E_\ell - E_{\ell-1} = \frac{\hbar^2}{2I}\ell(\ell+1) - \frac{\hbar^2}{2I}(\ell-1)(\ell)$$

$$= \frac{\hbar^2}{I}\ell. \qquad \left[\begin{array}{c}\ell \text{ is for upper} \\ \text{energy state}\end{array}\right] \qquad \textbf{(40–3)}$$

We see that the transition energy increases directly with $\ell$. Figure 40–17 shows some of the allowed rotational energy levels and transitions. Measured absorption lines fall in the microwave or far-infrared regions of the spectrum (energies $\approx 10^{-3}$ eV), and their frequencies are generally 2, 3, 4, $\cdots$ times higher than the lowest one, as predicted by Eq. 40–3.

**EXERCISE A** Determine the three lowest rotational energy states (in eV) for a nitrogen molecule which has a moment of inertia $I = 1.39 \times 10^{-46}\,\text{kg}\cdot\text{m}^2$.

The moment of inertia of the molecule in Fig. 40–16 rotating about its center of mass (Section 10–5) is

$$I = m_1 r_1^2 + m_2 r_2^2,$$

where $r_1$ and $r_2$ are the distances of each atom from their common center of mass. We can show (in Example 40–4 below) that $I$ can be written

$$I = \frac{m_1 m_2}{m_1 + m_2} r^2 = \mu r^2, \qquad \textbf{(40–4)}$$

where $r = r_1 + r_2$ is the distance between the two atoms of the molecule and $\mu = m_1 m_2/(m_1 + m_2)$ is called the **reduced mass**. If $m_1 = m_2$, then $\mu = \frac{1}{2}m_1 = \frac{1}{2}m_2$.

**EXAMPLE 40–4** **Reduced mass.** Show that the moment of inertia of a diatomic molecule rotating about its center of mass can be written

$$I = \mu r^2,$$

where

$$\mu = \frac{m_1 m_2}{m_1 + m_2}$$

is the reduced mass, Eq. 40–4, and $r$ is the distance between the atoms.

**SOLUTION** The moment of inertia of a single particle of mass $m$ a distance $r$ from the rotation axis is $I = mr^2$ (Eq. 10–11 or 10–13). For our diatomic molecule (Fig. 40–16)

$$I = m_1 r_1^2 + m_2 r_2^2.$$

Now $r = r_1 + r_2$ and $m_1 r_1 = m_2 r_2$ because the axis of rotation passes through the center of mass. Hence

$$r_1 = r - r_2 = r - \frac{m_1}{m_2} r_1.$$

Solving for $r_1$ gives

$$r_1 = \frac{r}{1 + \dfrac{m_1}{m_2}} = \frac{m_2 r}{m_1 + m_2}.$$

Similarly,

$$r_2 = \frac{m_1 r}{m_1 + m_2}.$$

Then (see first equation of this Solution)

$$I = m_1\left(\frac{m_2 r}{m_1 + m_2}\right)^2 + m_2\left(\frac{m_1 r}{m_1 + m_2}\right)^2 = \frac{m_1 m_2 (m_1 + m_2) r^2}{(m_1 + m_2)^2}$$

$$= \frac{m_1 m_2}{m_1 + m_2} r^2 = \mu r^2,$$

where

$$\mu = \frac{m_1 m_2}{m_1 + m_2},$$

which is what we wished to show.

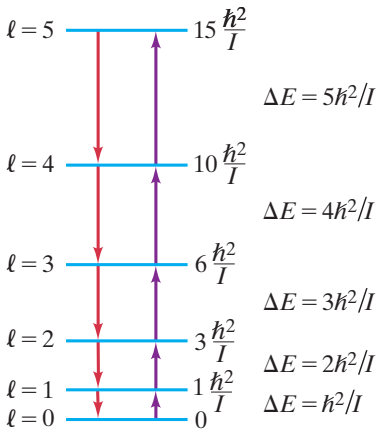


**FIGURE 40–17** Rotational energy levels and allowed transitions (emission and absorption) for a diatomic molecule. Upward-pointing arrows represent absorption of a photon, and downward arrows represent emission of a photon.

**EXAMPLE 40–5** **Rotational transition.** A rotational transition $\ell = 1$ to $\ell = 0$ for the molecule CO has a measured absorption wavelength $\lambda_1 = 2.60\,\text{mm}$ (microwave region). Use this to calculate (*a*) the moment of inertia of the CO molecule, and (*b*) the CO bond length, *r*. (*c*) Calculate the wavelengths of the next three rotational transitions, and the energies of the photon emitted for each of these four transitions.

**APPROACH** The absorption wavelength is used to find the energy of the absorbed photon. The moment of inertia $I$ is found from Eq. 40–3, and the bond length $r$ from Eq. 40–4.

**SOLUTION** (*a*) The photon energy, $E = hf = hc/\lambda$, equals the rotational energy level difference, $\Delta E_{\text{rot}}$. From Eq. 40–3, we can write

$$\frac{\hbar^2}{I}\ell = \Delta E_{\text{rot}} = hf = \frac{hc}{\lambda_1}.$$

With $\ell = 1$ (the upper state) in this case, we solve for $I$:

$$I = \frac{\hbar^2\ell}{hc}\lambda_1 = \frac{h\lambda_1}{4\pi^2 c} = \frac{(6.63\times10^{-34}\,\text{J}\cdot\text{s})(2.60\times10^{-3}\,\text{m})}{4\pi^2(3.00\times10^{8}\,\text{m/s})}$$
$$= 1.46\times10^{-46}\,\text{kg}\cdot\text{m}^2.$$

(*b*) The masses of C and O are 12.0 u and 16.0 u, respectively, where $1\,\text{u} = 1.66\times10^{-27}\,\text{kg}$. Thus the reduced mass is

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(12.0)(16.0)}{28.0}(1.66\times10^{-27}\,\text{kg}) = 1.14\times10^{-26}\,\text{kg}$$

or 6.86 u. Then, from Eq. 40–4, the bond length is

$$r = \sqrt{\frac{I}{\mu}} = \sqrt{\frac{1.46\times10^{-46}\,\text{kg}\cdot\text{m}^2}{1.14\times10^{-26}\,\text{kg}}} = 1.13\times10^{-10}\,\text{m} = 0.113\,\text{nm}.$$

(*c*) From Eq. 40–3, $\Delta E \propto \ell$. Hence $\lambda = c/f = hc/\Delta E$ is proportional to $1/\ell$. Thus, for $\ell = 2$ to $\ell = 1$ transitions, $\lambda_2 = \frac{1}{2}\lambda_1 = 1.30\,\text{mm}$. For $\ell = 3$ to $\ell = 2$, $\lambda_3 = \frac{1}{3}\lambda_1 = 0.87\,\text{mm}$. And for $\ell = 4$ to $\ell = 3$, $\lambda_4 = 0.65\,\text{mm}$. All are close to measured values. The energies of the photons, $hf = hc/\lambda$, are respectively $4.8\times10^{-4}\,\text{eV}$, $9.5\times10^{-4}\,\text{eV}$, $1.4\times10^{-3}\,\text{eV}$, and $1.9\times10^{-3}\,\text{eV}$.

## Vibrational Energy Levels in Molecules

The potential energy of the two atoms in a typical diatomic molecule has the shape shown in Fig. 40–8 or 40–9, and Fig. 40–18 again shows the potential energy for the $H_2$ molecule (solid curve). This potential energy curve, at least in the vicinity of the equilibrium separation $r_0$, closely resembles the potential energy of a simple harmonic oscillator, $U = \frac{1}{2}kx^2$, which is shown superposed in dashed lines. Thus, for small displacements from $r_0$, each atom experiences a restoring

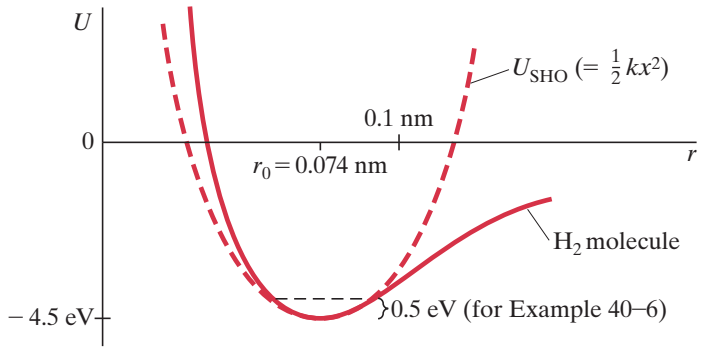

**FIGURE 40–18** Potential energy for the $H_2$ molecule and for a simple harmonic oscillator ($U_{\text{SHO}} = \frac{1}{2}kx^2$, with $|x| = |r - r_0|$) The 0.50-eV energy height marked is for use in Example 40–6 to estimate $k$. [Note that $U_{\text{SHO}} = 0$ is not the same as $U = 0$ for the molecule.]

PSE5_CH40_v1.7_23-Jun-20

force approximately proportional to the displacement, and the molecule vibrates as a simple harmonic oscillator (SHO). The classical frequency of vibration is

$$f = \frac{1}{2\pi}\sqrt{\frac{k}{\mu}}, \qquad \textbf{(40–5)}$$

where $k$ is the "stiffness constant" (as for a spring, Chapter 14) and instead of the mass $m$ we must again use the reduced mass $\mu = m_1 m_2/(m_1 + m_2)$. (This is shown in Problem 21.) The Schrödinger equation for the SHO potential energy yields solutions for energy that are quantized according to

$$E_{\text{vib}} = (\nu + \tfrac{1}{2})hf \qquad \nu = 0, 1, 2, \cdots, \qquad \textbf{(40–6)}$$

where the frequency $f$ is given by Eq. 40–5 and $\nu$ is an integer called the **vibrational quantum number**. The lowest energy state $(\nu = 0)$ is not zero (as for rotation) but has $E = \frac{1}{2}hf$. This is called the **zero-point energy**.† Higher states have energy $\frac{3}{2}hf$, $\frac{5}{2}hf$, and so on, as shown in Fig. 40–19. Transitions between vibrational energy levels are subject to the **selection rule**

$$\Delta\nu = \pm 1,$$

so allowed transitions occur only between adjacent states‡ and all give off photons of energy

$$\Delta E_{\text{vib}} = hf. \qquad \textbf{(40–7)}$$

This is very close to experimental values for small $\nu$; but for higher energies, the potential-energy curve (Fig. 40–18) begins to deviate from a perfect SHO curve, which affects the wavelengths and frequencies of the transitions. Typical transition energies are on the order of $10^{-1}$ eV, about 10 to 100 times larger than for rotational transitions, with wavelengths in the infrared region of the spectrum $(\approx 10^{-5}\,\text{m})$.

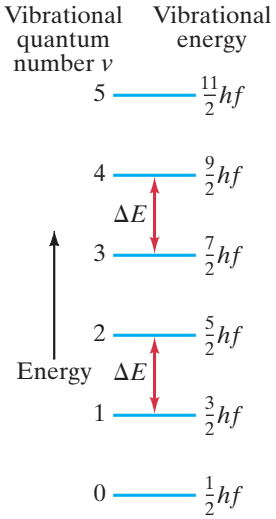

**FIGURE 40–19** Allowed vibrational energies of a diatomic molecule, where $f$ is the fundamental frequency of vibration, given by Eq. 40–5. The energy levels are equally spaced. Transitions are allowed only between adjacent levels $(\Delta\nu = \pm 1)$.

**EXAMPLE 40–6 ESTIMATE** **Wavelength for $H_2$.** (*a*) Use the curve of Fig. 40–18 to estimate the value of the stiffness constant $k$ for the $H_2$ molecule, and then (*b*) estimate the fundamental wavelength for vibrational transitions.

**APPROACH** To find $k$, we arbitrarily choose an energy height of 0.50 eV which is indicated in Fig. 40–18. By measuring directly on the graph, we find that this energy corresponds to a vibration on either side of $r_0 = 0.074$ nm of about $x = \pm 0.017$ nm.

**SOLUTION** (*a*) For SHO, $U_{\text{SHO}} = \frac{1}{2}kx^2$ and $U_{\text{SHO}} = 0$ at $x = 0$ $(r = r_0)$; then

$$k = \frac{2U_{\text{SHO}}}{x^2} \approx \frac{2(0.50\,\text{eV})(1.6\times10^{-19}\,\text{J/eV})}{(1.7\times10^{-11}\,\text{m})^2} \approx 550\,\text{N/m}.$$

**NOTE** This value of $k$ would also be reasonable for a macroscopic spring.
(*b*) The reduced mass is $\mu = m_1 m_2/(m_1 + m_2) = m_1/2 = \frac{1}{2}(1.0\,\text{u})(1.66\times10^{-27}\,\text{kg}) = 0.83\times10^{-27}\,\text{kg}$. Hence, using Eq. 40–5,

$$\lambda = \frac{c}{f} = 2\pi c\sqrt{\frac{\mu}{k}} = 2\pi(3.0\times10^8\,\text{m/s})\sqrt{\frac{0.83\times10^{-27}\,\text{kg}}{550\,\text{N/m}}} = 2300\,\text{nm},$$

which is in the infrared region of the spectrum.

Experimentally, we do the inverse process: The wavelengths of vibrational transitions for a given molecule are measured, and from this the stiffness constant $k$ can be calculated. The values of $k$ calculated in this way are a measure of the strength of the molecular bond.

†Recall this phenomenon for a square well, Fig. 38–8.

‡Forbidden transitions with $\Delta\nu = 2$ occur with much lower probability, but their observation can be important in some cases, such as in astronomy.

**EXAMPLE 40–7** **Vibrational energy levels in hydrogen.** Hydrogen molecule vibrations emit infrared radiation of wavelength around 2300 nm. (*a*) What is the separation in energy between adjacent vibrational levels? (*b*) What is the lowest vibrational energy state?

**APPROACH** The energy separation between adjacent vibrational levels is $\Delta E_{\text{vib}} = hf = hc/\lambda$. The lowest energy (Eq. 40–6) has $\nu = 0$.

**SOLUTION** (*a*)

$$\Delta E_{\text{vib}} = hf = \frac{hc}{\lambda} = \frac{(6.63\times10^{-34}\,\text{J}\cdot\text{s})(3.00\times10^{8}\,\text{m/s})}{(2300\times10^{-9}\,\text{m})(1.60\times10^{-19}\,\text{J/eV})} = 0.54\,\text{eV},$$

where the denominator includes the conversion factor from joules to eV.

(*b*) The lowest vibrational energy has $\nu = 0$ in Eq. 40–6:

$$E_{\text{vib}} = (\nu + \tfrac{1}{2})hf = \tfrac{1}{2}hf = 0.27\,\text{eV}.$$

**EXERCISE B** What is the energy of the first vibrational state above the ground state in the hydrogen molecule?

## Rotational Plus Vibrational Levels

When energy is imparted to a molecule, both the rotational and vibrational modes can be excited. Because rotational energies are an order of magnitude or so smaller than vibrational energies, which in turn are smaller than the electronic energy levels, we can represent the grouping of levels as shown in Fig. 40–20. Transitions between energy levels, with emission of a photon, are subject to the **selection rules**:

$$\Delta\nu = \pm 1 \qquad \text{and} \qquad \Delta\ell = \pm 1.$$

Some allowed and forbidden (marked ×) transitions are indicated in Fig. 40–20. Not all transitions and levels are shown, and the separation between vibrational levels, and (even more) between rotational levels, has been exaggerated. But we can clearly see the origin of the very closely spaced lines that give rise to the band spectra, as mentioned with reference to Fig. 40–15 earlier in this Section.

The spectra are quite complicated, so we consider briefly only transitions within the same electronic level, such as those at the top of Fig. 40–20. A transition from a state with quantum numbers $\nu$ and $\ell$, to one with quantum numbers $\nu + 1$ and $\ell \pm 1$ (see the selection rules above), will absorb† a photon of energy:

$$\Delta E = \Delta E_{\text{vib}} + \Delta E_{\text{rot}}$$

$$= hf + (\ell + 1)\frac{\hbar^2}{I} \qquad \begin{bmatrix} \ell \to \ell + 1 \\ (\Delta\ell = +1) \end{bmatrix}, \quad \ell = 0, 1, 2, \cdots \qquad \textbf{(40–8a)}$$

$$= hf - \ell\frac{\hbar^2}{I} \qquad \begin{bmatrix} \ell \to \ell - 1 \\ (\Delta\ell = -1) \end{bmatrix}, \quad \ell = 1, 2, 3, \cdots, \qquad \textbf{(40–8b)}$$

where we have used Eqs. 40–3 and 40–7. Note that for $\ell \to \ell - 1$ transitions, $\ell$ cannot be zero because there is then no state with $\ell = -1$. Equations 40–8 predict an absorption spectrum like that shown schematically in Fig. 40–21,

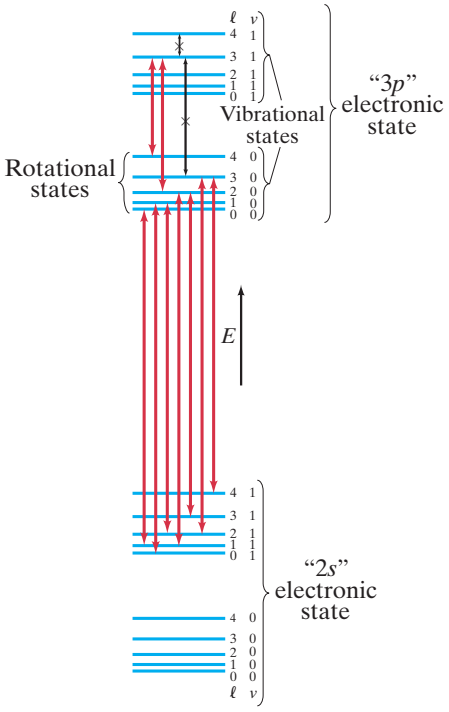

**FIGURE 40–20** Combined electronic, vibrational, and rotational energy levels. Transitions marked with an × are not allowed by selection rules.

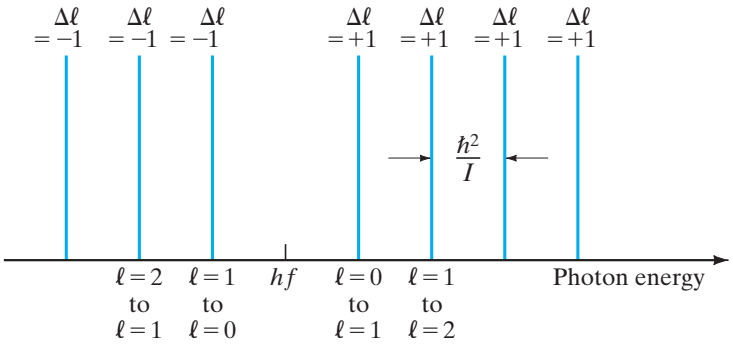

**FIGURE 40–21** Expected spectrum for transitions between combined rotational and vibrational states.

†Eqs. 40–8 are for absorption; for emission of a photon, the transition would be $\nu \to \nu - 1$, $\ell \to \ell \pm 1$.

PSE5_CH40_v1.7_23-Jun-20

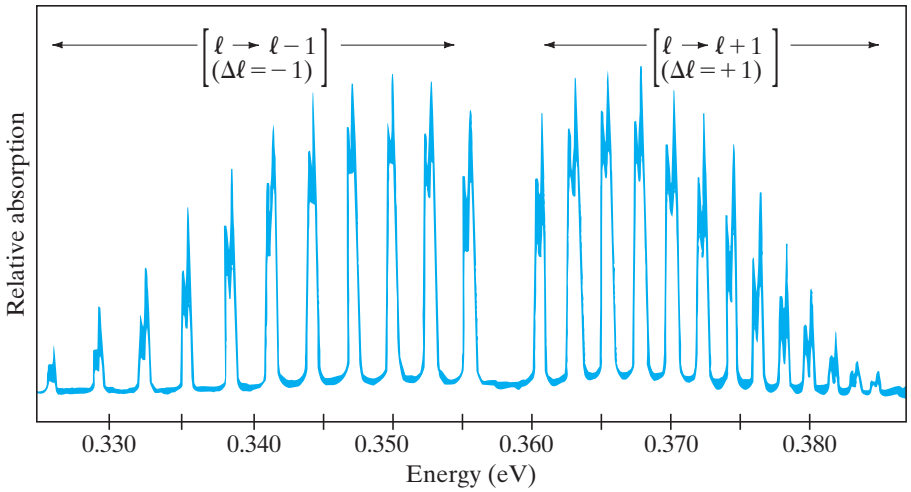

**FIGURE 40–22** Absorption spectrum for HCl molecules. Lines on the left correspond to transitions where $\ell \to \ell - 1$; those on the right are for $\ell \to \ell + 1$. Each line has a double peak because chlorine has two isotopes of different mass and different moment of inertia.

with transitions $\ell \to \ell - 1$ on the left and $\ell \to \ell + 1$ on the right. Figure 40–22 shows the molecular absorption spectrum of HCl, which follows this pattern very well. (Each line in the spectrum of Fig. 40–22 is split into two because Cl consists of two isotopes of different mass; hence there are two kinds of HCl molecule with slightly different moments of inertia $I$.)

**EXAMPLE 40–8** **ESTIMATE** **The HCl molecule.** Estimate the moment of inertia of the HCl molecule using the absorption spectrum shown in Fig. 40–22. For the purposes of a rough estimate you can ignore the difference between the two isotopes.

**APPROACH** The locations of the peaks in Fig. 40–22 should correspond to Eqs. 40–8. We don't know what value of $\ell$ each peak corresponds to in Fig. 40–22, but we can estimate the energy difference between peaks to be about $\Delta E' = 0.0025\,\text{eV}$.

**SOLUTION** From Eqs. 40–8, the energy difference between two peaks is given by

$$\Delta E' = \Delta E_{\ell+1} - \Delta E_\ell = \frac{\hbar^2}{I}.$$

Then

$$I = \frac{\hbar^2}{\Delta E'} = \frac{(6.626 \times 10^{-34}\,\text{J}\cdot\text{s}/2\pi)^2}{(0.0025\,\text{eV})(1.6 \times 10^{-19}\,\text{J/eV})} = 2.8 \times 10^{-47}\,\text{kg}\cdot\text{m}^2.$$

**NOTE** To get an idea of what this number means, we write $I = \mu r^2$ (Eq. 40–4), where $\mu$ is the reduced mass (Example 40–4); then we calculate $\mu$:

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(1.0\,\text{u})(35\,\text{u})}{36\,\text{u}}(1.66 \times 10^{-27}\,\text{kg/u}) = 1.6 \times 10^{-27}\,\text{kg};$$

the bond length is given by (Eq. 40–4)

$$r = \left(\frac{I}{\mu}\right)^{\frac{1}{2}} = \left(\frac{2.8 \times 10^{-47}\,\text{kg}\cdot\text{m}^2}{1.6 \times 10^{-27}\,\text{kg}}\right)^{\frac{1}{2}} = 1.3 \times 10^{-10}\,\text{m},$$

which is the expected order of magnitude for a bond length.

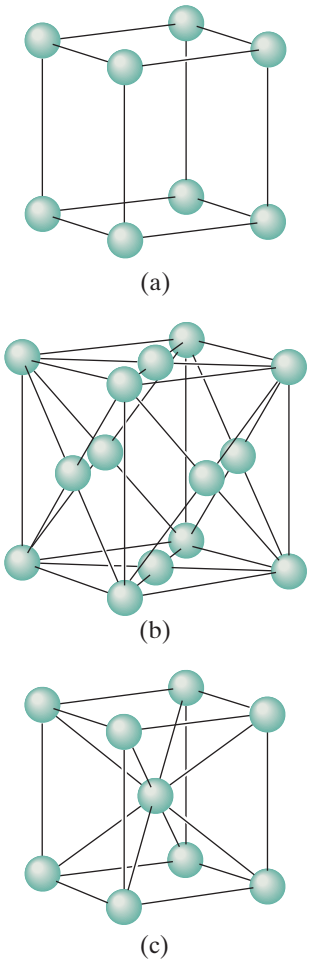

**FIGURE 40–23** Arrangement of atoms in (a) a simple cubic crystal, (b) face-centered cubic crystal (note the atom at the center of each face), and (c) body-centered cubic crystal. Each of these "cells" is repeated in three dimensions to the edges of the macroscopic crystal.

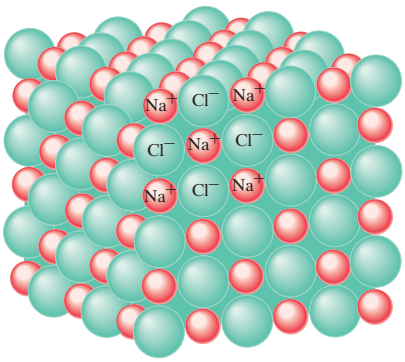

**FIGURE 40–24** Diagram of an NaCl crystal, showing the "packing" of atoms.

# 40–5 Bonding in Solids

Quantum mechanics has been a great tool for understanding the structure of solids. This active field of research today is called **solid-state physics**, or **condensed-matter physics** so as to include liquids as well. The rest of this Chapter is devoted to this subject, and we begin with a brief look at the structure of solids and the bonds that hold them together.

Although some solid materials are *amorphous* in structure (such as glass), in that the atoms and molecules show no long-range order, we are interested here in the large class of *crystalline* substances whose atoms, ions, or molecules are generally accepted to form an orderly array known as a **lattice**. Figure 40–23 shows three of the possible arrangements of atoms in a crystal: simple cubic, face-centered cubic, and body-centered cubic. The NaCl crystal is face-centered cubic (see Fig. 40–24), with one $Na^+$ ion or one $Cl^-$ ion at each "lattice point" (i.e., considering Na and Cl *separately*).

The molecules of a solid are held together in a number of ways. The most common are by *covalent* bonding (such as between the carbon atoms of the diamond crystal) and by *ionic* bonding (as in a NaCl crystal). Often the bonds are partially covalent and partially ionic. Our discussion of these bonds earlier in this Chapter for molecules applies equally well here to solids.

Let us look for a moment at the NaCl crystal of Fig. 40–24. Each $Na^+$ ion feels an attractive Coulomb potential due to each of the six "nearest neighbor" $Cl^-$ ions surrounding it.† Note that one $Na^+$ does not "belong" exclusively to one $Cl^-$, so we must not think of ionic solids as consisting of individual molecules. Each $Na^+$ also feels a repulsive Coulomb potential due to other $Na^+$ ions, although this is weaker since the other $Na^+$ ions are farther away. Thus we expect a net attractive potential

$$U = -\alpha \frac{1}{4\pi\epsilon_0}\frac{e^2}{r}.$$

The factor $\alpha$ is called the *Madelung constant*. If each $Na^+$ were surrounded by only the six $Cl^-$ ions, $\alpha$ would be 6, but the influence of all the other ions reduces it to a value $\alpha = 1.75$ for the NaCl crystal. The potential must also include a term representing the repulsive force when the wave functions of the inner shells and subshells overlap, and this has the form $U = B/r^m$, where $m$ is a small integer. The sum of these two terms suggests a potential energy

$$U = -\frac{\alpha}{4\pi\epsilon_0}\frac{e^2}{r} + \frac{B}{r^m}, \qquad \textbf{(40–9)}$$

which has the same form as Eq. 40–1 for molecules (Section 40–2). It can be shown (Problem 28) that, at the equilibrium distance $r_0$,

$$U = U_0 = -\frac{\alpha}{4\pi\epsilon_0}\frac{e^2}{r_0}\left(1 - \frac{1}{m}\right).$$

This $U_0$ is known as the *ionic cohesive energy*; it is a sort of "binding energy"—the energy (per ion) needed to take the solid apart into separated ions, one by one.

A different type of bond occurs in metals. Metal atoms have relatively loosely held outer electrons. **Metallic bond** theories propose that in a metallic solid, these outer electrons roam rather freely among all the metal atoms which, without their outer electrons, act like positive ions. According to the theory the electrostatic attraction between the metal ions and this negative electron "gas" is responsible, at least in part, for holding the solid together. The binding energy of metal bonds is typically 1 to 3 eV, somewhat weaker than ionic or covalent bonds (5 to 10 eV in solids). The "free electrons," then, are responsible for the high electrical and

†One to each side in 3 dimensions: to the left, to the right, above, below, in front and behind.

thermal conductivity of metals (see Sections 40–6 and 40–7). This theory also nicely accounts for the shininess of smooth metal surfaces: the free electrons can vibrate at any frequency, so when light of a range of frequencies falls on a metal, the electrons can vibrate in response and re-emit light of those same frequencies. Hence the reflected light will consist largely of the same frequencies as the incident light. Compare this to nonmetallic materials that have a distinct color—the atomic electrons exist only in certain energy states, and when white light falls on them, the atoms absorb at certain frequencies, and reflect other frequencies which make up the color we see.

Here is a brief comparison of important strong bonds:

- ionic: electrons are "grabbed" from one atom by another;
- covalent: electrons are shared by atoms within a single molecule;
- metallic: electrons are shared by all atoms in the metal.

The atoms or molecules of some materials, such as the noble gases, can form only **weak bonds** with each other. As we saw in Section 40–3, weak bonds have very low binding energies and would not be expected to hold atoms together as a liquid or solid at room temperature. The noble gases condense only at very low temperatures, where the (thermal) kinetic energy per atom is small and the weak attraction can then hold the atoms together.

**EXERCISE C** Return to Chapter-Opening Question 1, page 1186, and answer it again now. Try to explain why you may have answered differently the first time.

## 40–6 Free-Electron Theory of Metals; Fermi Energy

Let us look more closely at the free-electron theory of metals mentioned in the preceding Section. Let us imagine the electrons trapped within the metal, moving around in a potential well: inside the metal, the potential energy is zero, but at the edges of the metal there are high potential walls. Since very few electrons leave the metal at low temperature, we can imagine the walls as being almost infinitely high (as in Section 38–8). At higher temperatures, electrons do leave the metal (we know that thermionic emission occurs, Section 23–10), so we must recognize that the well is of finite depth. In this simple model, the electrons are trapped within the metal, but are free to move about inside the well whose size is macroscopic—the size of the piece of metal. The energy, which is kinetic energy, will be quantized; but the spacing between energy levels will be very tiny (see Eq. 38–13) because the width of the potential well $\ell$ is very large. Indeed, for a cube 1 cm on a side, the number of states with energy between, say, 5.0 and 5.5 eV is on the order of $10^{22}$ (see Example 40–9).

To deal with such vast numbers of states, which are so closely spaced as to seem continuous, we need to use statistical methods. We define a quantity known as the **density of states**, $g(E)$, whose meaning is similar to the Maxwell distribution, Eq. 18–6 (see Section 18–2). That is, the quantity $g(E)\,dE$ represents the number of states per unit volume that have energy between $E$ and $E + dE$. A careful calculation (see Problem 44), which must treat the potential well as three dimensional, shows that

$$g(E) = \frac{8\sqrt{2}\,\pi m^{3/2}}{h^3} E^{1/2} \qquad \textbf{(40–10)}$$

where $m$ is the mass of the electron. This function is plotted in Fig. 40–25.

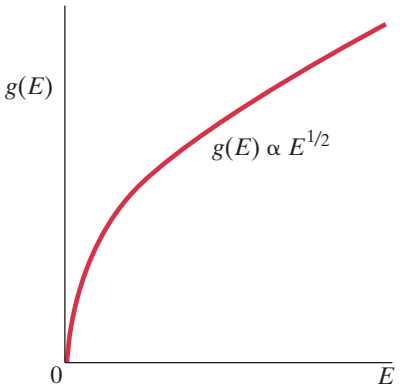

**FIGURE 40–25** Density of states $g(E)$ as a function of energy $E$ (Eq. 40–10).

**EXERCISE D** What are the units for $g(E)$?

**EXAMPLE 40–9** | **ESTIMATE** **Electron states in copper.** Estimate the number of states in the range 5.0 to 5.5 eV available to electrons in a 1.0-cm cube of copper metal.

**APPROACH** Since $g(E)$ is the number of states per unit volume per unit energy interval, the number $N$ of states is approximately (it is approximate because $\Delta E$ is not small)

$$N \approx g(E)V\,\Delta E,$$

where the volume $V = 1.0\,\text{cm}^3 = 1.0 \times 10^{-6}\,\text{m}^3$ and $\Delta E = 0.50\,\text{eV}$.

**SOLUTION** We evaluate $g(E)$ at 5.25 eV, and find (Eq. 40–10):

$$N \approx g(E)V\,\Delta E = \frac{8\sqrt{2}\pi(9.1 \times 10^{-31}\,\text{kg})^{\frac{3}{2}}}{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})^3}\sqrt{(5.25\,\text{eV})(1.6 \times 10^{-19}\,\text{J/eV})}$$
$$\times (1.0 \times 10^{-6}\,\text{m}^3)(0.50\,\text{eV})(1.6 \times 10^{-19}\,\text{J/eV})$$
$$\approx 8 \times 10^{21}$$

states in $1.0\,\text{cm}^3$. Note that the type of metal did not enter the calculation.

Equation 40–10 gives us the density of states. Now we must ask: How are the states available to an electron gas actually populated? Let us first consider the situation at absolute zero, $T = 0\,\text{K}$. For a classical ideal gas, all the particles would be in the lowest state, with zero kinetic energy $(= \frac{3}{2}kT = 0)$—recall Eq. 18–4. But the situation is vastly different for an electron gas because electrons obey the exclusion principle. Electrons do not obey classical statistics but rather a quantum statistics called **Fermi–Dirac statistics**[†] that takes into account the exclusion principle. All particles that have spin $\frac{1}{2}$ (or other half-integral spin: $\frac{3}{2}, \frac{5}{2}$, etc.), such as electrons, protons, and neutrons, obey Fermi–Dirac statistics and are referred to as **fermions**,[‡] as we saw in Section 39–4. The electron gas in a metal is often called a **Fermi gas**. According to the exclusion principle, no two electrons in the metal can have the same set of quantum numbers. Therefore, in each of the energy states available for the electrons in our "gas," there can be at most two electrons: one with spin up $(m_s = +\frac{1}{2})$ and one with spin down $(m_s = -\frac{1}{2})$. (This factor of 2 has already been included in Eq. 40–10.) Thus, at $T = 0\,\text{K}$, the possible energy levels will be filled, two electrons each, up to a maximum level called the **Fermi level**. This is shown in Fig. 40–26, where the vertical axis is labeled $n_o(E)$ for "density of occupied states." The energy of the state at the Fermi level is called the **Fermi energy**, $E_F$. To determine $E_F$, we integrate Eq. 40–10 from $E = 0$ to $E = E_F$ (all states up to $E_F$ are filled at $T = 0\,\text{K}$):

$$\frac{N}{V} = \int_0^{E_F} g(E)\,dE, \qquad \textbf{(40–11)}$$

where $N/V$ is the number of conduction electrons per unit volume in the metal. Then, solving for $E_F$, the result (see Example 40–10 below) is

$$E_F = \frac{h^2}{8m}\left(\frac{3}{\pi}\frac{N}{V}\right)^{\frac{2}{3}}. \qquad \textbf{(40–12)}$$

The average energy in this distribution (see Problem 38) is

$$\overline{E} = \tfrac{3}{5}E_F. \qquad \textbf{(40–13)}$$

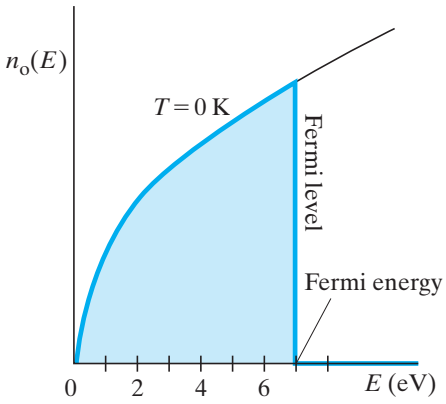

**FIGURE 40–26** At $T = 0\,\text{K}$, all states up to energy $E_F$, called the Fermi energy, are filled. (Shown here for copper.)

[†]Developed independently by Enrico Fermi (Figs. 41–8, 38–2, 37–10) in early 1926 and by P. A. M. Dirac a few months later.

[‡]Particles with integer spin (0, 1, 2, etc.), such as the photon, obey *Bose–Einstein* statistics and are called *bosons*, as mentioned in Section 39–4.

PSE5_CH40_v1.7_23-Jun-20

For copper, $E_F = 7.0\,\text{eV}$ (see Example 40–10) and $\overline{E} = 4.2\,\text{eV}$. This is very much greater than the energy of thermal motion at room temperature $\left(\frac{3}{2}kT \approx 0.04\,\text{eV}\right)$. Clearly, all motion does not stop at absolute zero.

At $T = 0$, all states with energy below $E_F$ are occupied, and all states above $E_F$ are empty. What happens for $T > 0$? We expect that at least some of the electrons will increase in energy due to thermal motion. Classically, the distribution of occupied states would be given by the Boltzmann factor, $e^{-E/kT}$ (see Eqs. 39–16). But for our electron gas, a quantum-mechanical system obeying the exclusion principle, the probability of a given state of energy $E$ being occupied is given by the **Fermi–Dirac probability function** (or **Fermi factor**):

$$f(E) = \frac{1}{e^{(E-E_F)/kT} + 1}, \qquad \textbf{(40–14)}$$

where $E_F$ is the Fermi energy. This function is plotted in Fig. 40–27 for two temperatures, $T = 0\,\text{K}$ and $T = 1200\,\text{K}$ (just below the melting point of copper).

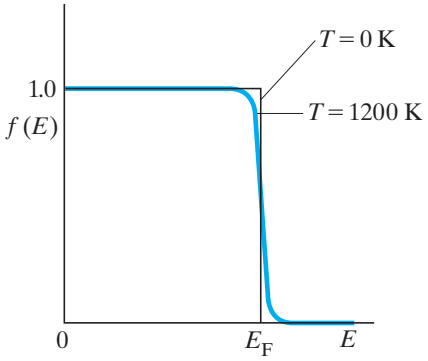

**FIGURE 40–27** The Fermi–Dirac probability function for two temperatures, $T = 0\,\text{K}$ (black line) and $T = 1200\,\text{K}$ (blue curve). For $f(E) = 1$, a state with energy $E$ is certainly occupied. For $f(E) = 0.5$, which occurs at $E = E_F$, the state with $E_F$ has a 50% chance of being occupied.

At $T = 0$ (or as $T$ approaches zero) the factor $e^{(E-E_F)/kT}$ in Eq. 40–14 is zero if $E < E_F$ and is $\infty$ if $E > E_F$. Thus

$$f(E) = \begin{cases} 1 & E < E_F \\ 0 & E > E_F \end{cases} \quad \text{at} \quad T = 0.$$

This is what is plotted in black in Fig. 40–27 and is consistent with Fig. 40–26: all states up to the Fermi level are occupied [probability $f(E) = 1$] and all states above are unoccupied. For $T = 1200\,\text{K}$, the Fermi factor changes only a little, as shown in Fig. 40–27 as the blue curve. Note that at any temperature $T$, when $E = E_F$, then Eq. 40–14 gives $f(E) = 0.50$, meaning the state at $E = E_F$ has a 50% chance of being occupied by an electron. Alternatively, at $E = E_F$, half the available states are filled and half are empty. To see how $f(E)$ affects the actual distribution of electrons in energy states, we must weight the density of possible states, $g(E)$, by the probability that those states will be occupied, $f(E)$. The product of these two functions gives the **density of occupied states**,

$$n_o(E) = g(E)f(E) = \frac{8\sqrt{2}\,\pi m^{3/2}}{h^3}\frac{E^{1/2}}{e^{(E-E_F)/kT} + 1}. \qquad \textbf{(40–15)}$$

Then $n_o(E)\,dE$ represents the number of electrons per unit volume with energy between $E$ and $E + dE$ in thermal equilibrium at temperature $T$. This is plotted in Fig. 40–28 for $T = 1200\,\text{K}$, a temperature at which a metal is so hot it would glow. We see that the distribution differs very little from that at $T = 0$. We see also that the changes that do occur are concentrated about the Fermi level.

**⚠ CAUTION**

*At the Fermi level, there are as many filled states as empty ones*

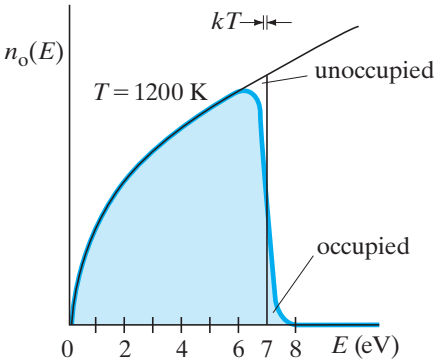

**FIGURE 40–28** The density of occupied states for the electron gas in copper. The width $kT$ shown above the graph represents thermal energy at $T = 1200\,\text{K}$.

**CAUTION**

*Average electron energy in metals changes only slightly from $T = 0\,\text{K}$ to $T = 1200\,\text{K}$*

A few electrons from slightly below the Fermi level move to energy states slightly above it. The average energy of the electrons increases only very slightly when the temperature is increased from $T = 0\,\text{K}$ to $T = 1200\,\text{K}$. This is very different from the behavior of an ideal gas, for which kinetic energy increases directly with $T$. Nonetheless, this behavior is readily understood as follows. Energy of thermal motion at $T = 1200\,\text{K}$ is about $\frac{3}{2}kT \approx 0.1\,\text{eV}$. The Fermi level, on the other hand, is on the order of several eV: for copper it is $E_\text{F} \approx 7.0\,\text{eV}$. An electron at $T = 1200\,\text{K}$ may have 7 eV of energy, but it can acquire at most only a few times 0.1 eV of energy by a (thermal) collision with the lattice. Only electrons very near the Fermi level would find vacant states close enough to make such a transition. Essentially none of the electrons could increase in energy by, say, 3 eV, so electrons farther down in the electron gas are unaffected. Only electrons near the top of the energy distribution can be thermally excited to higher states. And their new energy (and speed) is on the average only slightly higher than their old energy. This model of free electrons in a metal as a "gas," though incomplete, provides good explanations for the thermal and electrical conductivity of metals.

**EXERCISE E** Return to Chapter-Opening Question 2, page 1186, and answer it again now. Try to explain why you may have answered differently the first time.

**EXAMPLE 40–10 The Fermi level.** For the metal copper, determine (*a*) the Fermi energy, (*b*) the average energy of electrons, and (*c*) the speed of electrons at the Fermi level (this is called the *Fermi speed*).

**APPROACH** We first derive Eq. 40–12 by combining Eqs. 40–10 and 40–11:

$$\frac{N}{V} = \frac{8\sqrt{2}\,\pi m^{3/2}}{h^3}\int_0^{E_\text{F}} E^{1/2}\,dE = \frac{8\sqrt{2}\,\pi m^{3/2}}{h^3}\frac{2}{3}E_\text{F}^{3/2}$$

$$= \frac{16\sqrt{2}\,\pi m^{3/2}}{3h^3}E_\text{F}^{3/2}.$$

Solving for $E_\text{F}$, we obtain [note: $(16\sqrt{2})^{2/3} = (\sqrt{512})^{2/3} = (512)^{1/3} = 8$]:

$$E_\text{F} = \frac{h^2}{8m}\left(\frac{3}{\pi}\frac{N}{V}\right)^{\frac{2}{3}},$$

and this is Eq. 40–12. We calculated $N/V$, the number of conduction electrons per unit volume in copper, in Example 25–14 to be $N/V = 8.4 \times 10^{28}\,\text{m}^{-3}$.

**SOLUTION** (*a*) The Fermi energy for copper is thus

$$E_\text{F} = \frac{(6.63\times10^{-34}\,\text{J}\cdot\text{s})^2}{8(9.1\times10^{-31}\,\text{kg})}\left[\frac{3(8.4\times10^{28}\,\text{m}^{-3})}{\pi}\right]^{\frac{2}{3}}\frac{1}{1.6\times10^{-19}\,\text{J/eV}} = 7.0\,\text{eV}.$$

(*b*) From Eq. 40–13,

$$\overline{E} = \tfrac{3}{5}E_\text{F} = 4.2\,\text{eV}.$$

(*c*) In our model, we have taken $U = 0$ inside the metal (assuming a 3-D infinite potential well, Section 38–8, Eq. 40–10, and Problem 44). Then $E$ is only kinetic energy $= \frac{1}{2}mv^2$. Therefore, at the Fermi level, the Fermi speed is

$$v_\text{F} = \sqrt{\frac{2E_\text{F}}{m}} = \sqrt{\frac{2(7.0\,\text{eV})(1.6\times10^{-19}\,\text{J/eV})}{9.1\times10^{-31}\,\text{kg}}} = 1.6\times10^6\,\text{m/s},$$

a very high speed. The temperature of a classical gas would have to be extremely high to produce an average particle speed this large.

**EXAMPLE 40–11** **Incorrect classical calculation.** Let us see what result we get if the electrons are treated as a classical ideal gas. That is, estimate the average kinetic energy of electrons at room temperature using the kinetic theory of gases, Chapter 18.

**APPROACH** The average kinetic energy of particles in an ideal gas was given in Chapter 18, Eq. 18–4, as

$$\overline{K} = \tfrac{3}{2}kT,$$

where $k$ is Boltzmann's constant and $T \approx 300\,\text{K}$.

**SOLUTION** The ideal gas model gives

$$\overline{K} = \frac{3}{2}(1.38\times10^{-23}\,\text{J/K})\,(300\,\text{K})\left(\frac{1}{1.6\times10^{-19}\,\text{J/eV}}\right) = 0.039\,\text{eV}.$$

This result is far from the quantum calculation. It is off by a factor of 100: Example 40–10 gave 4.2 eV. The ideal gas model does not work for electrons which obey the exclusion principle. Indeed, we see here how important and powerful the exclusion principle is. Comparing Examples 40–10 and 40–11, we see how profoundly the exclusion principle changes everything.

**EXERCISE F** Determine the Fermi energy for gold $(\text{density} = 19{,}300\,\text{kg/m}^3)$. (*a*) 5.5 eV, (*b*) 6.2 eV, (*c*) 7.2 eV, (*d*) 8.1 eV, (*e*) 8.4 eV.

The simple model of an electron gas presented here provides good explanations for the electrical and thermal properties of conductors. But it does not explain why some materials are good conductors and others are good insulators. To provide an explanation, our model of electrons inside a metal as moving in a uniform potential well needs to be refined to include the effect of the lattice. Figure 40–29 shows a "periodic" potential that takes into account the attraction of electrons for each atomic ion in the lattice. Here we have taken $U = 0$ for an electron free of the metal; so within the metal, electron energies are less than zero (just as for molecules, or for the H atom in which the ground state has $E = -13.6\,\text{eV}$). The quantity $eW_0$ represents the minimum energy to remove an electron from the metal, where $W_0$ is the *work function* (see Section 37–2). The crucial outcome of putting a periodic potential (more easily approximated with narrow square wells) into the Schrödinger equation is that the allowed energy states are divided into *bands*, with energy gaps in between. Only electrons in the highest band, close to the Fermi level, are able to move about freely within the metal crystal. In the next Section we will see physically why there are bands and how they explain the properties of conductors, insulators, and semiconductors.

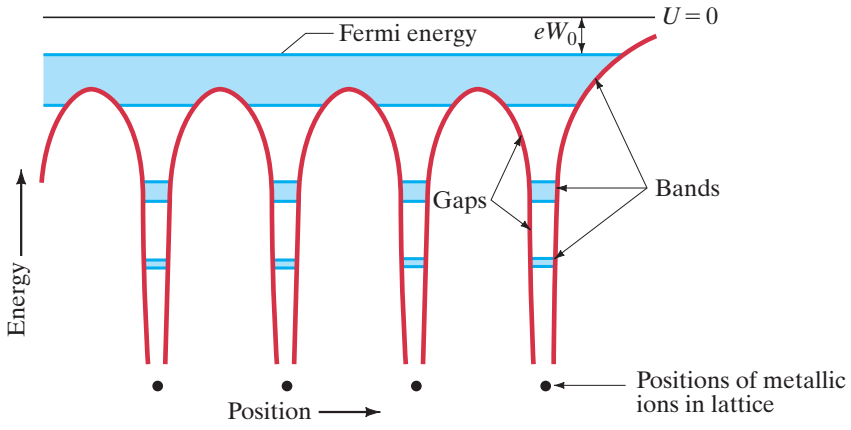

**FIGURE 40–29** Potential energy for an electron in a metal crystal, with deep potential wells in the vicinity of each ion in the crystal lattice.

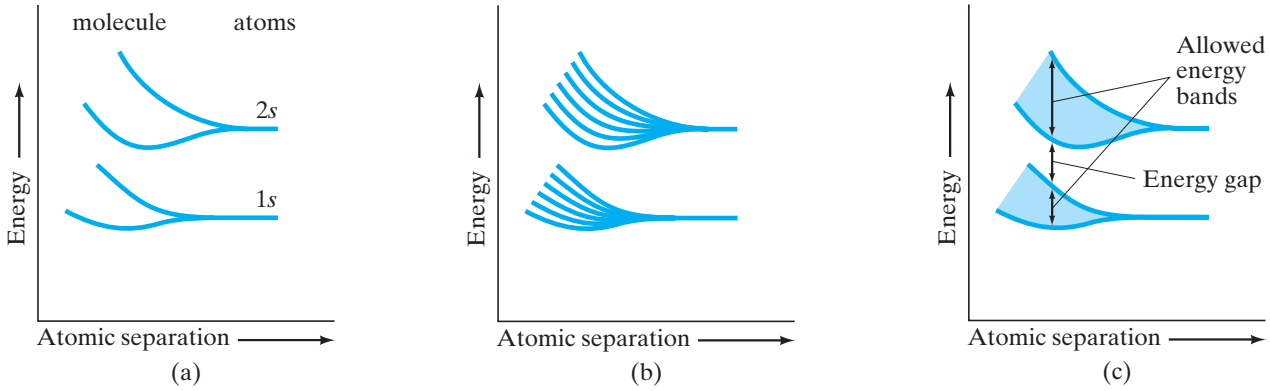
## 40–7 Band Theory of Solids

We saw in Section 40–1 that when two hydrogen atoms approach each other, the wave functions overlap, and the two 1*s* states (one for each atom) divide into two states of different energy. (As we saw, only one of these states, $S = 0$, has low enough energy to give a bound $H_2$ molecule.) Figure 40–30a shows this situation for 1*s* and 2*s* states for two atoms: as the two atoms get closer (toward the left in Fig. 40–30a), the 1*s* and 2*s* states split into two levels. If six atoms come together, as in Fig. 40–30b, each of the states splits into six levels. If a large number of atoms come together to form a solid, then each of the original atomic levels becomes a **band** as shown in Fig. 40–30c. The energy levels are so close together in each band that they seem essentially continuous. This is why the spectrum of heated solids (Section 37–1) appears continuous. (See also Fig. 40–15 and its discussion at the start of Section 40–4.)



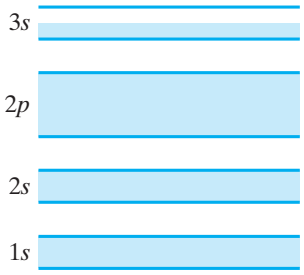


**FIGURE 40–30** The splitting of 1*s* and 2*s* atomic energy levels as (a) two atoms approach each other (the atomic separation decreases toward the left on the graph), (b) the same for six atoms, and (c) for many atoms when they come together to form a solid.

**FIGURE 40–31** Energy bands for sodium (Na).

The crucial aspect of a good **conductor** is that the highest energy band containing electrons is only partially filled. Consider sodium metal, for example, whose energy bands are shown in Fig. 40–31. The 1*s*, 2*s*, and 2*p* bands are full (just as in a sodium atom) and don't concern us. The 3*s* band, however, is only half full. (Thus, the Fermi level is in the middle of the 3*s* band.) To see why the band is half full, recall that the exclusion principle stipulates that in an atom, only two electrons can be in the 3*s* state, one with spin up and one with spin down. These two spin states have slightly different energy. For a solid consisting of *N* atoms, the 3*s* band will contain 2*N* possible energy states (the 2 because of the 2 spin states). A sodium atom has a single 3*s* electron, so in a sample of sodium metal containing *N* atoms, there are *N* electrons in the 3*s* band, and *N* unoccupied states (total = 2*N*). When a potential difference is applied across the metal, electrons can respond by accelerating and increasing their energy, since there are plenty of unoccupied states of slightly higher energy available. Hence, a current flows readily and sodium is a good conductor. The characteristic of all good conductors is that the highest energy band is only partially filled, or two bands overlap so that unoccupied states are available. An example of the latter is magnesium, which has two 3*s* electrons, so its 3*s* band is filled. But the unfilled 3*p* band overlaps the 3*s* band in energy, so there are lots of available states for the electrons to move into. Thus magnesium, too, is a good conductor.

In a material that is a good **insulator**, on the other hand, the highest band containing electrons, called the **valence band**, is completely filled. The next highest energy band, called the **conduction band**, is separated from the valence band by a "forbidden" **energy gap** (or **band gap**), $E_g$, of typically 5 to 10 eV. So at room temperature (300 K), where thermal energies (that is, average kinetic energy—see

PSE5_CH40_v1.7_23-Jun-20

Chapter 18) are on the order of $\frac{3}{2}kT \approx 0.04\,\text{eV}$, almost no electrons can acquire the 5 eV needed to reach the conduction band. When a potential difference is applied across the material, no available states are accessible to the electrons, and no current flows. Hence, the material is a good insulator.

Figure 40–32 compares the relevant energy bands (a) for conductors, (b) for insulators, and also (c) for the important class of materials known as **semiconductors**. The bands for a pure (or **intrinsic**) semiconductor, such as silicon or germanium, are like those for an insulator, except that the unfilled conduction band is separated from the filled valence band by a much smaller energy gap, $E_g$, which for silicon is $E_g = 1.12\,\text{eV}$. At room temperature, electrons are moving about with varying amounts of kinetic energy $\left(K = \frac{3}{2}kT\right)$, according to kinetic theory, Chapter 18. A few electrons can acquire enough thermal energy to reach the conduction band, and so a very small current may flow when a voltage is applied. At higher temperatures, more electrons have enough energy to jump the gap (top end of thermal distribution—see Fig. 18–3). Often this effect can more than offset the effects of more frequent collisions due to increased disorder at higher temperature, so the resistivity of semiconductors can *decrease* with increasing temperature (see Table 25–1). But this is not the whole story of semiconductor conduction. When a potential difference is applied to a semiconductor, the few electrons in the conduction band move toward the positive electrode. Electrons in the valence band try to do the same thing, and a few can because there are a small number of unoccupied states which were left empty by the electrons reaching the conduction band. Such unfilled electron states are called **holes**. Each electron in the valence band that fills a hole in this way as it moves toward the positive electrode leaves behind its own hole, so the holes migrate toward the negative electrode. As the electrons tend to accumulate at one side of the material, the holes tend to accumulate on the opposite side. We will look at this phenomenon in more detail in the next Section.

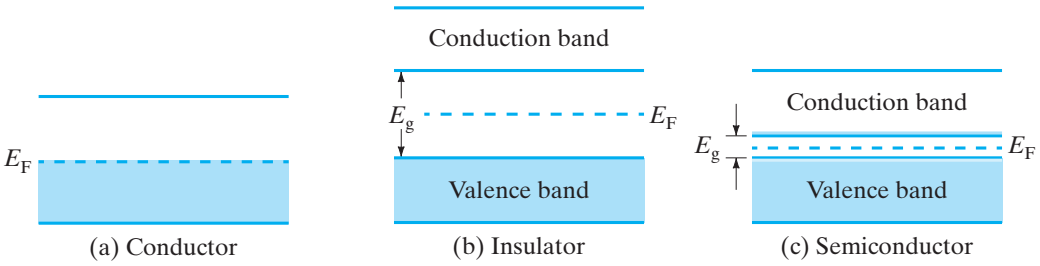

**FIGURE 40–32** Energy bands for (a) a conductor, (b) an insulator, which has a large energy gap $E_g$, and (c) a semiconductor, which has a small energy gap $E_g$. Shading represents occupied states. Pale shading in (c) represents electrons that can pass from the top of the valence band to the bottom of the conduction band due to thermal agitation at room temperature (exaggerated). The Fermi level $E_F$ is shown for each (see Example 40–13.)

**EXAMPLE 40–12** **Calculating the energy gap.** It is found that the conductivity of a certain semiconductor increases when light of wavelength 345 nm or shorter strikes it, suggesting that electrons are being promoted from the valence band to the conduction band. What is the energy gap, $E_g$, for this semiconductor?

**APPROACH** The longest wavelength (lowest energy) photon to cause an increase in conductivity has $\lambda = 345\,\text{nm}$, and its energy $(= hf)$ equals the energy gap.

**SOLUTION** The gap energy equals the energy of a $\lambda = 345\text{-nm}$ photon:

$$E_g = hf = \frac{hc}{\lambda} = \frac{(6.63\times10^{-34}\,\text{J}\cdot\text{s})(3.00\times10^{8}\,\text{m/s})}{(345\times10^{-9}\,\text{m})(1.60\times10^{-19}\,\text{J/eV})} = 3.6\,\text{eV}.$$

We can use the Fermi–Dirac statistics that we discussed in the previous Section also here, to make calculations on semiconductors, as the next Example shows.

**EXAMPLE 40–13** **ESTIMATE** **Free electrons in semiconductors and insulators.** Use the Fermi–Dirac probability function, Eq. 40–14, to estimate the order of magnitude of the numbers of free electrons in the conduction band of a solid containing $10^{21}$ atoms, assuming the solid is at room temperature ($T = 300\,\text{K}$) and is (*a*) a semiconductor with $E_g \approx 1.1\,\text{eV}$, (*b*) an insulator with $E_g \approx 5\,\text{eV}$. Compare to a conductor.

**CAUTION**
*For semiconductors and insulators, the Fermi level is between the valence and conduction bands*

**APPROACH** At $T = 0$, all states above the Fermi energy $E_F$ are empty, and all those below are full. So for semiconductors and insulators we can take $E_F$ to be about midway between the valence and conduction bands, Fig. 40–33, and it does not change significantly as we go to room temperature. We can thus use Eq. 40–14 to find the fraction of electrons in the conduction band at room temperature for the two cases.

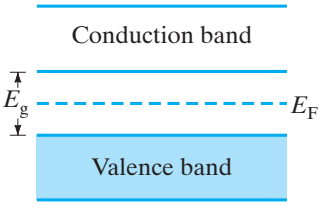

**FIGURE 40–33** Example 40–13: The Fermi energy is midway between the valence band and the conduction band.

**SOLUTION** (*a*) For the semiconductor, the gap $E_g \approx 1.1\,\text{eV}$, so $E - E_F \approx 0.55\,\text{eV}$ for the lowest states in the conduction band. Since at room temperature we have $kT \approx 0.026\,\text{eV}$, then $(E - E_F)/kT \approx 0.55\,\text{eV}/0.026\,\text{eV} \approx 21$ and

$$f(E) = \frac{1}{e^{(E-E_F)/kT} + 1} \approx \frac{1}{e^{21}} \approx 10^{-9}.$$

Thus about 1 atom in $10^9$ can contribute an electron to the conductivity.
(*b*) For the insulator with $E - E_F \approx 5.0\,\text{eV} - \frac{1}{2}(5.0\,\text{eV}) = 2.5\,\text{eV}$, we get

$$f(E) \approx \frac{1}{e^{2.5/0.026} + 1} \approx \frac{1}{e^{96}} \approx 10^{-42}.$$

Thus in an ordinary sample containing $10^{21}$ atoms, there would be no free electrons in an insulator $(10^{21} \times 10^{-42} = 10^{-21})$, about $10^{12}$ $(10^{21} \times 10^{-9})$ free electrons in a semiconductor, and about $10^{21}$ free electrons in a good conductor.

**PHYSICS APPLIED**
*Transparency*

**CONCEPTUAL EXAMPLE 40–14** **Which is transparent?** The energy gap for silicon is 1.12 eV at room temperature, whereas that of zinc sulfide (ZnS) is 3.6 eV. Which one of these is opaque to visible light, and which is transparent?

**RESPONSE** Visible light photons span energies from roughly 1.8 eV to 3.1 eV ($E = hf = hc/\lambda$ where $\lambda = 400\,\text{nm}$ to 700 nm and $1\,\text{eV} = 1.6 \times 10^{-19}\,\text{J}$). Light is absorbed by the electrons in a material. Silicon's energy gap is small enough to absorb these photons, thus bumping electrons well up into the conduction band, so silicon is opaque. On the other hand, zinc sulfide's energy gap is so large that no visible light photons would be absorbed; they would pass right through the material which would thus be transparent.

## 40–8 Semiconductors and Doping

Nearly all electronic devices today use semiconductors—mainly silicon (Si), although the first transistor (1948) was made with germanium (Ge). An atom of silicon has four outer electrons (group IV of the Periodic Table) that act to hold the atoms in the regular lattice structure of the crystal, shown schematically in

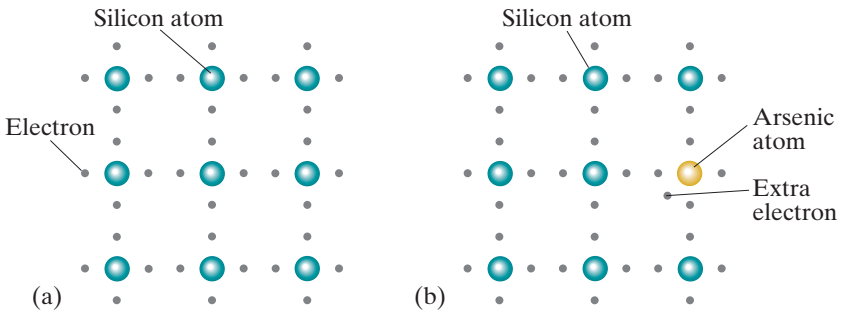

**FIGURE 40–34** Two-dimensional representation of a silicon crystal. (a) Four (outer) electrons surround each silicon atom. (b) Silicon crystal doped with a small percentage of arsenic atoms: the extra electron doesn't fit into the crystal lattice and so is free to move about. This is an *n*-type semiconductor.

Fig. 40–34a. Silicon acquires properties useful for electronics when a tiny amount of impurity is introduced into the crystal structure (perhaps 1 part in $10^6$ or $10^7$). This is called **doping** the semiconductor. Two kinds of doped semiconductor can be made, depending on the type of impurity used. The impurity can be an element whose atoms have five outer electrons (group V in the Periodic Table), such as arsenic. Then we have the situation shown in Fig. 40–34b, with a few arsenic atoms holding positions in the crystal lattice where normally silicon atoms are. Only four of arsenic's electrons fit into the bonding structure. The fifth does not fit in and can move relatively freely, somewhat like the electrons in a conductor. Because of this small number of extra electrons, a doped semiconductor becomes slightly conducting. The density of conduction electrons in an **intrinsic** (= undoped) semiconductor at room temperature is very low, usually less than 1 per $10^9$ atoms. With an impurity concentration of perhaps 1 in $10^6$ when doped, the conductivity will be much higher and it can be controlled with great precision. An arsenic-doped silicon crystal is an ***n*-type semiconductor** because *negative* charges (electrons) carry the electric current.

**CAUTION**

*Density of free electrons in intrinsic semiconductor is about 1 in $10^9$ atoms; if doped, about 1 in $10^6$*

In a ***p*-type semiconductor**, a small percentage of semiconductor atoms are replaced by atoms with three outer electrons (group III in the Periodic Table), such as boron. As shown in Fig. 40–35a, there is a **hole** in the lattice structure near a boron atom because it has only three outer electrons. An electron from a nearby silicon atom can jump into this hole and fill it. But this leaves a hole where that electron had previously been, Fig. 40–35b. The vast majority of atoms are silicon, so holes are almost always next to a silicon atom. Since silicon atoms require four outer electrons to be neutral, this means there is a net positive charge at the hole. Whenever an electron moves to fill a hole, the positive hole is then at the previous position of that electron. Another electron can then fill this hole, and the hole thus moves to a new location; and so on. This type of semiconductor is called ***p*-type** because it is the positive holes that carry the electric current.[†] Note, however, that both *p-type* and *n-type* semiconductors have *no net charge* on them.

**CAUTION**

*p-type semiconductors act as though + charges move—but electrons actually do the moving*

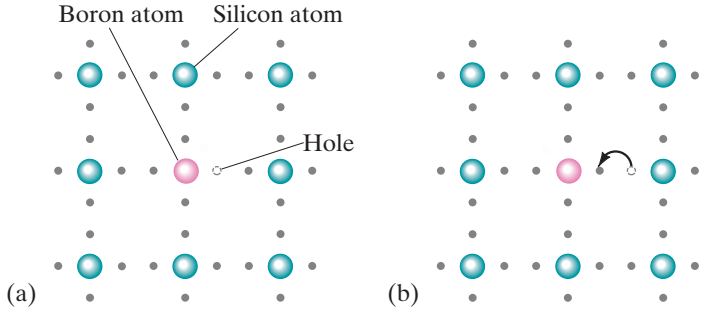

**FIGURE 40–35** A *p*-type semiconductor, boron-doped silicon. (a) Boron has only three outer electrons, so there is an empty spot, or *hole* in the structure. (b) An electron from a silicon atom can jump into the hole and fill it. As a result, the hole moves to a new location (to the right in this diagram), to where the electron used to be.

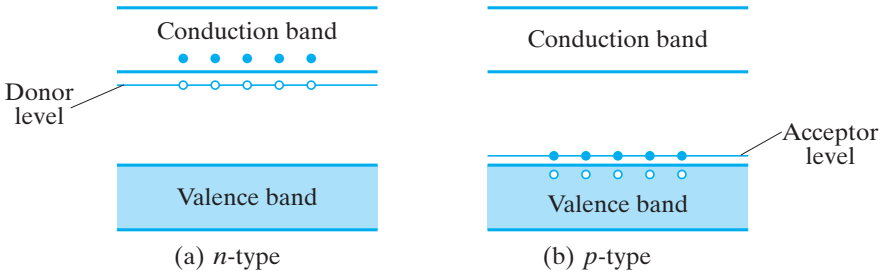
[†]Each electron that fills a hole moves a very short distance (~1 atom < 1 nm) whereas holes move much larger distances and so are the real carriers of the current. We can tell the current is carried by positive charges (holes) by using the Hall effect, Section 27–8.



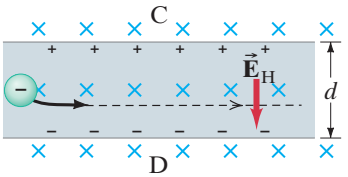


**FIGURE 40–36** Impurity energy levels in doped semiconductors.

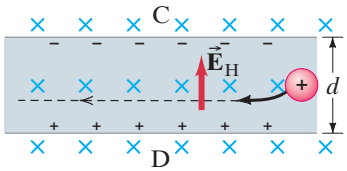

According to band theory (Section 40–7), in a doped semiconductor the impurity provides additional energy states between the bands as shown in Fig. 40–36. In an *n*-type semiconductor, the impurity energy level lies just below the conduction band, Fig. 40–36a. Electrons in this energy level need only about 0.05 eV in Si to reach the conduction band which is on the order of the thermal energy, $\frac{3}{2}kT$ ($\approx 0.04$ eV at 300 K). At room temperature, the tiny % of electrons in this donor level (roughly $\approx 1$ in $10^6$) can readily make the transition upward to the conduction band. This energy level can thus supply electrons to the conduction band, so it is called a **donor** level. In *p*-type semiconductors, the impurity energy level is just above the valence band (Fig. 40–36b). It is called an **acceptor** level because electrons from the valence band can jump into it with only average thermal energy. Positive holes are left behind in the valence band, and as other electrons move into these holes, the holes move as discussed earlier.

**EXERCISE G** Which of the following impurity atoms in silicon would produce a *p*-type semiconductor? (*a*) Ge; (*b*) Ne; (*c*) Al; (*d*) As; (*e*) Ga; (*f*) none of the above.

**FIGURE 27–33** (Repeated.) The Hall effect. (a) Negative charges moving to the right as the current. (b) The same current, but as positive charges moving to the left.

(a)

(b)

**CONCEPTUAL EXAMPLE 40–15** **Determining charge of conductors.** How can we determine if a *p*-type semiconductor has a current that is really due to the motion of holes? Or, is this just a convenient model?

**RESPONSE** Recall from Section 27–8 that the Hall effect can be used to distinguish the sign of the charges involved in a current. When placed in a magnetic field, the current in a particular direction can result in a voltage perpendicular to that current due to the magnetic force on the moving charges (Fig. 27–33, repeated here). The direction of this *Hall voltage* depends on the sign of the charges carrying the current. In this way, it has been demonstrated that it really is moving holes that are responsible for the current in a *p*-type semiconductor.

## 40–9 Semiconductor Diodes, LEDs, OLEDs

Semiconductor diodes and transistors are essential components of modern electronic devices. The miniaturization achieved today allows many billions of diodes, transistors, resistors, etc., to be fabricated (adding doping atoms) on a single *chip* less than a millimeter on a side.

At the interface between an *n*-type and a *p*-type semiconductor, a ***pn* junction diode** is formed. Separately, the two semiconductors are electrically neutral. But near the junction, a few electrons diffuse from the *n*-type into the *p*-type semiconductor, where they fill a few of the holes. The *n*-type is left with a positive charge, and the *p*-type acquires a net negative charge. Thus an "intrinsic" *potential difference* is established, with the *n* side positive relative to the *p* side, and this prevents further diffusion of electrons. The "junction" is actually a very thin layer between the charged *n* and *p* semiconductors where all holes are filled with electrons. This junction region is called the **depletion layer** (depleted of electrons and holes).†

†One way to form the *pn* boundary at the **nanometer** thickness on chips is to implant (or diffuse) *n*-type donor atoms into the surface of a *p*-type semiconductor, converting a layer of the *p*-type semiconductor into *n*-type.

If a battery is connected to a diode with the positive terminal to the *p* side and the negative terminal to the *n* side as in Fig. 40–37a, the externally applied voltage opposes the intrinsic potential difference and the diode is said to be **forward biased**. If the voltage is great enough, about 0.6 V for Si at room temperature, it overcomes that intrinsic potential difference and a large current can flow. The positive holes in the *p*-type semiconductor are repelled by the positive terminal of the battery, and the electrons in the *n*-type are repelled by the negative terminal of the battery. The holes and electrons meet at the junction, and the electrons cross over and fill the holes. A current is flowing. The positive terminal of the battery is continually pulling electrons off the *p* end, forming new holes, and electrons are being supplied by the negative terminal at the *n* end.

When the diode is **reverse biased**, as in Fig. 40–37b, the holes in the *p* end are attracted to the battery's negative terminal and the electrons in the *n* end are attracted to the positive terminal. Almost no current carriers meet near the junction and, ideally, no current flows.

A graph of current versus voltage for a typical diode is shown in Fig. 40–38. A forward bias greater than 0.6 V allows a large current to flow. In reverse bias, a real diode allows a small amount of reverse current to flow; for most practical purposes, it is negligible.†

The symbol for a diode is

[diode]

where the arrow represents the direction conventional (+) current flows readily.

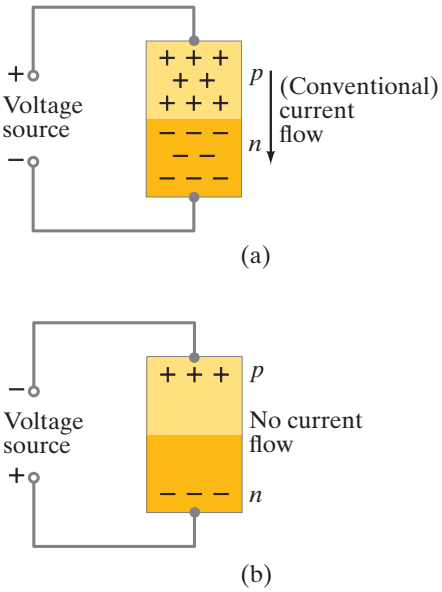

**FIGURE 40–37** Schematic diagram showing how a semiconductor diode operates. Current flows when the voltage is connected in forward bias, as in (a), but not when connected in reverse bias, as in (b).

**EXAMPLE 40–16** **A diode.** The diode whose current–voltage characteristics are shown in Fig. 40–38 is connected in series with a 4.0-V battery in forward bias and a resistor. If a current of 15 mA is to pass through the diode, what resistance must the resistor have?

**APPROACH** We use Fig. 40–38, where we see that the voltage drop across the diode is about 0.7 V when the current is 15 mA. Then we use simple circuit analysis and Ohm's law (Chapters 25 and 26).

**SOLUTION** The voltage drop across the resistor is $4.0\,\text{V} - 0.7\,\text{V} = 3.3\,\text{V}$, so $R = V/I = (3.3\,\text{V})/(1.5 \times 10^{-2}\,\text{A}) = 220\,\Omega$.

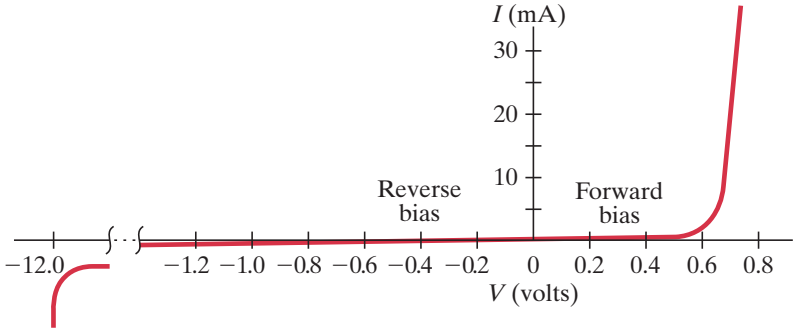

**FIGURE 40–38** Current through a silicon *pn* diode as a function of applied voltage.

A diode is called a **nonlinear device** because the current is not proportional to the voltage. That is, a graph of current versus voltage (Fig. 40–38) is not a straight line, as it is for a resistor (which ideally *is* linear).

## Zener Diode

If the voltage across a diode connected in reverse bias is increased greatly, breakdown occurs. The electric field across the junction becomes so large that ionization of atoms results. The electrons thus pulled off their atoms contribute to a larger and larger current as breakdown continues. The voltage remains constant over a wide range of currents. This is shown on the far left in Fig. 40–38.

†At room temperature, the reverse current is a few pA in Si; but it increases rapidly with temperature, and may render a diode ineffective above 200°C.

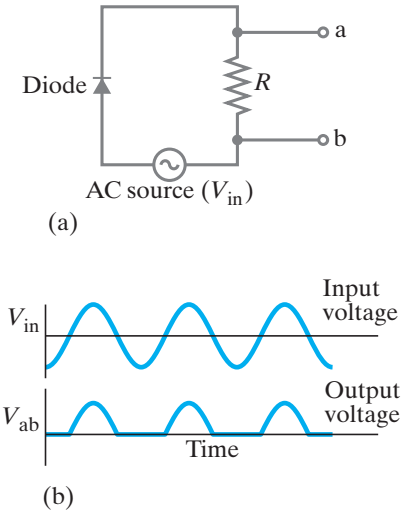

**FIGURE 40–39** (a) A simple (half-wave) rectifier circuit using a semiconductor diode. (b) AC source input voltage, and output voltage across $R$, as functions of time.

This property of diodes can be used to accurately regulate a voltage supply. A diode designed for this purpose is called a **zener diode**. When placed across the output of an unregulated power supply, a zener diode can maintain the voltage at its own breakdown voltage as long as the supply voltage is always above this point. Zener diodes can be obtained corresponding to voltages of a few volts to hundreds of volts.

## Rectifiers

Because a *pn* junction diode allows current to flow only in one direction (as long as the voltage is not too high), it can serve as a **rectifier**—to change ac into dc. A simple rectifier circuit is shown in Fig. 40–39a. The ac source applies a voltage across the diode alternately positive and negative. Only during half of each cycle will a current pass through the diode; only then is there a current through the resistor $R$. Hence, a graph of the voltage $V_{ab}$ across $R$ as a function of time looks like the output voltage shown in Fig. 40–39b. This **half-wave rectification** is not exactly dc, but it is unidirectional. More useful is a **full-wave rectifier** circuit, which uses two diodes (or sometimes four) as shown in Fig. 40–40a. At any given instant, either one diode or the other will conduct current to the right. Therefore, the output across the load resistor $R$ will be as shown in Fig. 40–40b. Actually this is the voltage if the capacitor $C$ were not in the circuit. The capacitor tends to store charge and, if the time constant $RC$ is sufficiently long, helps to smooth out the current as shown in Fig. 40–40c. (The variation in output shown in Fig. 40–40c is called **ripple voltage**.)

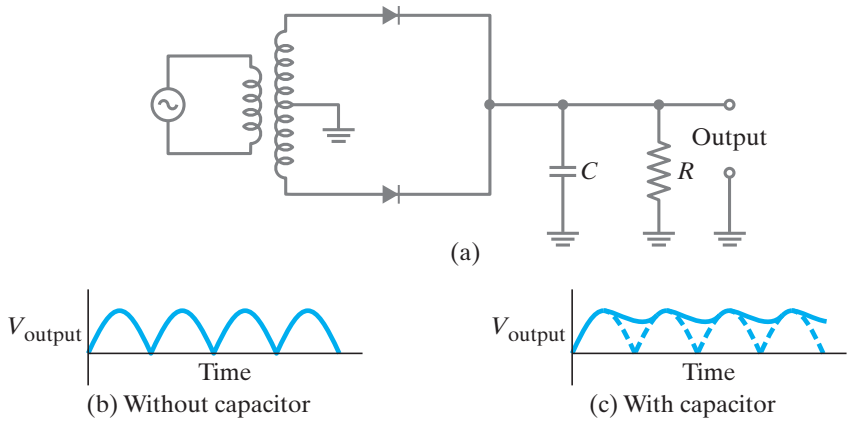

**FIGURE 40–40** (a) Full-wave rectifier circuit (including a transformer so the magnitude of the voltage can be changed). (b) Output voltage in the absence of capacitor $C$. (c) Output voltage with the capacitor in the circuit.

Rectifier circuits are important because most line voltage in buildings is ac, and most electronic devices require a dc voltage for their operation. Hence, diodes are found in nearly all electronic devices including radios, TV sets, computers, and chargers for cell phones and other devices.

## Photovoltaic Cells

**Solar cells**, also called **photovoltaic cells**, are rather heavily doped *pn* junction diodes used to convert sunlight into electric energy. Photons are absorbed, creating electron–hole pairs if the photon energy is greater than the band gap energy, $E_g$ (see Figs. 40–32c and 40–36). That is, the absorbed photon excites an electron from the valence band up to the conduction band, leaving behind a hole in the valence band. The created electrons and holes produce a current that, when connected to an external circuit, becomes a source of emf and power. A typical silicon *pn* junction may produce about 0.6 V. Many are connected in series to produce a higher voltage. Such series strings are connected in parallel within a **photovoltaic panel**. Research includes experimenting with combinations of semiconductors. A good photovoltaic panel can have an output of perhaps 50 W/m$^2$, averaged over

PSE5_CH40_v1.7_23-Jun-20

day and night, sunny and cloudy. The world's total electricity demand is on the order of $10^{12}$ W, which could be met with solar cells covering an area of only about 200 km × 200 km of Earth's surface.[†]

**Photodiodes** (Section 37–2) and **semiconductor particle detectors** (Section 41–11) operate similarly.

## LEDs

PHYSICS APPLIED
*LEDs and applications*
*Car safety (brakes)*

A **light-emitting diode (LED)** is sort of the reverse of a photovoltaic cell. When a *pn* junction is forward biased, a current begins to flow. Electrons cross from the *n*-region into the *p*-region, recombining with holes, and a photon can be emitted with an energy about equal to the band gap energy, $E_g$. This does not work well with silicon diodes.[‡] But high light-emission is achieved with **compound semiconductors**, typically involving a group III and a group V element such as gallium and arsenic (= gallium arsenide = GaAs). Remarkably, GaAs has a crystal structure very similar to Si. See Fig. 40–41. For doping of GaAs, group VI atoms (like Se) can serve as donors, and group II atoms (valence +2, such as Zn) as acceptors. The energy gap for GaAs is $E_g = 1.42$ eV, corresponding to near-infrared photons with wavelength 870 nm (almost visible). Such infrared LEDs are suitable for use in remote-control devices for TVs, DVD players, stereos, car door locks, and so on.

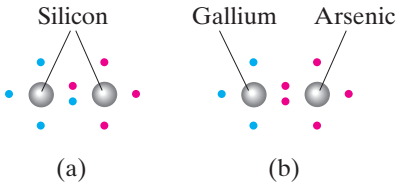

**FIGURE 40–41** (a) Two Si atoms forming the covalent bond showing the electrons in different colors for each of the two separate atoms. (In Fig. 40–34a we showed each atom separately to emphasize the four outer electrons in each.) (b) A gallium–arsenic pair, also covalently bonded.

The first visible-light LED, developed in the early 1960s, was made of a semiconductor compound of gallium, arsenic, and phosphorus (= GaAsP) which emitted red light. The red LED soon found use as the familiar indicator lights (on–off) on electronic devices, and as the bright red read-out on calculators and digital clocks (brighter than the dimmer LCD readouts which rely on reflected light and cannot be seen in the dark unless there is built-in backlighting). Further development led to LEDs with higher $E_g$ and shorter wavelengths: first yellow, then finally in 1995, blue (InGaN). A blue LED was important because it gave the possibility of a **white-light LED**. White light can be approximated by LEDs in two ways: (1) using a red, a yellow–green, and a blue LED; (2) using a blue LED with coatings of "powders" or "phosphors" that are fluorescent (Section 39–8). For the latter, the high-energy blue LED photons are themselves emitted, plus they can excite the various phosphors to excited states which decay in two or more steps, emitting light of lower energy and longer wavelengths. Figure 40–42 shows typical spectra of both types. The first type, shown in Fig. 40–42a, can contain 4 or 5 LED types to better reproduce the full visible spectrum. Today the second type with phosphors (Fig. 40–42b) produces such good white color that it is used for household bulbs and even in museums.[§]

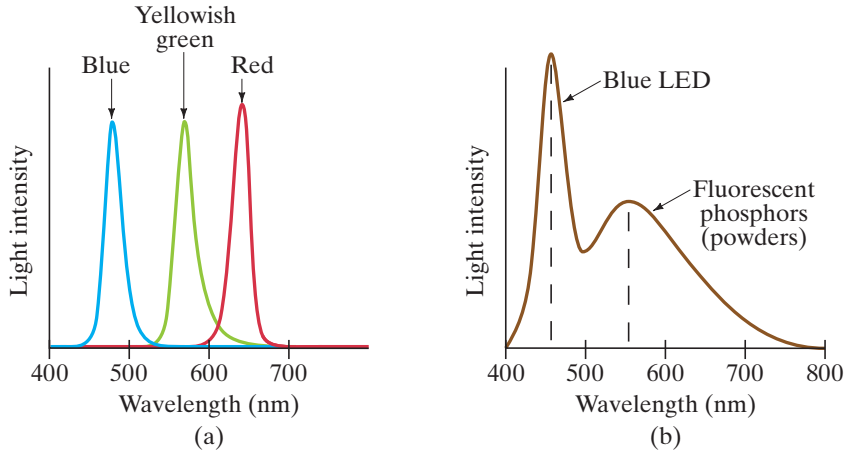

**FIGURE 40–42** (a) A combination of three LEDs of three different colors gives a sort of white color, but there are large wavelength gaps, so some colors would not be reflected and would appear black. (b) A blue LED with fluorescent phosphors or powders gives a better approximation of white light. (Thanks to M. Vannoni and G. Molesini for (b).)

[†]Electricity makes up about 5% of total global energy use.

[‡]Electron-hole recombination in silicon results mostly in heat, as lattice vibrations called **phonons**.

[§]The renowned frescoes by Michelangelo in the Sistine Chapel (Rome) are now lit only by LED lighting.

**FIGURE 40–43** LED flashlights. Note the tiny LEDs, each maybe $\frac{1}{2}$ cm in diameter.

LED "bulbs" are also used in flashlights (Fig. 40–43), street lighting, traffic signals, car brake lights, billboards, backlighting for LCD screens, and large display screens at stadiums.

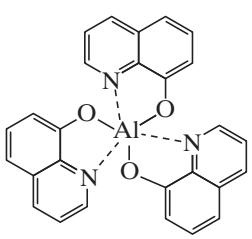
LED lights, sometimes called **solid-state** lighting, are longer-lived (20,000 to 50,000 hours vs. 1000–2000 for ordinary bulbs), more efficient (on the order of 10 times better), and rugged. A small town in Italy, Torraca, was the first to have all its street lighting be LED (2007). LEDs can be as small as 1 or 2 mm wide, and are individual units with wires connected directly to them. They can be used for large TV screens in stadiums, but a home TV is not yet available and would require much smaller LED size, meaning fabrication of many on a crystalline semiconductor, and the pixels would be addressed as discussed in Section 23–10 for LCD screens. [When you see a home TV advertised as LED, it is an LCD screen (Section 34–8) using LEDs as the backlight.]

## *Pulse Oximeter

A **pulse oximeter** uses two LEDs to measure the % oxygen ($O_2$) saturation in your blood. One LED is red, 660 nm, and the other IR (900–940 nm). The LED beams pass through a finger (Fig. 40–44) or earlobe and are detected by a photodiode. Oxygenated red blood cells absorb less red and more infrared light than deoxygenated cells. A ratio of absorbed light (red/IR) of 0.5 corresponds to nearly 100% $O_2$ saturation; a ratio of 1.0 is about 85% and 2.0 corresponds to about 50% (bad). The LED measures during complete pulses, including blood surges, and the device can also count your heartbeat rate.

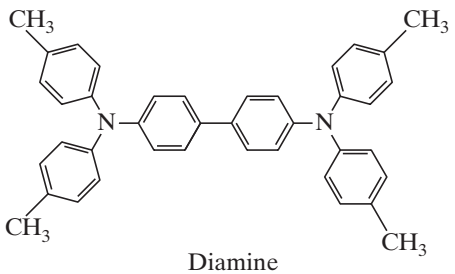
**FIGURE 40–44** A pulse oximeter.

## **pn* Diode Lasers



**Diode lasers**, using a *pn*-junction in forward bias like an LED, are the most compact of lasers and are very common: they read CDs and DVDs and are used as pointers and in laser printers. They emit photons like an LED but, like all lasers (Section 39–9), need to have an *inverted population* of states for the lasing frequency. This is achieved by applying a high forward-bias voltage. The large current brings many electrons into the conduction band at the junction layer, and holes into the valence band, and before the electrons have time to combine with holes, they form an inverted population. When one electron drops down into a hole and emits a photon, that photon stimulates other electrons to drop down as well, *in phase*, creating coherent laser light. Opposite ends of the crystal are made parallel and very smooth so they act as the mirrors needed for lasing, as shown in our laser diagram, Fig. 39–19.

## *OLED (Organic LED)



Many organic compounds have semiconductor properties. Useful ones can have mobile electrons and holes. A practical organic **electroluminescent (EL)** device, an **organic light-emitting diode (OLED)** was first described in the late 1980s.

Organic compounds contain carbon (C), hydrogen (H), often nitrogen and oxygen, and sometimes other atoms. We usually think of them as coming from life—plants and animals. They are also found in petroleum, and some can be synthesized in the lab. Organic compounds can be complex, and often contain the familiar hexagonal "benzene ring" with C atoms at all (or most) of the six corners. The two organic compounds shown in Fig. 40–45 were used as *n*-type and *p*-type layers in the earliest useful OLED. **Polymers**, long organic molecules with repeating structural units, can also be used for an OLED.

**FIGURE 40–45** These two organic molecules were used in the first OLEDs (1987). The hexagons have carbon at each corner, and an attached hydrogen, unless otherwise noted.

$Alq_3$

Diamine

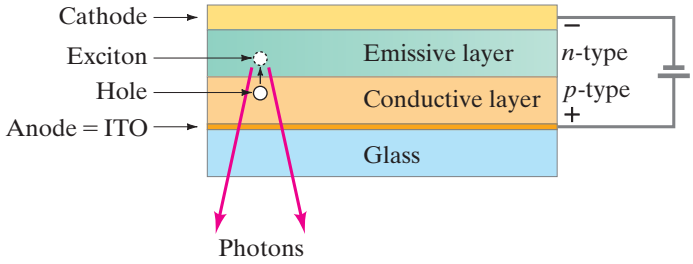


**FIGURE 40–46** An OLED with two organic layers. Hole–electron recombination into an exciton (dashed circle) occurs in the emissive layer, followed by photon emission. Photons emitted in the wrong direction (upward in the diagram) reduce efficiency.

The simplest OLED consists of two organic layers, the **emissive layer** and the **conductive layer**, each 20 to 50 nm thick, sandwiched between two electrodes, Fig. 40–46. The anode is typically transparent, to let the light out. It can be made of a very thin layer of indium–tin oxide (**ITO**), which is transparent and conductive, coated on a glass slab. The cathode is often metallic, but could also be made of transparent material.

OLEDs can be smaller and thinner than ordinary inorganic LEDs. They can be more easily constructed as a unit for a screen display than for inorganic LEDs. Their use as screens on cell phones, cameras, and TVs produces greater contrast, and they need less power (important for battery life of portable devices) than LCD screens. Why? They need no backlight (like LCDs) because they emit the light themselves. OLEDs can be fabricated as a matrix, usually active matrix (**AMOLED**), using the same type of addressing described in Section 23–10 for LCDs. OLED displays are much thinner than LCDs and retain brightness at larger viewing angles. They can even be fabricated on curved or flexible substrates—try the windshield of your car (Fig. 40–47). The array may be RGBG (similar to a Bayer mosaic, Fig. 33–18) or RGBW where W = white is meant to give greater brightness. The subpixels can also be stacked, one above the other (similar to the Foveon, Fig. 33–19).

**FIGURE 40–47** Head up displays on curved windshields can use curved OLEDs to show, for example, your speed without having to look down at the speedometer.

## *OLED Functioning (advanced)

According to band theory, when a voltage is applied ($\approx 2$ to 5 V), electrons are attracted or "injected" (engineering term) into energy states of the **lowest unoccupied molecular orbitals (LUMO)** of the emissive layer. At the same time, electrons are withdrawn from the **highest occupied molecular orbitals (HOMO)** of the conductive layer—which is equivalent to **holes** being "injected" into the conductive layer. The LUMO and HOMO energy levels are analogous to the conduction and valence bands of inorganic silicon diodes (Fig. 40–36). Holes travel in the HOMO, electrons in the LUMO. ("Orbital" is a chemistry word for the states occupied by the electrons in a molecule.)

When electrons and holes meet near the junction (Fig. 40–46), they can form a sort of bound state (like in the hydrogen atom) known as an **exciton**. An exciton has a small binding energy (0.1 to 1 eV), and a very short lifetime on the order of nanoseconds. When an exciton "decays" (the negative electron and positive hole combine), a photon is emitted. These photons are the useful output.

The energy $hf$ of the photon, and its frequency corresponding to the color, depends on the energy structure of the exciton. The energy gap, LUMO–HOMO, sets an upper limit on $hf$, but the vibrational energy levels of the molecules reduce that by varying amounts, as does the binding energy of the exciton. The spectrum has a peak, like those in Fig. 40–42a, but is wider, 100–200 nm at half maximum. The organic molecules are chosen so that the photons have frequencies in the color range desired, say for a display subpixel: bluish (B), greenish (G), or red (R).

The conductive layer is also called the **hole transport layer (HTL)**, which name expresses its purpose. The emissive layer, on the other hand (Fig. 40–46), serves two purposes: (1) it serves to transport electrons toward the junction, and (2) it is in this layer (near the junction) that holes meet electrons to form excitons and then combine and emit light. These two functions can be divided in a more sophisticated OLED that has three layers: Adjacent to the cathode is the **electron transport layer (ETL)**, plus there is an **emissive layer (EML)** sandwiched between the ETL and the HTL. The emissive layer can be complex, containing a **host** material plus a **guest** compound in small concentration—a kind of doping—to fine-tune energy levels and efficiency.

# 40–10 Transistors: Bipolar and MOSFETs

The **bipolar junction transistor** was invented in 1948 by J. Bardeen, W. Shockley, and W. Brattain. It consists of a crystal of one type of doped semiconductor sandwiched between two of the opposite type. Both *npn* and *pnp* transistors can be made, and they are shown schematically in Fig. 40–48a. The three semiconductors are given the names **collector**, **base**, and **emitter**. The symbols for *npn* and *pnp* transistors are shown in Fig. 40–48b. The arrow is always placed on the emitter and indicates the direction of (conventional) current flow in normal operation.

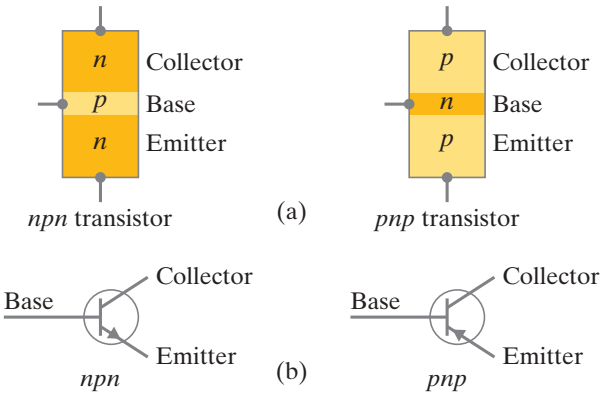

**FIGURE 40–48** (a) Schematic diagram of *npn* and *pnp* transistors. (b) Symbols for *npn* and *pnp* transistors.

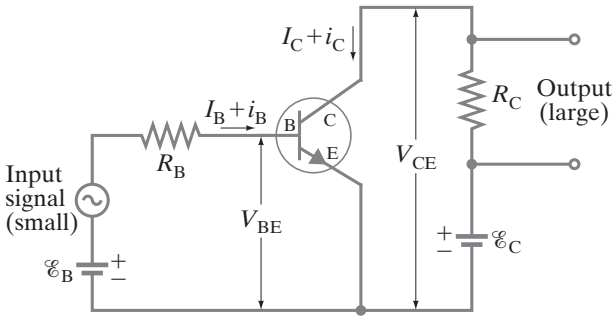

**FIGURE 40–49** An *npn* transistor used as an amplifier. $I_B$ is the current produced by $\mathscr{E}_B$ (in the absence of a signal), $i_B$ is the ac signal current (= change in $I_B$).

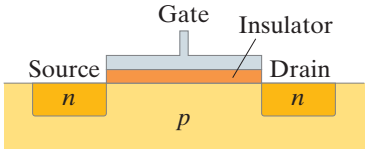
The operation of an *npn* transistor as an **amplifier** is shown in Fig. 40–49. A dc voltage $V_{CE}$ is maintained between the collector and emitter by battery $\mathscr{E}_C$. The voltage applied to the base is called the *base bias voltage*, $V_{BE}$. If $V_{BE}$ is positive, conduction electrons in the emitter are attracted into the base. The base region is very thin, much less than 1 $\mu$m, so most of these electrons flow right across into the collector which is maintained at a positive voltage. A large current, $I_C$, flows between collector and emitter and a much smaller current, $I_B$, through the base. In the steady state, $I_B$ and $I_C$ can be considered dc. But a small variation (= ac) in the base voltage due to an input signal attracts (or repels) charge that passes through into the collector and thus can cause a large *change* in the collector current and a large change in the voltage drop across the output resistor $R_C$. Hence a transistor can *amplify* a small signal into a larger one.

Typically a small ac signal (call it $i_B$) is to be amplified, and when added to the base bias current (and voltage) causes the current and voltage at the collector to vary at the same rate but magnified. Thus, what is important for amplification is the *change* in collector current for a given input *change* in base current. We label these ac signal currents (= changes in $I_C$ and $I_B$) as $i_C$ and $i_B$. The **current gain** is defined as the ratio

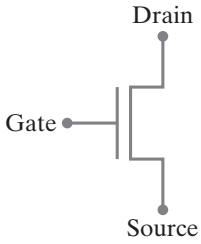
$$\beta_I = \frac{\text{output (collector) ac current}}{\text{input (base) ac current}} = \frac{i_C}{i_B}.$$

$\beta_I$ may be on the order of 10 to 100. Similarly, the **voltage gain** is



$$\beta_V = \frac{\text{output (collector) ac voltage}}{\text{input (base) ac voltage}}.$$

Transistors are the basic elements in modern electronic amplifiers of all sorts.



A *pnp* transistor operates like an *npn*, except that holes move instead of electrons. The collector voltage is negative, and so is the base voltage in normal operation.

Another kind of transistor, very important, is the **MOSFET** (metal-oxide semiconductor field-effect transistor) common in **digital circuits** as a type of switch. Its construction is shown in Fig. 40–50a, and its symbol in Fig. 40–50b. What is called the emitter in a bipolar transistor is called the **source** in a MOSFET, and the collector is called the **drain**. The base is called the **gate**. The gate acts to let a current flow, or not, from the source to the drain, depending on the electric field it (the gate)

**FIGURE 40–50** (a) Construction of a MOSFET of *n*- and *p*-type semiconductors and a gate of metal or heavily doped silicon (= a good conductor). (b) Symbol for a MOSFET which suggests its function.

(a)

(b)

provides across an insulator that separates it from the *p*-type semiconductor below, Fig. 40–50a. Hence the name "field-effect transistor" (FET).[†] MOSFETs are often used like switches, on or off, which in digital circuits can allow the storage of a binary bit, a "1" or a "0." We discussed uses of MOSFETs relative to digital TV (Section 23–10) and computer memory storage (Section 29–8).

## *40–11 Integrated Circuits, 14-nm Technology

Although individual transistors are very small compared to the once-used vacuum tubes, they are huge compared to **integrated circuits** or **chips** (photo at start of this Chapter), invented in 1959 independently by Jack Kilby and Robert Noyce. Tiny amounts of impurities can be inserted or injected at particular locations within a single silicon crystal or wafer. These can be arranged to form diodes, transistors, resistors (undoped semiconductors), and very thin connecting "wires" (= conductors) which are heavily doped thin lines. Capacitors and inductors can also be formed, but also can be connected separately. Integrated circuits are the heart of computers, televisions, calculators, cameras, cell phones, and the electronic instruments that control aircraft, space vehicles, and automobiles.

A tiny chip, a few millimeters on a side, may contain billions of transistors and other circuit elements. The number of elements/mm$^2$ has been doubling every 2 or 3 years. We often hear of the **technology generation**, which is a number that refers to the minimum width of a conducting line ("wire") or to the gate of a MOSFET (which may be slightly smaller than a wire). Since 2003 we have passed from 90-nm technology to 65-nm, to 45-nm, to 32-nm, to 22-nm, every 2 to 3 years, and now 14-nm technology. The next step to 10-nm, which means less than 20 atoms wide, may involve new structures and quantum-mechanical effects, and may not be easy to achieve. Smaller means more diodes and transistors per mm$^2$ and therefore greater speed (faster response time) because the distance signals have to travel is less. Smaller also can mean lower power consumption and longer battery life, as well as slimmer and lighter devices. Size, speed, and power have all been improved 10 to 100 million times in the last half century or so.

[†]The "MOS" comes from a version with a **M**etal gate, silicon di**O**xide insulator, and a **S**emiconductor (*p*-type shown in Fig. 40–50a). The gate can also be heavily doped silicon (= good conductor).

## Summary

Quantum mechanics explains the bonding together of atoms to form **molecules**. In a **covalent bond**, the atoms share electrons. The electron clouds of two or more atoms overlap because of constructive interference between the electron waves. The positive nuclei are attracted to this concentration of negative charge between them, forming the bond.

An **ionic bond** is an extreme case of a covalent bond in which one or more electrons from one atom spend much more time around the other atom than around their own. The atoms then act as oppositely charged ions that attract each other, forming the bond.

These **strong bonds** hold molecules together, and also hold atoms and molecules together in solids. Also important are **weak bonds** (or **van der Waals bonds**), which are generally dipole attractions between molecules.

When atoms combine to form molecules, the energy levels of the outer electrons are altered because they now interact with each other. Additional energy levels also become possible because the atoms can vibrate with respect to each other, and the molecule as a whole can rotate. The energy levels for both vibrational and rotational motion are quantized, and are very close together (typically, $10^{-1}$ eV to $10^{-3}$ eV apart). Each atomic energy level thus becomes a set of closely spaced levels corresponding to the vibrational and rotational motions. Transitions from one level to another appear as many very closely spaced lines. The resulting spectra are called **band spectra**.

The quantized rotational energy levels are given by

$$E_{\text{rot}} = \ell(\ell + 1)\frac{\hbar^2}{2I}, \qquad \ell = 0, 1, 2, \cdots, \qquad \textbf{(40–2)}$$

where $I$ is the moment of inertia of the molecule.

The energy levels for vibrational motion are given by

$$E_{\text{vib}} = \left(\nu + \tfrac{1}{2}\right)hf, \qquad \nu = 0, 1, 2, \cdots, \qquad \textbf{(40–6)}$$

where $f$ is the classical natural frequency of vibration for the molecule. Transitions between energy levels are subject to the selection rules $\Delta\ell = \pm 1$ and $\Delta\nu = \pm 1$.

Some **solids** are bound together by covalent and ionic bonds, just as molecules are. In metals, the electrostatic force between free electrons and positive ions helps form the **metallic bond**.

In the free-electron theory of metals, electrons occupy the possible energy states according to the exclusion principle. At $T = 0\,\text{K}$, all possible states are filled up to a maximum energy level called the **Fermi energy**, $E_F$, the magnitude of which is typically a few eV. All states above $E_F$ are vacant at $T = 0\,\text{K}$.

At normal temperatures (300 K) the distribution of occupied states is only slightly altered and is given by the **Fermi–Dirac probability function**

$$f(E) = \frac{1}{e^{(E-E_F)/kT} + 1}. \qquad \textbf{(40–14)}$$

In a crystalline solid, the possible energy states for electrons are arranged in **bands**. Within each band the levels are very close together, but between the bands there may be forbidden **energy gaps**. Good conductors are characterized by the highest occupied band (the **conduction band**) being only partially full, so lots of states are available to electrons to move about and accelerate when a voltage is applied. In a good insulator, the highest occupied energy band (the **valence band**) is completely full, and there is a large energy gap (5 to 10 eV) to the next highest band, the *conduction band*. At room temperature, molecular kinetic energy (thermal energy) available due to collisions is only about 0.04 eV, so almost no electrons can jump from the valence to the conduction band in an insulator. In a **semiconductor**, the gap between valence and conduction bands is much smaller, on the order of 1 eV, so a few electrons can make the transition from the essentially full valence band to the nearly empty conduction band, allowing a small amount of conductivity.

In a **doped** silicon semiconductor, a small percentage of impurity atoms with five or three valence electrons replace a few of the normal silicon atoms with their four valence electrons. A five-electron impurity produces an ***n*-type** semiconductor with negative electrons as carriers of current. A three-electron impurity produces a ***p*-type** semiconductor in which positive **holes** carry the current. The energy level of impurity atoms lies slightly below the conduction band in an *n*-type semiconductor, and acts as a **donor** from which electrons readily pass into the conduction band. The energy level of impurity atoms in a *p*-type semiconductor lies slightly above the valence band and acts as an **acceptor** level, since electrons from the valence band easily reach it, leaving holes behind to act as charge carriers.

A semiconductor **diode** consists of a ***pn* junction** and allows current to flow in one direction only; *pn* junction diodes are used as **rectifiers** to change ac to dc, as photovoltaic cells to produce electricity from sunlight, and as lasers. **Light-emitting diodes (LED)** use compound semiconductors which can emit light when a forward-bias voltage is applied; uses include readouts, infrared remote controls, normal lighting (household light bulbs, flashlights, street lights), and very large TV screens. LEDs using organic molecules or polymers (**OLED**) are used as screens on cell phones and other displays. Common **transistors** consist of three semiconductor sections, either as ***pnp*** or ***npn***. Transistors can amplify electrical signals and in computers serve as switches or **gates** for the 1s and 0s of digital bits. An integrated circuit consists of a tiny semiconductor crystal or **chip** on which many transistors, diodes, resistors, and other circuit elements are constructed by placement of impurities.

# Questions

1. What type of bond would you expect for (*a*) the $N_2$ molecule, (*b*) the HCl molecule, (*c*) Fe atoms in a solid?
2. Describe how the molecule $CaCl_2$ could be formed.
3. Does the $H_2$ molecule have a permanent dipole moment? Does $O_2$? Does $H_2O$? Explain.
4. Although the molecule $H_3$ is not stable, the ion $H_3^+$ is. Explain, using the Pauli exclusion principle.
5. Would you expect the molecule $H_2^+$ to be stable? If so, where would the single electron spend most of its time?
6. Compare the potential energy diagram for an $H_2$ molecule with the potential energy diagram for ATP formation from ADP and Ⓟ. Explain the significance of the difference in shapes of the two diagrams. (See Section 40–2.)
7. Explain why the carbon atom $(Z = 6)$ usually forms four bonds with hydrogen-like atoms.
8. The energy of a molecule can be divided into four categories. What are they?
9. (*a*) Why are weak bonds important in cells? (*b*) Explain why heating proteins too much may cause them to denature—that is, lose the specific shape they need to function. (See Section 40–3.) (*c*) What is the strongest weak bond, and why? (*d*) If this bond, and the other weak bonds, were stronger (that is, too strong), what would be the consequence for protein synthesis?
10. Explain why metals are shiny.
11. If conduction electrons are free to roam about in a metal, why don't they leave the metal entirely?
12. Explain why the resistivity of metals increases with increasing temperature whereas the resistivity of semiconductors may decrease with increasing temperature.
13. Compare the resistance of a *pn* junction diode connected in forward bias to its resistance when connected in reverse bias.
14. Explain on the basis of energy bands why the sodium chloride crystal is a good insulator. [*Hint*: Consider the shells of $Na^+$ and $Cl^-$ ions.]
15. Which aspects of Fig. 40–28 are peculiar to copper, and which are valid in general?
16. What is the main difference between *n*-type and *p*-type semiconductors?
17. A silicon semiconductor is doped with phosphorus. Will these atoms be donors or acceptors? What type of semiconductor will this be?
18. Figure 40–51 shows a "bridge-type" full-wave rectifier. Explain how the current is rectified and how current flows during each half cycle.

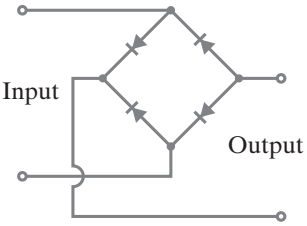


**FIGURE 40–51**
Question 18.

19. A transistor can amplify an electronic signal, meaning it can increase the power of an input signal. Where does it get the energy to increase the power?

**20.** In a transistor, the base–emitter junction and the base–collector junction are essentially diodes. Are these junctions reverse-biased or forward-biased in the application shown in Fig. 40–49?

**21.** Do diodes and transistors obey Ohm's law? Explain.

**22.** Can a diode be used to amplify a signal? Explain.

**23.** Explain how a transistor can be used as a switch.

## MisConceptual Questions

**1.** Which of the following is true for covalently bound diatomic molecules such as $H_2$?
(*a*) All electrons in the two atoms have identical quantum numbers.
(*b*) The molecule has fewer electrons than the two separate atoms do.
(*c*) The molecule has less energy than two separate atoms.
(*d*) The energy of the molecule is greatest when the atoms are separated by one bond length.

**2.** A hydrogen atom $(Z = 1)$ is bonded to a lithium atom $(Z = 3)$ in lithium hydride, LiH. Which of the following are possible spin states of the two shared electrons?
(*a*) $+\frac{1}{2}, +\frac{1}{2}$.
(*b*) $-\frac{1}{2}, -\frac{1}{2}$.
(*c*) $+\frac{1}{2}, -\frac{1}{2}$.
(*d*) Both (*a*) and (*b*).
(*e*) Any of the above.

**3.** Ionic bonding is related to
(*a*) magnetic dipole interactions.
(*b*) the transfer of one or more electrons from one atom to another.
(*c*) the sharing of electrons among atoms.
(*d*) the transfer of electrons to the solid.
(*e*) oscillation dipoles.

**4.** Consider Fig. 40–11. As the last phosphate group approaches and then bonds to the ADP molecule, which of the following is true? Choose all that apply.
(*a*) The phosphate group is first repelled and then attracted to the ADP molecule.
(*b*) The phosphate group is always attracted to the ADP molecule.
(*c*) The phosphate group is always repelled by the ADP molecule.
(*d*) The system first loses and then stores potential energy.
(*e*) Both binding energy and activation energy are negative.
(*f*) Both binding energy and activation energy are positive.

**5.** Which type of bond holds the molecules of the DNA double helix together?
(*a*) Covalent bond.
(*b*) Ionic bond.
(*c*) Einstein bond.
(*d*) Van der Waals bond.

**6.** Which of the following is usually the weakest bond?
(*a*) Hydrogen bond.
(*b*) Covalent bond.
(*c*) Ionic bond.
(*d*) Van der Waals bond.

**7.** Which of the following apply to metallic bonds?
(*a*) Free electrons are shared by all atoms.
(*b*) Atoms bond to hydrogen molecules.
(*c*) Unequal charge distributions around neutral atoms create strong bonds.
(*d*) Electrons are stolen from one atom by another.

**8.** Why are metals good conductors?
(*a*) Gaining a tiny bit of energy by applying a voltage allows their electrons to move.
(*b*) They have more electrons than protons, so some of the electrons are extra and free to move.
(*c*) They have more protons than electrons, so some of the protons are extra and free to move.
(*d*) Gaining a tiny bit of energy allows their protons to move.
(*e*) Electrons are tightly bound to their atoms.

**9.** The speed of the conduction electrons in a metal
(*a*) is nearly the speed of light.
(*b*) depends mostly on the Fermi energy.
(*c*) depends on the absolute temperature according to $v = \sqrt{3KT/m}$.
(*d*) depends mostly on the current flow.

**10.** In an insulator
(*a*) electrons must gain a large amount of energy to find an empty state in the conduction band.
(*b*) there is a slight deficit of electrons making it difficult for electrons to move.
(*c*) the exclusion principle keeps electrons out of the conduction band.
(*d*) there is no conduction band in an insulator.

**11.** Doping a semiconductor will
(*a*) increase the number of outer electrons of atoms.
(*b*) decrease the number of outer electrons of atoms.
(*c*) change the size of the band gap.
(*d*) either (*a*) or (*b*).
(*e*) either (*a*), (*b*), or (*c*).

**12.** In a *p*-type semiconductor, a hole is
(*a*) a region in the molecular structure where an atom is missing.
(*b*) an extra electron from one of the donor atoms.
(*c*) an extra positively charged particle in the molecular structure.
(*d*) a region missing an electron relative to the rest of the molecular structure.

**13.** Which of the following would *not* be used as an impurity in doping silicon?
(*a*) Germanium.
(*b*) Gallium.
(*c*) Boron.
(*d*) Phosphorus.
(*e*) Arsenic.

**14.** Which of the following statements about a diode is true?
(*a*) When reverse biased, a diode normally passes very little current.
(*b*) When you double the voltage applied across a forward biased diode, you double the current flowing through it.
(*c*) A diode is either *npn* or *pnp*.
(*d*) A forward biased diode always has the same current flow regardless of the applied voltage.
(*e*) None of these statements are true.

# Problems

## 40–1 to 40–3 Molecular Bonds

1. (I) Estimate the binding energy of a KCl molecule by calculating the electrostatic potential energy when the $K^+$ and $Cl^-$ ions are at their stable separation of 0.28 nm. Assume each has a charge of magnitude 1.0 $e$.
2. (II) The measured binding energy of KCl is 4.43 eV. From the result of Problem 1, estimate the contribution to the binding energy of the repelling electron clouds at the equilibrium distance $r_0 = 0.28$ nm.
3. (II) The equilibrium distance $r_0$ between two atoms in a molecule is called the **bond length**. Using the bond lengths of homogeneous molecules (like $H_2$, $O_2$, and $N_2$), one can estimate the bond length of heterogeneous molecules (like CO, CN, and NO). This is done by summing half of each bond length of the homogenous molecules to estimate that of the heterogeneous molecule. Given the following bond lengths: $H_2$ (= 74 pm), $N_2$ (= 145 pm), $O_2$ (= 121 pm), $C_2$ (= 154 pm), estimate the bond lengths for: HN, CN, and NO.
4. (II) Binding energies are often measured experimentally in kcal per mole, and then the binding energy in eV per molecule is calculated from that result. What is the conversion factor in going from kcal per mole to eV per molecule? What is the binding energy of KCl (= 4.43 eV) in kcal per mole?
5. (III) Estimate the binding energy of the $H_2$ molecule, assuming the two H nuclei are 0.074 nm apart and the two electrons spend 33% of their time midway between them.
6. (III) Estimate the energy associated with the repulsion of the electron shells of a lithium fluoride (LiF) molecule. The ionization energy of lithium is 5.39 eV, and it takes 3.41 eV to remove the extra electron from an $F^-$ ion. The bond length is 0.156 nm, and the binding energy of LiF is 5.95 eV.
7. (III) (*a*) Apply reasoning similar to that in the text for the $S = 0$ and $S = 1$ states in the formation of the $H_2$ molecule to show why the molecule $He_2$ is *not* formed. (*b*) Explain why the $He_2^+$ molecular ion *could* form. (Experiment shows it has a binding energy of 3.1 eV at $r_0 = 0.11$ nm.)

## 40–4 Molecular Spectra

8. (I) Show that the quantity $\hbar^2/I$ has units of energy.
9. (I) What is the reduced mass of the molecules (*a*) KCl; (*b*) $O_2$; (*c*) HCl?
10. (I) Estimate the moment of inertia of a hydrogen molecule around an axis perpendicular to a line connecting the two atoms, at their CM.
11. (II) Suppose two 1.5-mg masses were made into a small dumbbell. (*a*) Given that the rotational states of this system would be quantized, what would the angular velocity of the dumbbell be in the $\ell = 1$ state? Assume the masses are separated by 1.0 mm. (*b*) If this dumbbell rotated at 50 rpm, what would be its singular momentum state $\ell$?
12. (II) (*a*) Calculate the "characteristic rotational energy," $\hbar^2/2I$, for the $O_2$ molecule whose bond length is 0.121 nm. (*b*) What are the energy and wavelength of photons emitted in an $\ell = 3$ to $\ell = 2$ transition?
13. (II) The "characteristic rotational energy," $\hbar^2/2I$, for $N_2$ is $2.48 \times 10^{-4}$ eV. Calculate the $N_2$ bond length.
14. (II) The equilibrium separation of H atoms in the $H_2$ molecule is 0.074 nm (Fig. 40–8). Calculate the energies and wavelengths of photons for the rotational transitions (*a*) $\ell = 1$ to $\ell = 0$, (*b*) $\ell = 2$ to $\ell = 1$, and (*c*) $\ell = 3$ to $\ell = 2$.
15. (II) Determine the wavelength of the photon emitted when the CO molecule makes the rotational transition $\ell = 5$ to $\ell = 4$. [*Hint*: See Example 40–5.]
16. (II) Calculate the bond length for the NaCl molecule given that three successive wavelengths for rotational transitions are 23.1 mm, 11.6 mm, and 7.71 mm.
17. (II) Estimate the longest wavelength emitted by a lithium hydride (LiH) molecule for a change in its rotational state if its equilibrium separation is 0.16 nm.
18. (II) Explain why there is no transition for $\Delta E = hf$ in Fig. 40–21 (and Fig. 40–22). See Eqs. 40–8.
19. (II) The fundamental vibration frequency for the CO molecule is $6.42 \times 10^{13}$ Hz. Determine (*a*) the reduced mass, and (*b*) the effective value of the "stiffness" constant $k$. Compare to $k$ for the $H_2$ molecule.
20. (II) Li and Br form a molecule for which the lowest vibrational frequency is $1.7 \times 10^{13}$ Hz. What is the effective stiffness constant $k$?
21. (II) (*a*) Use the curve of Fig. 40–18 to estimate the stiffness constant $k$ for the $H_2$ molecule. (Recall that $U = \frac{1}{2}kx^2$.) (*b*) Then estimate the fundamental wavelength for vibrational transitions using the classical formula (Chapter 14), but use only $\frac{1}{2}$ the mass of an H atom (because both H atoms move).
22. (III) Imagine the two atoms of a diatomic molecule as if they were connected by a spring, Fig. 40–52. Show that the classical frequency of vibration is given by Eq. 40–5. [*Hint*: Let $x_1$ and $x_2$ be the displacements of each mass from initial equilibrium positions; then $m_1 d^2x_1/dt^2 = -kx$, and $m_2 d^2x_2/dt^2 = -kx$, where $x = x_1 + x_2$. Find another relationship between $x_1$ and $x_2$, assuming that the center of mass of the system stays at rest, and then show that $\mu\, d^2x/dt^2 = -kx$.]

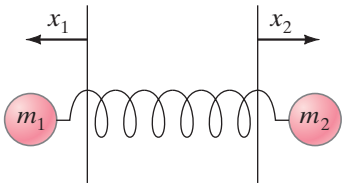

**FIGURE 40–52**
Problem 22.

## 40–5 Bonding in Solids

23. (I) Estimate the ionic cohesive energy for NaCl taking $\alpha = 1.75$, $m = 8$, and $r_0 = 0.28$ nm.
24. (II) Common salt, NaCl, has a density of 2.165 g/cm$^3$. The molecular weight of NaCl is 58.44. Estimate the distance between nearest neighbor Na and Cl ions. [*Hint*: Each ion can be considered to be at the corner of a cube.]
25. (II) Repeat the previous Problem for KCl whose density is 1.99 g/cm$^3$.
26. (II) The spacing between "nearest neighbor" Na and Cl ions in a NaCl crystal is 0.24 nm. What is the spacing between two nearest neighbor Na ions?
27. (III) For a long one-dimensional chain of alternating positive and negative ions, show that the Madelung constant would be $\alpha = 2 \ln 2$. [*Hint*: Use a series expansion for $\ln(1 + x)$.]

**28.** (III) (*a*) Starting from Eq. 40–9, show that the ionic cohesive energy is given by $U_0 = -(\alpha e^2/4\pi\epsilon_0 r_0)(1 - 1/m)$. Determine $U_0$ for (*b*) NaI $(r_0 = 0.33\,\text{nm})$ and (*c*) MgO $(r_0 = 0.21\,\text{nm})$. Assume $m = 10$. (*d*) If you used $m = 8$ instead, how far off would your answers be? Assume $\alpha = 1.75$.

## 40–6 Free-Electron Theory of Metals

**29.** (II) Estimate the number of possible electron states in a 1.00-cm$^3$ cube of silver between $0.975E_F$ and $E_F\,(= 5.48\,\text{eV})$.

**30.** (II) Estimate the number of states between 7.00 eV and 7.05 eV that are available to electrons in a 1.0-cm$^3$ cube of copper.

**31.** (II) What, roughly, is the ratio of the density of molecules in an ideal gas at 285 K and 1 atm (say $O_2$) to the density of free electrons (assume one per atom) in a metal (copper) also at 285 K?

**32.** (II) Calculate the energy which has 85.0% occupancy probability for copper at (*a*) $T = 295\,\text{K}$; (*b*) $T = 750\,\text{K}$.

**33.** (II) Calculate the energy which has 15.0% occupancy probability for copper at (*a*) $T = 295\,\text{K}$; (*b*) $T = 950\,\text{K}$.

**34.** (II) What is the occupancy probability for a conduction electron in copper at $T = 295\,\text{K}$ for an energy $E = 1.015E_F$?

**35.** (II) The atoms in zinc metal $(\rho = 7.1 \times 10^3\,\text{kg/m}^3)$ each have two free electrons. Calculate (*a*) the density of conduction electrons, (*b*) their Fermi energy, and (*c*) their Fermi speed.

**36.** (II) Calculate the Fermi energy and Fermi speed for sodium, which has a density of $0.97 \times 10^3\,\text{kg/m}^3$ and has one conduction electron per atom.

**37.** (II) Given that the Fermi energy of aluminum is 11.63 eV, (*a*) calculate the density of free electrons using Eq. 40–12, and (*b*) estimate the valence of aluminum using this model and the known density $(2.70 \times 10^3\,\text{kg/m}^3)$ and atomic mass (27.0) of aluminum.

**38.** (II) Show that the average energy of conduction electrons in a metal at $T = 0\,\text{K}$ is $\overline{E} = \frac{3}{5}E_F$ (Eq. 40–13) by calculating

$$\overline{E} = \frac{\int E\,n_o(E)\,dE}{\int n_o(E)\,dE}.$$

**39.** (II) The neutrons in a neutron star (Chapter 44) can be treated as a Fermi gas with neutrons in place of the electrons in our model of an electron gas. Determine the Fermi energy for a neutron star of radius 12 km and mass 2.5 times that of our Sun. Assume that the star is made entirely of neutrons and is of uniform density.

**40.** (II) For a one-dimensional potential well of width $\ell$, start with Eq. 38–13 and show that the number of states per unit energy interval for an electron gas is given by

$$g_\ell(E) = \sqrt{\frac{8m\ell^2}{h^2 E}}.$$

Remember that there can be two electrons (spin up and spin down) for each value of $n$. [*Hint*: Write the quantum number $n$ in terms of $E$. Then $g_\ell(E) = 2\,dn/dE$ where $dn$ is the number of energy levels between $E$ and $E + dE$.]

**41.** (II) Show that the probability for the state at the Fermi energy being occupied is exactly $\frac{1}{2}$, independent of temperature.

**42.** (II) A very simple model of a "one-dimensional" metal consists of $N$ electrons confined to a rigid box of width $\ell$. We neglect the Coulomb interaction between the electrons. (*a*) Calculate the Fermi energy for this one-dimensional metal ($E_F$ = the energy of the most energetic electron at $T = 0\,\text{K}$), taking into account the Pauli exclusion principle. You can assume for simplicity that $N$ is even. (*b*) What is the smallest amount of energy, $\Delta E$, that this 1-D metal can absorb? (*c*) Find the limit of $\Delta E/E_F$ for large $N$. What does this result say about how well metals can conduct?

**43.** (II) (*a*) For copper at room temperature $(T = 293\,\text{K})$, calculate the Fermi factor, Eq. 40–14, for an electron with energy 0.12 eV above the Fermi energy. This represents the probability that this state is occupied. Is this reasonable? (*b*) What is the probability that a state 0.12 eV below the Fermi energy is occupied? (*c*) What is the probability that the state in part (*b*) is unoccupied?

**44.** (III) Proceed as follows to derive the density of states, $g(E)$, the number of states per unit volume per unit energy interval, Eq. 40–10. Let the metal be a cube of side $\ell$. Extend the discussion of Section 38–8 for an infinite well to three dimensions, giving energy levels

$$E = \frac{h^2}{8m\ell^2}(n_1^2 + n_2^2 + n_3^2).$$

(Explain the meaning of $n_1, n_2, n_3$.) Each set of values for the quantum numbers $n_1, n_2, n_3$ corresponds to one state. Imagine a space where $n_1, n_2, n_3$ are the axes, and each state is represented by a point on a cubic lattice in this space, each separated by 1 unit along an axis. Consider the octant $n_1 > 0$, $n_2 > 0$, $n_3 > 0$. Show that the number of states $N$ within a radius $R = (n_1^2 + n_2^2 + n_3^2)^{\frac{1}{2}}$ is $2\left(\frac{1}{8}\right)\left(\frac{4}{3}\pi R^3\right)$. Then, to get Eq. 40–10, set $g(E) = (1/V)(dN/dE)$, where $V = \ell^3$ is the volume of the metal.

## 40–7 Band Theory of Solids

**45.** (I) A semiconductor is struck by light of slowly increasing frequency and begins to conduct when the wavelength of the light is 620 nm; estimate the energy gap $E_g$.

**46.** (I) Calculate the longest-wavelength photon that can cause an electron in silicon $(E_g = 1.12\,\text{eV})$ to jump from the valence band to the conduction band.

**47.** (II) The energy gap between valence and conduction bands in germanium is 0.72 eV. What range of wavelengths can a photon have to excite an electron from the top of the valence band into the conduction band?

**48.** (II) We saw that there are $2N$ possible electron states in the 3*s* band of Na, where $N$ is the total number of atoms. How many possible electron states are there in the (*a*) 2*s* band, (*b*) 2*p* band, and (*c*) 3*p* band? (*d*) State a general formula for the total number of possible states in any given electron band.

**49.** (II) The energy gap $E_g$ in germanium is 0.72 eV. When used as a photon detector, roughly how many electrons can be made to jump from the valence to the conduction band by the passage of a 710-keV photon that loses all its energy in this fashion?

### 40–8 Semiconductors and Doping

**50.** (II) Suppose that a silicon semiconductor is doped with phosphorus so that one silicon atom in $1.3 \times 10^6$ is replaced by a phosphorus atom. Assuming that the "extra" electron in every phosphorus atom is donated to the conduction band, by what factor is the density of conduction electrons increased? The density of silicon is 2330 kg/m$^3$, and the density of conduction electrons in pure silicon is about $10^{16}$ m$^{-3}$ at room temperature.

### 40–9 Diodes

**51.** (I) At what wavelength will an LED radiate if made from a material with an energy gap $E_g = 1.8$ eV?

**52.** (I) If an LED emits light of wavelength $\lambda = 630$ nm, what is the energy gap (in eV) between valence and conduction bands?

**53.** (II) A silicon diode, whose current–voltage characteristics are given in Fig. 40–38, is connected in series with a battery and an 860-Ω resistor. What battery voltage is needed to produce a 16-mA current?

**54.** (II) Suppose that the diode of Fig. 40–38 is connected in series to a 120-Ω resistor and a 2.0-V battery. What current flows in the circuit? [*Hint*: Draw a line on Fig. 40–38 representing the current in the resistor as a function of the voltage across the diode; the intersection of this line with the characteristic curve will give the answer.]

**55.** (II) Sketch the resistance as a function of current, for $V > 0$, for the diode shown in Fig. 40–38.

**56.** (II) An ac voltage of 120 V rms is to be rectified. Estimate very roughly the average current in the output resistor $R$ (42 kΩ) for (*a*) a half-wave rectifier (Fig. 40–39), and (*b*) a full-wave rectifier (Fig. 40–40) without capacitor.

**57.** (II) A semiconductor diode laser emits 1.1-$\mu$m light. Assuming that the light comes from electrons and holes recombining, what is the band gap in this laser material?

**58.** (III) A silicon diode passes significant current only if the forward-bias voltage exceeds about 0.6 V. Make a rough estimate of the average current in the output resistor $R$ of (*a*) a half-wave rectifier (Fig. 40–39), and (*b*) a full-wave rectifier (Fig. 40–40) without a capacitor. Assume that $R = 150\ \Omega$ in each case and that the ac voltage is 9.0 V rms in each case.

**59.** (III) A 120-V rms 60-Hz voltage is to be rectified with a full-wave rectifier as in Fig. 40–40, where $R = 24\ \text{k}\Omega$, and $C = 35\ \mu\text{F}$. (*a*) Make a rough estimate of the average current. (*b*) What happens if $C = 0.10\ \mu\text{F}$? [*Hint*: See Section 26–5.]

### 40–10 Transistors

**60.** (I) Draw a circuit diagram (like Fig. 40–49) showing how a *pnp* transistor can operate as an amplifier. Show polarities, etc.

**61.** (II) If the current gain of the transistor amplifier in Fig. 40–49 is $\beta = i_C/i_B = 95$, what value must $R_C$ have if a 1.0-$\mu$A ac base current is to produce an ac output voltage of 0.40 V?

**62.** (II) Suppose that the current gain of the transistor in Fig. 40–49 is $\beta = i_C/i_B = 85$. If $R_C = 3.9\ \text{k}\Omega$, calculate the ac output voltage for an ac input current of 2.0 $\mu$A.

**63.** (II) An amplifier has a voltage gain of 75 and a 25-kΩ load (output) resistance. What is the peak output current through the load resistor if the input voltage is an ac signal with a peak of 0.080 V?

**64.** (II) A transistor, whose current gain $\beta = i_C/i_B = 65$, is connected as in Fig. 40–49 with $R_B = 3.8\ \text{k}\Omega$ and $R_C = 7.8\ \text{k}\Omega$. Calculate (*a*) the voltage gain, and (*b*) the power amplification.

**65.** (II) From Fig. 40–49, write an equation for the relationship between the base current $(I_B)$, the collector current $(I_C)$, and the emitter current ($I_E$, not labeled in Fig. 40–49). Assume the ac current $i_B = i_C = 0$.

## General Problems

**66.** Estimate the number of states from 4.0 eV to 6.2 eV available to electrons in a 10-cm cube of iron.

**67.** A full-wave rectifier (Fig. 40–40) uses two diodes to rectify a 75-V rms 60-Hz ac voltage. If $R = 7.8\ \text{k}\Omega$ and $C = 36\ \mu\text{F}$, what will be the approximate percent variation in the output voltage? The variation in output voltage (Fig. 40–40c) is called *ripple voltage*. [*Hint*: See Section 26–5 and assume the discharge of the capacitor is approximately linear.]

**68.** In the ionic salt KF, the separation distance between ions is about 0.27 nm. (*a*) Estimate the electrostatic potential energy between the ions assuming them to be point charges (magnitude 1*e*). (*b*) When F "grabs" an electron, it releases 3.41 eV of energy, whereas 4.34 eV is required to ionize K. Find the binding energy of KF relative to free K and F atoms, neglecting the energy of repulsion.

**69.** A strip of silicon 1.8 cm wide and 1.0 mm thick is immersed in a magnetic field of strength 1.3 T perpendicular to the strip (Fig. 40–53). When a current of 0.28 mA is run through the strip, there is a resulting Hall effect voltage of 18 mV across the strip (Section 27–8). How many electrons per silicon atom are in the conduction band? The density of silicon is 2330 kg/m$^3$.

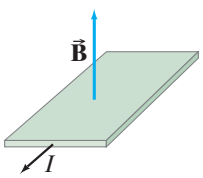

**FIGURE 40–53**
Problem 69.

**70.** One possible form for the potential energy $(U)$ of a diatomic molecule (Fig. 40–8) is called the *Morse Potential*:

$$U = U_0\left[1 - e^{-a(r-r_0)}\right]^2.$$

(*a*) Show that $r_0$ represents the equilibrium distance and $U_0$ the dissociation energy. (*b*) Graph $U$ from $r = 0$ to $r = 4r_0$, assuming $a = 18\ \text{nm}^{-1}$, $U_0 = 4.6$ eV, and $r_0 = 0.13$ nm.

**71.** Do we need to consider quantum effects for everyday rotating objects? Estimate the differences between rotational energy levels for a spinning baton compared to the energy of the baton. Assume the baton consists of a uniform 32-cm-long bar with a mass of 260 g and two small end masses, each of mass 350 g, and that it rotates at 1.6 rev/s about the bar's center.

**72.** For $H_2$, estimate how many rotational states there are between vibrational states.

**73.** Explain, using the Boltzmann factor (Eq. 39–16), why the heights of the peaks in Fig. 40–22 are different from one another. Explain also why the lines are not equally spaced. [*Hint*: Does the moment of inertia necessarily remain constant?]

**74.** The rotational absorption spectrum of a molecule displays peaks about $9.2 \times 10^{11}$ Hz apart. Determine the moment of inertia of this molecule.

**75.** A TV remote control emits IR light. If the detector on the TV set is *not* to react to visible light, could it make use of silicon as a "window" with its energy gap $E_g = 1.12\,\text{eV}$? What is the shortest-wavelength light that can strike silicon without causing electrons to jump from the valence band to the conduction band?

**76.** For $O_2$ with a bond length 0.121 nm, what is the moment of inertia about an axis through the CM perpendicular to the line joining the atoms?

**77.** The **Fermi temperature** $T_F$ is defined as that temperature at which the thermal energy $kT$ (without the $\frac{3}{2}$) is equal to the Fermi energy: $kT_F = E_F$. (*a*) Determine the Fermi temperature for copper. (*b*) Show that for $T \gg T_F$, the Fermi factor (Eq. 40–14) approaches the Boltzmann factor. (Note: This last result is not very useful for understanding conductors. Why?)

**78.** Consider a monatomic solid with a weakly bound cubic lattice, with each atom connected to six neighbors, each bond having a binding energy of $3.6 \times 10^{-3}\,\text{eV}$. When this solid melts, its latent heat of fusion goes directly into breaking the bonds between the atoms. Estimate the latent heat of fusion for this solid, in J/mol. [*Hint*: Show that in a simple cubic lattice (Fig. 40–54), there are *three* times as many bonds as there are atoms, when the number of atoms is large.]

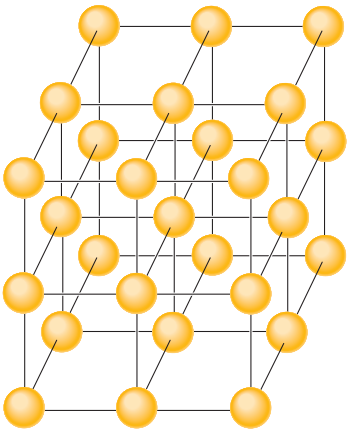

**FIGURE 40–54** Problem 78.

**79.** The energy gap between valence and conduction bands in zinc sulfide is 3.6 eV. What range of wavelengths can a photon have to excite an electron from the top of the valence band into the conduction band?

**80.** Most of the Sun's radiation has wavelengths shorter than 1100 nm. For a solar cell to absorb all this, what energy gap ought the material have?

**81.** Green and blue LEDs became available many years after red LEDs were first developed. Approximately what energy gaps would you expect to find in green (525 nm) and in blue (465 nm) LEDs?

**82.** For an arsenic donor atom in a doped silicon semiconductor, assume that the "extra" electron moves in a Bohr orbit about the arsenic ion. For this electron in the ground state, take into account the dielectric constant $K = 12$ of the Si lattice (which represents the weakening of the Coulomb force due to all the other atoms or ions in the lattice), and estimate (*a*) the binding energy, and (*b*) the orbit radius for this extra electron. [*Hint*: Substitute $\epsilon = K\epsilon_0$ in Coulomb's law; see Section 24–5.]

**83.** The fundamental vibration frequency for the HCl molecule is $8.66 \times 10^{13}\,\text{Hz}$. Determine (*a*) the reduced mass, and (*b*) the effective value of the stiffness constant $k$. Compare to $k$ for the $H_2$ molecule.

**84.** A zener diode voltage regulator is shown in Fig. 40–55. Suppose that $R = 2.80\,\text{k}\Omega$ and that the diode breaks down at a reverse voltage of 130 V. (The current increases rapidly at this point, as shown on the far left of Fig. 40–38 at a voltage of $-12$ V on that diagram.) The diode is rated at a maximum current of 120 mA. (*a*) If $R_{\text{load}} = 21.0\,\text{k}\Omega$, over what range of supply voltages will the circuit maintain the output voltage at 130 V? (*b*) If the supply voltage is 275 V, over what range of load resistance will the voltage be regulated?

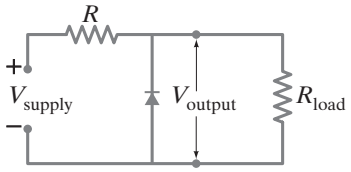

**FIGURE 40–55** Problem 84.

**85.** The average translational kinetic energy of an atom or molecule is about $\overline{K} = \frac{3}{2}kT$ (see Chapter 18), where $k = 1.38 \times 10^{-23}\,\text{J/K}$ is Boltzmann's constant. At what temperature $T$ will $\overline{K}$ be on the order of the bond energy (and hence the bond easily broken by thermal motion) for (*a*) a covalent bond (say $H_2$) of binding energy 4.0 eV, and (*b*) a "weak" hydrogen bond of binding energy 0.12 eV?

**86.** When EM radiation is incident on diamond, it is found that light with wavelengths shorter than 226 nm will cause the diamond to conduct. What is the energy gap between the valence band and the conduction band for diamond?

**87.** A diatomic molecule is found to have an activation energy of 1.4 eV. When the molecule is disassociated, 1.6 eV of energy is released. Draw a potential energy curve for this molecule.

**88.** Use the uncertainty principle to estimate the binding energy of the $H_2$ molecule by calculating the difference in kinetic energy of the electrons between (i) when they are in separate atoms and (ii) when they are in the molecule. Take $\Delta x$ for the electrons in the separated atoms to be the radius of the first Bohr orbit, 0.053 nm, and for the molecule take $\Delta x$ to be the separation of the nuclei, 0.074 nm. [*Hint*: Let $\Delta p \approx \Delta p_x$.]

**89.** The band gap of silicon is 1.12 eV. (*a*) For what range of wavelengths will silicon be transparent? (See Example 40–14.) In what region of the electromagnetic spectrum does this transparent range begin? (*b*) If window glass is transparent for all visible wavelengths, what is the minimum possible band gap value for glass (assume $\lambda = 400\,\text{nm}$ to $700\,\text{nm}$)? [*Hint*: If the photon has less energy than the band gap, the photon will pass through the solid without being absorbed.]

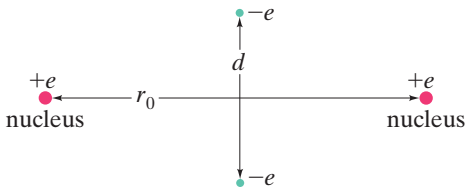
**90.** For a certain semiconductor, the longest wavelength radiation that can be absorbed is 2.04 mm. What is the energy gap in this semiconductor?

## ANSWERS TO EXERCISES

**A:** 0, $5.00 \times 10^{-4}\,\text{eV}$, $1.50 \times 10^{-3}\,\text{eV}$.
**B:** 0.81 eV.
**C:** (*c*).
**D:** (*e*).
**E:** number/$(\text{J} \cdot \text{m}^3)$.
**F:** (*a*).
**G:** (*c*) and (*e*).

**91.** Assume conduction electrons in a semiconductor behave as an ideal gas. (This is not true for conduction electrons in a metal.) (*a*) Taking mass $m = 9 \times 10^{-31}$ kg and temperature $T = 300$ K, determine the de Broglie wavelength of a semiconductor's conduction electrons. (*b*) Given that the spacing between atoms in a semiconductor's atomic lattice is on the order of 0.3 nm, would you expect room-temperature conduction electrons to travel in straight lines or diffract when traveling through this lattice? Explain.

***92.** A simple picture of an $H_2$ molecule sharing two electrons is shown in Fig. 40–56. We assume the electrons are symmetrically located between the two protons, which are separated by $r_0 = 0.074$ nm. (*a*) When the electrons are separated by a distance $d$, write the total potential energy $U$ in terms of $d$ and $r_0$. (*b*) Make a graph of $U$ in eV as a function of $d$ in nm, and state where $U$ has a minimum on your graph, and for what range of $d$ values $U$ is negative. (*c*) Determine analytically the value of $d$ that gives minimum $U$ (greatest stability).



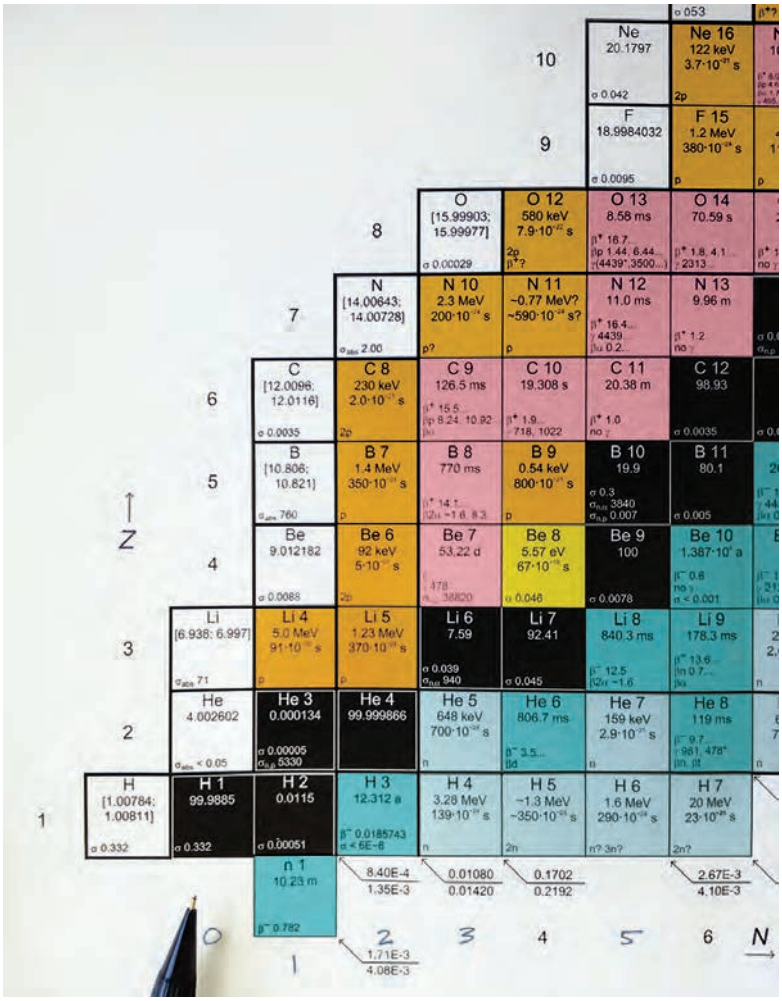


**FIGURE 40–56** Problem 92.

Now we begin our discussion of nuclear physics. We study the properties of nuclei, the various forms of radioactivity, and how radioactive decay can be used in a variety of fields to determine the age of old objects, from bones and trees to rocks and other mineral substances, and obtain information on the history of the Earth.

Shown is one version of a **Chart of the Nuclides**. Each horizontal row has a square for each known isotope (nuclide) of one element with a particular $Z$ value (= number of electrons in the neutral atom = number of protons in the nucleus). At the far left is a white box with the average atomic weight (or a range if uncertain) of the naturally occurring isotopes of that element. Each vertical column contains nuclides with the same neutron number $N$. For $N = 1$ (to right of pencil), starting at the bottom, there is a lone neutron, then above it ${}^{2}_{1}\text{H}$, then ${}^{3}_{2}\text{He}$ and ${}^{4}_{3}\text{Li}$. Each square is color coded: black means a stable nuclide. Radioactive nuclides are blue green for $\beta^-$ decay, pink for $\beta^+$ decay or electron capture ($\varepsilon$) such as ${}^{7}_{4}\text{Be}$, yellow for $\alpha$ decay, and so on. Thus ${}^{1}_{1}\text{H}$ and ${}^{2}_{1}\text{H}$ are stable but ${}^{3}_{1}\text{H}$ (tritium) undergoes $\beta^-$ decay with half-life = 12.3 years ("a" is for Latin "anno" = year). The squares contain the atomic mass of that isotope, or half-life and energy released if radioactive. Other details may be alternate decay modes and certain cross sections ($\sigma$).

## CHAPTER-OPENING QUESTION—Guess now!

If half of an 80-$\mu$g sample of ${}^{60}_{27}\text{Co}$ decays in 5.3 years, how much ${}^{60}_{27}\text{Co}$ is left in 10.6 years?

**(a)** 10 $\mu$g.
**(b)** 20 $\mu$g.
**(c)** 30 $\mu$g.
**(d)** 40 $\mu$g.
**(e)** 0 $\mu$g.

In the early part of the twentieth century, Rutherford's experiments (Section 37–9) led to the idea that at the center of an atom there is a tiny but massive nucleus with a positive charge. At the same time that quantum theory was being developed and scientists were attempting to understand the structure of the atom and its electrons, investigations into the nucleus itself had also begun. In this Chapter and the next, we take a brief look at *nuclear physics*.

# 41–1 Structure and Properties of the Nucleus

An important question for physicists was whether the nucleus had a structure, and what that structure might be. By the early 1930s, a model of the nucleus had been developed that is still useful. According to this model, a nucleus is made up of two types of particles: protons and neutrons. [These "particles" also have wave properties, but for ease of visualization and language, we usually refer to them simply as "particles."] A **proton** is the nucleus of the simplest atom, hydrogen. The proton has a positive charge $(= +e = +1.60 \times 10^{-19}\,\text{C},$ the same magnitude as for the electron) and its mass is measured to be

$$m_p = 1.67262 \times 10^{-27}\,\text{kg}.$$

The **neutron**, whose existence was ascertained in 1932 by the English physicist James Chadwick (1891–1974), is electrically neutral $(q = 0),$ as its name implies. Its mass is very slightly larger than that of the proton:

$$m_n = 1.67493 \times 10^{-27}\,\text{kg}.$$

These two constituents of a nucleus, neutrons and protons, are referred to collectively as **nucleons**.

Although a normal hydrogen nucleus consists of a single proton alone, the nuclei of all other elements consist of both neutrons and protons. The different nuclei are often referred to as **nuclides**. The number of protons in a nucleus (or nuclide) is called the **atomic number** and is designated by the symbol $Z$. The total number of nucleons, neutrons plus protons, is designated by the symbol $A$ and is called the **atomic mass number**, or sometimes simply **mass number**. This name is used since the mass of a nucleus is very closely $A$ times the mass of one nucleon. A nuclide with 7 protons and 8 neutrons thus has $Z = 7$ and $A = 15$. The **neutron number** $N$ is $N = A - Z$.

To specify a given nuclide, we need give only $A$ and $Z$. A special symbol is commonly used which takes the form

$$^{A}_{Z}\text{X},$$

where X is the chemical symbol for the element (see Appendix G, and the Periodic Table inside the back cover), $A$ is the atomic mass number, and $Z$ is the atomic number. For example, $^{15}_{7}\text{N}$ means a nitrogen nucleus containing 7 protons and 8 neutrons for a total of 15 nucleons. In a neutral atom, the number of electrons orbiting the nucleus is equal to the atomic number $Z$ (since the charge on an electron has the same magnitude but opposite sign to that of a proton). The main properties of an atom, and how it interacts with other atoms, are largely determined by the number of electrons. Hence $Z$ determines what kind of atom it is: carbon, oxygen, gold, or whatever. It is redundant to specify both the symbol of a nucleus and its atomic number $Z$ as described above. If the nucleus is nitrogen, for example, we know immediately that $Z = 7$. The subscript $Z$ is thus sometimes dropped and $^{15}_{7}\text{N}$ is then written simply $^{15}\text{N}$; in words we say "nitrogen fifteen."

For a particular type of atom (say, carbon), nuclei are found to contain different numbers of neutrons, although they all have the same number of protons. For example, carbon nuclei always have 6 protons, but they may have 5, 6, 7, 8, 9, or 10 neutrons. Nuclei that contain the same number of protons but different numbers of neutrons are called **isotopes**. Thus, $^{11}_{6}\text{C}$, $^{12}_{6}\text{C}$, $^{13}_{6}\text{C}$, $^{14}_{6}\text{C}$, $^{15}_{6}\text{C}$, and $^{16}_{6}\text{C}$ are all isotopes of carbon. The isotopes of a given element are not all equally common. For example, 98.9% of naturally occurring carbon (on Earth) is the isotope $^{12}_{6}\text{C}$, and about 1.1% is $^{13}_{6}\text{C}$. These percentages are referred to as the **natural abundances**.[†] Even hydrogen has isotopes: 99.99% of natural hydrogen is $^{1}_{1}\text{H}$, a simple proton, as the nucleus; there are also $^{2}_{1}\text{H}$, called **deuterium**, and $^{3}_{1}\text{H}$, **tritium**, which besides the proton contain 1 or 2 neutrons. (The bare nucleus in each case is called the **deuteron** and **triton**.)

[†]The mass value for each element as given in the Periodic Table (inside back cover) is an average weighted according to the natural abundances of its isotopes.

Many isotopes that do not occur naturally can be produced in the laboratory by means of nuclear reactions (more on this later). Indeed, all elements beyond uranium $(Z > 92)$ do not occur naturally on Earth and are only produced artificially (in the laboratory), as are many nuclides with $Z \leq 92$.

The approximate size of nuclei was determined originally by Rutherford from the scattering of charged particles by thin metal foils (Fig. 37–17). We cannot speak about a definite size for nuclei because of the wave–particle duality (Section 37–6): their spatial extent must remain somewhat fuzzy. Nonetheless a rough "size" can be measured by scattering high-speed electrons off nuclei. It is found that nuclei have a roughly spherical shape with a radius that increases with $A$ according to the approximate formula

$$r \approx (1.2 \times 10^{-15}\,\text{m})(A^{\frac{1}{3}}). \qquad \textbf{(41–1)}$$

Since the volume of a sphere is $V = \frac{4}{3}\pi r^3$, we see that the volume of a nucleus is approximately proportional to the number of nucleons, $V \propto A$ (because $(A^{\frac{1}{3}})^3 = A$). This is what we would expect if nucleons were like impenetrable billiard balls: if you double the number of balls, you double the total volume. Hence, all nuclei have nearly the same density, and it is enormous (see Example 41–2).

The metric abbreviation for $10^{-15}\,\text{m}$ is the fermi (after Enrico Fermi, Fig. 41–8) or the femtometer, fm (Table 1–4 or inside the front cover). Thus $1.2 \times 10^{-15}\,\text{m} = 1.2\,\text{fm}$ or 1.2 fermis.

**EXAMPLE 41–1** ESTIMATE **Nuclear sizes.** Estimate the diameter of the smallest and largest naturally occurring nuclei: (*a*) ${}^{1}_{1}\text{H}$, (*b*) ${}^{238}_{92}\text{U}$.

**APPROACH** The radius $r$ of a nucleus is related to its number of nucleons $A$ by Eq. 41–1. The diameter $d = 2r$.

**SOLUTION** (*a*) For hydrogen, $A = 1$, Eq. 41–1 gives

$$d = \text{diameter} = 2r \approx 2(1.2 \times 10^{-15}\,\text{m})(A^{\frac{1}{3}}) = 2.4 \times 10^{-15}\,\text{m}$$

since $A^{\frac{1}{3}} = 1^{\frac{1}{3}} = 1$.

(*b*) For uranium $d \approx (2.4 \times 10^{-15}\,\text{m})(238)^{\frac{1}{3}} = 15 \times 10^{-15}\,\text{m}$.

The range of nuclear diameters is only from 2.4 fm to 15 fm.

Because nuclear radii vary as $A^{\frac{1}{3}}$, the largest nuclei, such as uranium with $A = 238$, have a radius only about $\sqrt[3]{238} \approx 6$ times that of the smallest, hydrogen $(A = 1)$.

**EXAMPLE 41–2** ESTIMATE **Nuclear and atomic densities.** Compare the density of nuclear matter to the density of normal solids.

**APPROACH** The density of normal liquids and solids is on the order of $10^3$ to $10^4\,\text{kg/m}^3$ (see Table 13–1), and because the atoms are close packed, atoms have about this density too. We therefore compare the density (mass per volume) of a nucleus to that of its atom as a whole.

**SOLUTION** The mass of a proton is greater than the mass of an electron by a factor

$$\frac{1.67 \times 10^{-27}\,\text{kg}}{9.1 \times 10^{-31}\,\text{kg}} \approx 2000.$$

Thus, over 99.9% of the mass of an atom is in the nucleus, and for our estimate we can say the mass of the atom equals the mass of the nucleus, $m_{\text{nucl}}/m_{\text{atom}} = 1$. Atoms have a radius of about $10^{-10}\,\text{m}$ (Chapter 37) and nuclei on the order of $10^{-15}\,\text{m}$ (Eq. 41–1). Thus the ratio of nuclear density to atomic density is about

$$\frac{\rho_{\text{nucl}}}{\rho_{\text{atom}}} = \frac{(m_{\text{nucl}}/V_{\text{nucl}})}{(m_{\text{atom}}/V_{\text{atom}})} = \left(\frac{m_{\text{nucl}}}{m_{\text{atom}}}\right)\frac{\frac{4}{3}\pi r_{\text{atom}}^3}{\frac{4}{3}\pi r_{\text{nucl}}^3} \approx (1)\,\frac{(10^{-10})^3}{(10^{-15})^3} = 10^{15}.$$

The nucleus is $10^{15}$ times more dense than ordinary matter.

PSE5_CH41_v1.8_23Jun-20

The masses of nuclei can be determined from the radius of curvature of fast-moving nuclei (as ions) in a known magnetic field using a mass spectrometer, as discussed in Section 27–9. Indeed the existence of different isotopes of the same element (different number of neutrons) was discovered using this device. Nuclear masses can be specified in **unified atomic mass units** (u). On this scale, a neutral ${}^{12}_{6}\text{C}$ atom is given the exact value 12.000000 u. (A ${}^{12}_{6}\text{C}$ nucleus, without electrons, is slightly less than 12.000000.) A neutron then has a measured mass of 1.008665 u, a proton 1.007276 u, and a neutral hydrogen atom ${}^{1}_{1}\text{H}$ (proton plus electron) 1.007825 u. The masses of many nuclides are given in Appendix G. It should be noted that the masses in this Table, as is customary, are for the *neutral atom* (including electrons), and not for a bare nucleus.

**CAUTION**
*Masses are for neutral atom (nucleus plus electrons)*

Masses may be specified using the electron-volt energy unit, $1\,\text{eV} = 1.6022 \times 10^{-19}\,\text{J}$ (Section 23–8). This can be done because mass and energy are related, and the precise relationship is given by Einstein's equation $E = mc^2$ (Chapter 36). Since the mass of a proton is $1.67262 \times 10^{-27}\,\text{kg}$, or 1.007276 u, then 1 u is equal to

$$1.0000\,\text{u} = (1.0000\,\text{u})\left(\frac{1.67262 \times 10^{-27}\,\text{kg}}{1.007276\,\text{u}}\right) = 1.66054 \times 10^{-27}\,\text{kg};$$

this is equivalent to an energy (see Table inside front cover) in MeV ($= 10^6\,\text{eV}$) of

$$E = mc^2 = \frac{(1.66054 \times 10^{-27}\,\text{kg})(2.9979 \times 10^8\,\text{m/s})^2}{(1.6022 \times 10^{-19}\,\text{J eV})} = 931.5\,\text{MeV}.$$

The mass of one atomic mass unit is (solving for $m = E/c^2$)

**PROBLEM SOLVING**
*Atomic mass unit in MeV/$c^2$*

$$1\,\text{u} = 1.6605 \times 10^{-27}\,\text{kg} = 931.5\,\text{MeV}/c^2.$$

The rest masses of some of the basic particles are given in Table 41–1. As a rule of thumb, to remember, the masses of neutron and proton are about $1\,\text{GeV}/c^2$ ($= 1000\,\text{MeV}/c^2$) which is about 2000 times the mass of an electron ($\approx \frac{1}{2}\,\text{MeV}/c^2$).

**PROBLEM SOLVING**
*Masses of p and n are $\approx 1\,\text{GeV}/c^2$*

**TABLE 41–1**
**Rest Masses in Kilograms, Unified Atomic Mass Units, and MeV/$c^2$**

| | Mass | | |
|---|---|---|---|
| **Object** | **kg** | **u** | **MeV/$c^2$** |
| Electron | $9.1094 \times 10^{-31}$ | 0.00054858 | 0.51100 |
| Proton | $1.67262 \times 10^{-27}$ | 1.007276 | 938.27 |
| ${}^{1}_{1}\text{H}$ atom | $1.67353 \times 10^{-27}$ | 1.007825 | 938.78 |
| Neutron | $1.67493 \times 10^{-27}$ | 1.008665 | 939.57 |

Just as an electron has intrinsic spin and orbital angular momentum quantum numbers, so too do nuclei and their constituents, the proton and neutron. Both the proton and the neutron are spin-$\frac{1}{2}$ particles, just like the electron. A nucleus, made up of protons and neutrons, has a **nuclear spin** quantum number $I$ that is the vector sum of the spins of all its nucleons (plus any orbital angular momentum), and can be either integer or half integer, depending on whether it is made up of an even or an odd number of nucleons. [Orbital angular momentum is integer and doesn't affect half integer or whole for $I$.]

PSE5_CH41_v1.8_23Jun-20

The **total nuclear angular momentum** of a nucleus is given, as might be expected (see Section 39–2 and Eq. 39–15), by $\sqrt{I(I+1)}\,\hbar$.

*Nuclear magnetic moments* are measured in terms of the **nuclear magneton**

$$\mu_N = \frac{e\hbar}{2m_p}, \tag{41–2}$$

which is defined by analogy with the Bohr magneton for electrons ($\mu_B = e\hbar/2m_e$, Section 39–7). Since $\mu_N$ contains the proton mass, $m_p$, instead of the electron mass, it is about 2000 times smaller. The electron spin magnetic moment is about 2 Bohr magnetons. The proton's magnetic moment $\mu_p$ has been measured to be

$$\mu_p = 2.7928\,\mu_N.$$

There is no satisfactory explanation for this large factor. The neutron has a magnetic moment

$$\mu_n = -1.9135\,\mu_N,$$

which suggests that, although the neutron carries no net charge, it may have internal structure (quarks, as we discuss later). The minus sign for $\mu_n$ indicates that its magnetic moment is opposite to its spin.

Important applications based on nuclear spin are nuclear magnetic resonance (NMR) and magnetic resonance imaging (MRI). They are discussed in the next Chapter (Section 42–10).

# 41–2 Binding Energy and Nuclear Forces

## Binding Energies

The total mass of a stable nucleus is always less than the sum of the masses of its separate protons and neutrons, as the following Example shows.

**EXAMPLE 41–3** **$^4_2$He mass compared to its constituents.** Compare the mass of a $^4_2$He atom to the total mass of its constituent particles.

PROBLEM SOLVING
*Keep track of electron masses*

**APPROACH** The $^4_2$He nucleus contains 2 protons and 2 neutrons. Tables normally give the masses of neutral atoms—that is, nucleus plus its $Z$ electrons—since this is how masses are measured. We must therefore be sure to balance out the electrons when we compare masses. Thus we use the mass of a $^1_1$H atom rather than that of a proton alone. We look up the mass of the $^4_2$He atom in Appendix G (it includes the mass of 2 electrons), as well as the mass for the 2 neutrons and 2 hydrogen atoms (= 2 protons + 2 electrons).

**SOLUTION** The mass of a neutral $^4_2$He atom, from Appendix G, is 4.002603 u. The mass of two neutrons and two H atoms (2 protons including the 2 electrons) is

$$\begin{aligned} 2m_n &= 2(1.008665\,\text{u}) = 2.017330\,\text{u} \\ 2m(^1_1\text{H}) &= 2(1.007825\,\text{u}) = 2.015650\,\text{u} \\ \text{sum} &= 4.032980\,\text{u}. \end{aligned}$$

Thus the mass of $^4_2$He is measured to be less than the masses of its constituents by an amount $4.032980\,\text{u} - 4.002603\,\text{u} = 0.030377\,\text{u}$.

Where has this lost mass of 0.030377 u disappeared to? It must be $E = mc^2$.

PSE5_CH41_v1.8_23Jun-20

If the four nucleons suddenly came together to form a $^4_2$He nucleus, the mass "loss" would appear as energy of another kind (such as $\gamma$ radiation, or kinetic energy). The mass (or energy) difference in the case of $^4_2$He, given in energy units, is $(0.030377\,\text{u})\,(931.5\,\text{MeV/u}) = 28.30\,\text{MeV}$. This difference is referred to as the **total binding energy** of the nucleus. The total binding energy represents the amount of energy that must be put *into* a nucleus in order to break it apart into its constituents. If the mass of, say, a $^4_2$He nucleus were exactly equal to the mass of two neutrons plus two protons, the nucleus could fall apart without any input of energy. To be stable, the mass of a nucleus *must* be less than that of its constituent nucleons, so that energy input *is* needed to break it apart.

**CAUTION**
*Mass of nucleus must be less than mass of constituents*

Binding energy is not something a nucleus has—it is energy it "lacks" relative to the total mass of its separate constituents.

As a comparison, we saw in Chapter 37 that the binding energy of the one electron in the hydrogen atom is 13.6 eV; so the mass of a $^1_1$H atom is less than that of a single proton plus a single electron by $13.6\,\text{eV}/c^2$. Compared to the total mass of the hydrogen atom $(939\,\text{MeV}/c^2)$, this is incredibly small, 1 part in $10^8$. The binding energies of nuclei are on the order of MeV, so the eV binding energies of electrons can be ignored. Note that nuclear binding energies, compared to nuclear masses, are on the order of $(28\,\text{MeV}/4000\,\text{MeV}) \approx 1 \times 10^{-2}$, where we used helium's binding energy (see above) and mass $\approx 4 \times 940\,\text{MeV} \approx 4000\,\text{MeV}$.

**EXERCISE A** Determine how much less the mass of the $^7_3$Li nucleus is compared to that of its constituents. See Appendix G.

The difference between the mass of a nucleus, $M$, and its atomic number $A$, is called the **mass excess** $\Delta = M - A$. The quantity $A - M$ is called the **mass defect**. We mention this because some references use these quantities instead of $M$ as we do in Appendix G.

The **binding energy per nucleon** is defined as the total binding energy of a nucleus divided by $A$, the total number of nucleons. We calculated above that the binding energy of $^4_2$He is 28.3 MeV, so its binding energy per nucleon is $28.3\,\text{MeV}/4 = 7.1\,\text{MeV}$. Figure 41–1 shows the measured binding energy per nucleon as a function of $A$ for stable nuclei. The curve rises as $A$ increases and reaches a plateau at about 8.7 MeV per nucleon above $A \approx 40$. Beyond $A \approx 80$, the curve decreases slowly, indicating that larger nuclei are held together a little less tightly than those in the middle of the Periodic Table. We will see later that these characteristics allow the release of nuclear energy in the processes of fission and fusion.

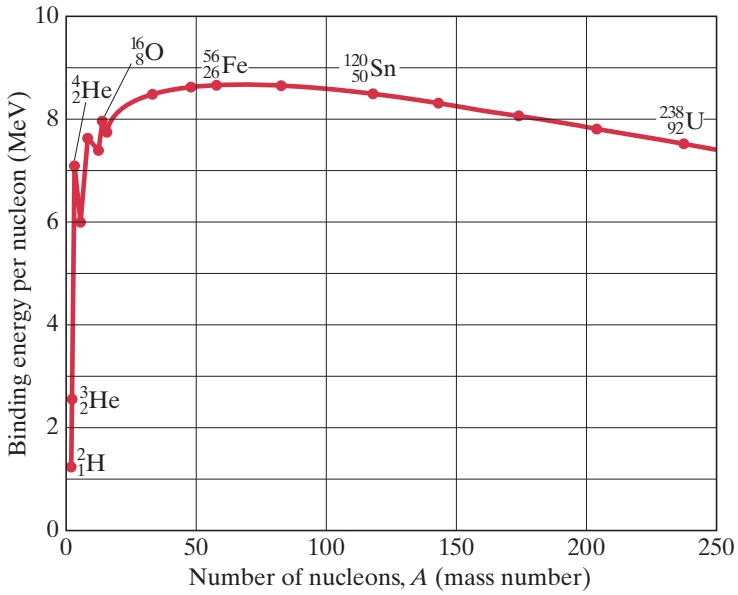

**FIGURE 41–1** Binding energy per nucleon for the more stable nuclides as a function of mass number $A$.

**EXAMPLE 41–4** **Binding energy for iron.** Calculate the total binding energy and the binding energy per nucleon for $^{56}_{26}\text{Fe}$, the most common stable isotope of iron.

**APPROACH** We subtract the mass of an $^{56}_{26}\text{Fe}$ atom from the total mass of 26 hydrogen atoms and 30 neutrons, all found in Appendix G. Then we convert mass units to energy units; finally we divide by $A = 56$, the total number of nucleons.

**SOLUTION** $^{56}_{26}\text{Fe}$ has 26 protons and 30 neutrons whose separate masses are

$$\begin{aligned} 26m\left(^{1}_{1}\text{H}\right) &= (26)(1.007825\,\text{u}) = 26.20345\,\text{u (includes 26 electrons)} \\ 30m_{\text{n}} &= (30)(1.008665\,\text{u}) = \underline{30.25995\,\text{u}} \\ \text{sum} &= 56.46340\,\text{u}. \\ \text{Subtract mass of } ^{56}_{26}\text{Fe}: &= \underline{-55.93494\,\text{u}}\ \text{(Appendix G)} \\ \Delta m &= 0.52846\,\text{u}. \end{aligned}$$

The total binding energy is thus

$$(0.52846\,\text{u})(931.5\,\text{MeV/u}) = 492.26\,\text{MeV}$$

and the binding energy per nucleon is

$$\frac{492.26\,\text{MeV}}{56\ \text{nucleons}} = 8.79\,\text{MeV}.$$

**NOTE** The binding energy per nucleon graph (Fig. 41–1) peaks about here, for iron. So the iron nucleus, and its neighbors are the most stable of nuclei.

**EXERCISE B** Determine the binding energy per nucleon for $^{16}_{8}\text{O}$.

**EXAMPLE 41–5** **Binding energy of last neutron.** What is the binding energy of the last neutron in $^{13}_{6}\text{C}$?

**APPROACH** If $^{13}_{6}\text{C}$ lost one neutron, it would be $^{12}_{6}\text{C}$. We subtract the mass of $^{13}_{6}\text{C}$ from the masses of $^{12}_{6}\text{C}$ and a free neutron.

**SOLUTION** Obtaining the masses from Appendix G, we have

$$\begin{aligned} \text{Mass } ^{12}_{6}\text{C} &= 12.000000\,\text{u} \\ \text{Mass } ^{1}_{0}\text{n} &= \underline{1.008665\,\text{u}} \\ \text{Total} &= 13.008665\,\text{u}. \\ \text{Subtract mass of } ^{13}_{6}\text{C}: &\quad \underline{-13.003355\,\text{u}} \\ \Delta m &= 0.005310\,\text{u} \end{aligned}$$

which in energy is $(931.5\,\text{MeV/u})(0.005310\,\text{u}) = 4.95\,\text{MeV}$. That is, it would require 4.95 MeV input of energy to remove one neutron from $^{13}_{6}\text{C}$.

## Nuclear Forces

We can analyze nuclei not only from the point of view of energy, but also from the point of view of the forces that hold them together. We would not expect a collection of protons and neutrons to come together spontaneously, since protons are all positively charged and thus exert repulsive electric forces on each other. Since stable nuclei *do* stay together, another force must be acting. This new force has to be stronger than the electric force in order to hold the nucleus together, and is called the **strong force** or **strong nuclear force**. The strong nuclear force acts as an attractive force between all nucleons, protons and neutrons alike. Thus protons attract each other via the strong nuclear force at the same time they repel each other via the electric force.

Neutrons, because they are electrically neutral, only attract other neutrons or protons via the strong nuclear force.

The strong nuclear force turns out to be far more complicated than the gravitational and electromagnetic forces. One important aspect of the strong nuclear force is that it is a **short-range** force: it acts only over a very short distance. It is very strong between two nucleons if they are less than about $10^{-15}$ m apart, but it is essentially zero if they are separated by a distance greater than this. Compare this to electric and gravitational forces, which decrease as $1/r^2$ but continue acting over any distances and are therefore called **long-range** forces.

The strong nuclear force has some strange features. For example, if a nuclide contains too many or too few neutrons relative to the number of protons, the binding of the nucleons is reduced; nuclides that are too unbalanced in this regard are unstable. As shown in Fig. 41–2, stable nuclei tend to have the same number of protons as neutrons $(N = Z)$ up to about $A = 30$. Beyond this, stable nuclei contain more neutrons than protons. This makes sense since, as $Z$ increases, the electrical repulsion increases, so a greater number of neutrons—which exert only the attractive strong nuclear force—are required to maintain stability. For very large $Z$, no number of neutrons can overcome the greatly increased electric repulsion. Indeed, there are no completely stable nuclides above $Z = 82$.

What we mean by a *stable nucleus* is one that stays together indefinitely. What then is an *unstable nucleus*? It is one that comes apart; and this results in radioactive decay. Before we discuss the important subject of radioactivity (next Section), we note that there is a second type of nuclear force that is much weaker than the strong nuclear force. It is called the **weak nuclear force** (or **weak force**), and we are aware of its existence only because it shows itself in certain types of radioactive decay. These two nuclear forces, the strong and the weak, together with the gravitational and electromagnetic forces, comprise the four fundamental types of force in nature.

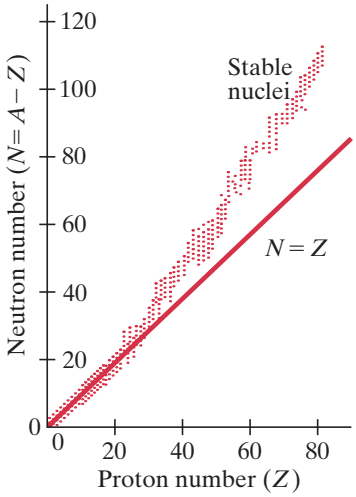

**FIGURE 41–2** Number of neutrons versus number of protons for stable nuclides, which are represented by dots. The straight line represents $N = Z$.

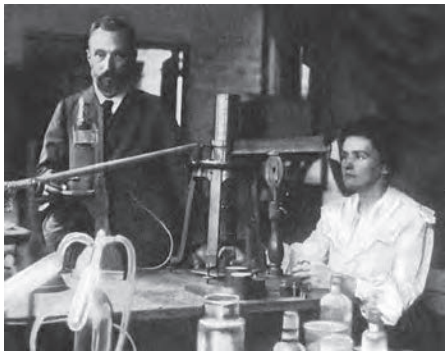

# 41–3 Radioactivity

Nuclear physics had its beginnings in 1896. In that year, Henri Becquerel (1852–1908) made an important discovery: in his studies of phosphorescence, he found that a certain mineral (which happened to contain uranium) would darken a photographic plate even when the plate was wrapped to exclude light. It was clear that the mineral emitted some new kind of radiation that, unlike X-rays (Section 35–10), occurred without any external stimulus. This new phenomenon eventually came to be called **radioactivity**.

Soon after Becquerel's discovery, Marie Curie (1867–1934) and her husband, Pierre Curie (1859–1906), isolated two previously unknown elements that were very highly radioactive (Fig. 41–3). These were named polonium and radium. Other radioactive elements were soon discovered as well. The radioactivity was found in every case to be unaffected by the strongest physical and chemical treatments, including strong heating or cooling or the action of strong chemicals. It was suspected that the source of radioactivity must be deep within the atom, coming from the nucleus. It became apparent that radioactivity is the result of the **disintegration** or **decay** of an unstable nucleus. Certain isotopes are not stable, and they decay with the emission of some type of radiation or "rays."

Many unstable isotopes occur in nature, and such radioactivity is called "natural radioactivity." Other unstable isotopes can be produced in the laboratory by nuclear reactions (Section 42–1); these are said to be produced "artificially" and to have "artificial radioactivity." Radioactive isotopes are sometimes referred to as **radioisotopes** or **radionuclides**.

**FIGURE 41–3** Marie and Pierre Curie in their laboratory (about 1906) where radium was discovered.

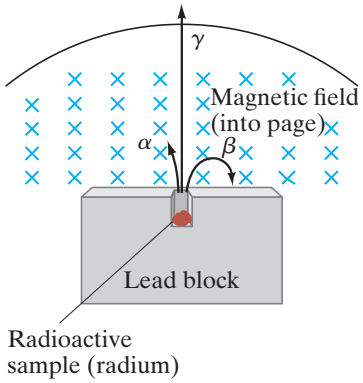

**FIGURE 41–4** Alpha and beta rays are bent in opposite directions by a magnetic field, whereas gamma rays are not bent at all.

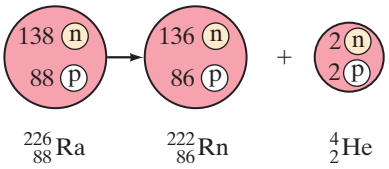
Rutherford and others began studying the nature of the rays emitted in radioactivity about 1898. They classified the rays into three distinct types according to their penetrating power. One type of radiation could barely penetrate a piece of paper. The second type could pass through as much as 3 mm of aluminum. The third was extremely penetrating: it could pass through several centimeters of lead and still be detected on the other side. They named these three types of radiation alpha ($\alpha$), beta ($\beta$), and gamma ($\gamma$), respectively, after the first three letters of the Greek alphabet.

Each type of ray was found to have a different charge and hence is bent differently in a magnetic field, Fig. 41–4; $\alpha$ rays are positively charged, $\beta$ rays are negatively charged, and $\gamma$ rays are neutral. It was soon found that all three types of radiation consisted of familiar kinds of particles. Gamma rays are very high-energy *photons* whose energy is even higher than that of X-rays. Beta rays were identified as *electrons*, identical to those that orbit the nucleus, but they are created within the nucleus itself when it decays. Alpha rays (or $\alpha$ particles) are simply the nuclei of *helium* atoms, ${}^4_2\text{He}$; that is, an $\alpha$ ray consists of two protons and two neutrons bound together.

We now discuss each of these three types of radioactivity, or decay, in more detail.



# 41–4 Alpha Decay

Experiments show that when nuclei decay, the number of nucleons (= mass number $A$) is conserved, as well as electric charge ($= Ze$). When a nucleus emits an $\alpha$ particle $\left({}^4_2\text{He}\right)$, the remaining nucleus will be different from the original: it has lost two protons and two neutrons. Radium 226 $\left({}^{226}_{88}\text{Ra}\right)$, for example, is an $\alpha$ emitter. It decays to a nucleus with $Z = 88 - 2 = 86$ and $A = 226 - 4 = 222$. The nucleus with $Z = 86$ is radon (Rn)—see Appendix G or the Periodic Table. Thus the radium decays to radon with the emission of an $\alpha$ particle. This is written

$$ {}^{226}_{88}\text{Ra} \rightarrow {}^{222}_{86}\text{Rn} + {}^4_2\text{He}. $$

See Fig. 41–5.

**FIGURE 41–5** Radioactive decay of radium to radon with emission of an alpha particle.

When $\alpha$ decay occurs, a different element is formed. The **daughter** nucleus $\left({}^{222}_{86}\text{Rn}\right.$ in this case$\left.\right)$ is different from the **parent** nucleus $\left({}^{226}_{88}\text{Ra}\right.$ in this case$\left.\right)$. This changing of one element into another is called **transmutation** of the elements.

Alpha decay can be written in general as

$$ {}^A_Z\text{N} \rightarrow {}^{A-4}_{Z-2}\text{N}' + {}^4_2\text{He} \qquad [\alpha \text{ decay}] $$

where $N$ is the parent, $N'$ the daughter, and $Z$ and $A$ are the atomic number and atomic mass number, respectively, of the parent.

**EXERCISE C** ${}^{154}_{66}\text{Dy}$ decays by $\alpha$ emission to what element? (*a*) Pb, (*b*) Gd, (*c*) Sm, (*d*) Er, (*e*) Yb.

Alpha decay occurs because the strong nuclear force is unable to hold very large nuclei together. The nuclear force is a short-range force: it acts only between neighboring nucleons. But the electric force acts all the way across a large nucleus. For very large nuclei, the large $Z$ means the repulsive electric force becomes so large (Coulomb's law) that the strong nuclear force is unable to hold the nucleus together.

We can express the instability of the parent nucleus in terms of energy (or mass): decay cannot occur unless the mass of the parent nucleus is greater than the mass of the daughter nucleus plus the mass of the $\alpha$ particle. The mass difference appears as kinetic energy, which is carried away by the $\alpha$ particle and the recoiling daughter nucleus. The total energy released is called the **disintegration energy**, $Q$, or the ***Q*-value** of the decay. From conservation of energy,

$$ M_\text{P}c^2 = M_\text{D}c^2 + m_\alpha c^2 + Q, $$

where $Q$ equals the kinetic energy of the daughter and $\alpha$ particle, and $M_\text{P}$, $M_\text{D}$, and $m_\alpha$ are the masses of the parent, daughter, and $\alpha$ particle, respectively.

PSE5_CH41_v1.8_23Jun-20

Thus

$$Q = M_P c^2 - (M_D + m_\alpha)c^2. \quad \textbf{(41–3)}$$

If the parent had *less* mass than the daughter plus the $\alpha$ particle (so $Q < 0$), the decay would violate conservation of energy. Such decays have never been observed, another confirmation of this great conservation law.

**EXAMPLE 41–6** **Uranium decay energy release.** Calculate the disintegration energy when $^{232}_{92}\text{U}$ (mass = 232.037156 u) decays to $^{228}_{90}\text{Th}$ (228.028741 u) with the emission of an $\alpha$ particle. (As always, masses given are for neutral atoms.)

**APPROACH** We use conservation of energy as expressed in Eq. 41–3. $^{232}_{92}\text{U}$ is the parent, $^{228}_{90}\text{Th}$ is the daughter.

**SOLUTION** Since the mass of the $^{4}_{2}\text{He}$ is 4.002603 u (Appendix G), the total mass in the final state $(m_{Th} + m_{He})$ is

$$228.028741\text{ u} + 4.002603\text{ u} = 232.031344\text{ u}.$$

The mass lost when the $^{232}_{92}\text{U}$ decays $(m_U - m_{Th} - m_{He})$ is

$$232.037156\text{ u} - 232.031344\text{ u} = 0.005812\text{ u}.$$

Because 1 u = 931.5 MeV, the energy $Q$ released is

$$Q = (0.005812\text{ u})(931.5\text{ MeV/u}) = 5.4\text{ MeV}$$

and this energy appears as kinetic energy of the $\alpha$ particle and the daughter nucleus.

**EXAMPLE 41–7** **Kinetic energy of the $\alpha$ in $^{232}_{92}\text{U}$ decay.** For the $^{232}_{92}\text{U}$ decay of Example 41–6, how much of the 5.4-MeV disintegration energy will be carried off by the $\alpha$ particle?

**APPROACH** In any reaction, momentum must be conserved as well as energy. The given 5.4 MeV $\ll$ masses of U and the $\alpha$, so we can use classical expression for kinetic energy.

**SOLUTION** Before disintegration, assuming the nucleus to be at rest, the total momentum was zero. After disintegration, the total vector momentum must still be zero so the magnitude of the $\alpha$ particle's momentum must equal the magnitude of the daughter's momentum (Fig. 41–6):

$$m_\alpha v_\alpha = m_D v_D.$$

Thus $v_\alpha = m_D v_D / m_\alpha$ and the $\alpha$'s kinetic energy is

$$K_\alpha = \tfrac{1}{2} m_\alpha v_\alpha^2 = \tfrac{1}{2} m_\alpha \left(\frac{m_D v_D}{m_\alpha}\right)^2 = \tfrac{1}{2} m_D v_D^2 \left(\frac{m_D}{m_\alpha}\right) = \left(\frac{m_D}{m_\alpha}\right) K_D$$

$$= \left(\frac{228.028741\text{ u}}{4.002603\text{ u}}\right) K_D = 57 K_D.$$

The total disintegration energy is $Q = K_\alpha + K_D = 57K_D + K_D = 58K_D$. Hence

$$K_\alpha = 57 K_D = \frac{57}{58} Q = 5.3\text{ MeV}.$$

The lighter $\alpha$ particle carries off (57/58) or 98% of the total kinetic energy. The total energy released is 5.4 MeV, so the daughter nucleus, which recoils in the opposite direction, carries off only 0.1 MeV.

**NOTE** The 5.4 MeV ***

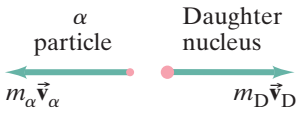


**FIGURE 41–6** Momentum conservation in Example 41–7.

## $\alpha$-Decay Theory—Tunneling

If the mass of the daughter nucleus plus the mass of the $\alpha$ particle is less than the mass of the parent nucleus (so the parent is energetically allowed to decay), why are there any parent nuclei at all? That is, why haven't radioactive nuclei all decayed long ago, right after they were formed? Why doesn't an unstable nucleus fall apart immediately? Why do many have such long half-lives? Consider a model of a nucleus that has an alpha particle trapped inside it. The potential energy "seen" by the $\alpha$ particle would have a shape like that shown in Fig. 41–7.

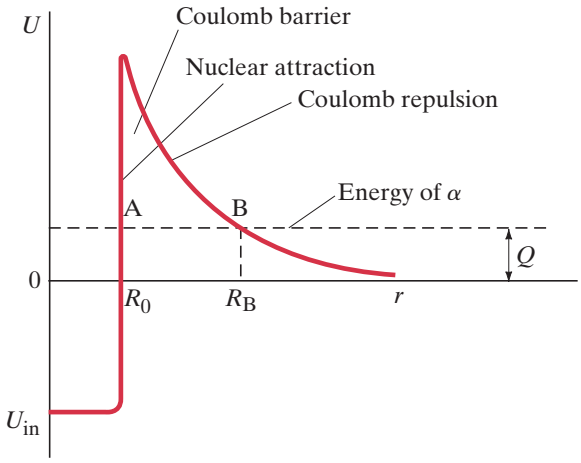

**FIGURE 41–7** Potential energy for alpha particle and (daughter) nucleus, showing the Coulomb barrier through which the $\alpha$ particle must tunnel to escape. The $Q$-value of the reaction is also shown. This plot assumes spherical symmetry, so the central well has diameter $2R_0$.

The potential energy well (approximately square) between $r = 0$ and $r = R_0$ represents the short-range attractive nuclear force. Beyond the nuclear radius, $R_0$, the Coulomb repulsion dominates (since the nuclear force drops to zero) and we see the characteristic $1/r$ dependence of the Coulomb potential. The $\alpha$ particle, trapped within the nucleus, can be thought of as moving back and forth between the potential walls. Since the potential energy just beyond $r = R_0$ is greater than the energy of the $\alpha$ particle (dashed line), the $\alpha$ particle could not escape the nucleus if it were governed by classical physics. But according to quantum mechanics, there is a nonzero probability that the $\alpha$ particle can **tunnel** through the **Coulomb barrier**, from point A to point B in Fig. 41–7, as we discussed in Section 38–10. The height and width of the barrier affect the rate at which nuclei decay (Section 41–8). Because of this barrier, the lifetimes of $\alpha$-unstable nuclei can be quite long, from a fraction of a microsecond to over $10^{10}$ years. Note in Fig. 41–7 that the $Q$-value represents the total kinetic energy when the $\alpha$ particle is far from the nucleus.

We can look at tunneling via the uncertainty principle which tells us that energy conservation can be violated by an amount $\Delta E$ for a length of time $\Delta t$ given by

$$(\Delta E)(\Delta t) \approx \frac{h}{2\pi}.$$

Thus quantum mechanics allows conservation of energy to be violated for brief periods that may be long enough for an $\alpha$ particle to "tunnel" through the barrier. $\Delta E$ would represent the energy difference between the average barrier height and the particle's energy, and $\Delta t$ the time to pass through the barrier. The height and width of this barrier controls the rate of decay and half-life of an isotope. The higher and wider the barrier, the less time an $\alpha$ particle has to escape (and less likely to do so) so the rate of decay would be lower and the half-life longer.

## Why $\alpha$ Particles?

Why, you may wonder, do nuclei emit this combination of four nucleons called an $\alpha$ particle? Why not just four separate nucleons, or even one? The answer

PSE5_CH41_v1.8_23Jun-20

is that the $\alpha$ particle is very strongly bound, so that its mass is significantly less than that of four separate nucleons. That helps the final state in $\alpha$ decay to have less total mass, thus allowing certain nuclides to decay which could not decay to, say, 2 protons plus 2 netrons. For example, $^{232}_{92}\text{U}$ could not decay to $2\text{p} + 2\text{n}$ because the masses of the daughter $^{228}_{90}\text{Th}$ plus four separate nucleons is $228.028741\ \text{u} + 2(1.007825\ \text{u}) + 2(1.008665\ \text{u}) = 232.061721\ \text{u}$, which is greater than the mass of the $^{232}_{92}\text{U}$ parent (232.037156 u). Such a decay would violate the conservation of energy. Indeed, we have never seen $^{232}_{92}\text{U} \rightarrow {}^{228}_{90}\text{Th} + 2\text{p} + 2\text{n}$. Similarly, it is almost always true that the emission of a single nucleon is energetically not possible; see Example 41–5.

### Smoke Detectors—An Application

One widespread application of nuclear physics is present in nearly every home in the form of an ordinary **smoke detector**. One type of smoke detector contains about 0.2 mg of the radioactive americium isotope, $^{241}_{95}\text{Am}$, in the form of $\text{AmO}_2$. The $\alpha$ radiation continually ionizes the nitrogen and oxygen molecules in the air space between two oppositely charged plates. The resulting conductivity allows a small steady electric current. If smoke enters, the radiation is absorbed by the smoke particles rather than by the air molecules, thus reducing the current. The current drop is detected by the device's electronics and sets off the alarm. The radiation dose that escapes from an intact americium smoke detector is much less than the natural radioactive background, and so can be considered relatively harmless. There is no question that smoke detectors save lives and reduce property damage.

*Smoke detector*

## 41–5 Beta Decay

### $\beta^-$ Decay

Transmutation of elements also occurs when a nucleus decays by $\beta$ decay—that is, with the emission of an electron or $\beta^-$ particle. The nucleus $^{14}_{6}\text{C}$, for example, emits an electron when it decays:

$$^{14}_{6}\text{C} \rightarrow {}^{14}_{7}\text{N} + \text{e}^- + \text{neutrino},$$

where $\text{e}^-$ is the symbol for the electron. The particle known as the neutrino has charge $q = 0$ and a very small mass, long thought to be zero. It was not initially detected and was only later hypothesized to exist, as we shall discuss later in this Section. No nucleons are lost when an electron is emitted, and the total number of nucleons, $A$, is the same in the daughter nucleus as in the parent. But because an electron has been emitted from the nucleus itself, the charge on the daughter nucleus is $+1e$ greater than that on the parent. The parent nucleus in the decay written above had $Z = +6$, so from charge conservation the nucleus remaining behind must have a charge of $+7e$. So the daughter nucleus has $Z = 7$, which is nitrogen.

It must be carefully noted that the electron emitted in $\beta$ decay is *not* an orbital electron. Instead, the electron is created *within the nucleus itself*. What happens is that one of the neutrons changes to a proton and in the process (to conserve charge) emits an electron. Indeed, free neutrons (whose mass is a bit more than a proton's) actually do decay in this fashion:

$$\text{n} \rightarrow \text{p} + \text{e}^- + \text{neutrino}.$$

To remind us of their origin in the nucleus, the electrons emitted in $\beta$ decay are often referred to as "$\beta$ particles." They are, nonetheless, indistinguishable from orbital electrons.

**CAUTION**
*$\beta$-decay $e^-$ comes from nucleus (it is not an orbital electron)*

**EXAMPLE 41–8** **Energy release in $^{14}_{6}$C decay.** How much energy is released when $^{14}_{6}$C decays to $^{14}_{7}$N by $\beta$ emission?

**APPROACH** We find the mass difference before and after decay, $\Delta m$. The energy released is $E = (\Delta m)c^2$. The masses given in Appendix G are those of the neutral atom, and we have to keep track of the electrons involved. Assume the parent nucleus has six orbiting electrons so it is neutral; its mass is 14.003242 u. The daughter in this decay, $^{14}_{7}$N, is not neutral since it has the same six orbital electrons circling it but the nucleus has a charge of $+7e$. However, the mass of this daughter with its six electrons, plus the mass of the emitted electron (which makes a total of seven electrons), is just the mass of a neutral nitrogen atom (including its 7 electrons).

**SOLUTION** The total mass in the final state is

$$(\text{mass of } ^{14}_{7}\text{N nucleus} + 6 \text{ electrons}) + (\text{mass of 1 electron}),$$

and this is equal to

$$\text{mass of neutral } ^{14}_{7}\text{N (includes 7 electrons)},$$

which from Appendix G is a mass of 14.003074 u. So the mass difference is $14.003242\text{ u} - 14.003074\text{ u} = 0.000168\text{ u}$, which is equivalent to an energy change $\Delta m\,c^2 = (0.000168\text{ u})\,(931.5\text{ MeV/u}) = 0.156\text{ MeV}$ or 156 keV. This energy goes into the kinetic energy of the electron and neutrino.

**NOTE** The neutrino doesn't contribute to either the mass or charge balance because it has $q = 0$ and $m \approx 0$.

**CAUTION**
*Be careful with atomic and electron masses in $\beta$ decay*

According to Example 41–8, we would expect the emitted electron to have a kinetic energy of 156 keV. (The daughter nucleus, because its mass is very much larger than that of the electron, recoils with very low velocity and hence gets very little of the kinetic energy—see Example 41–7.) Indeed, very careful measurements indicate that a few emitted $\beta$ particles do have kinetic energy close to this calculated value. But the vast majority of emitted electrons have somewhat less energy. In fact, the energy of the emitted electron can be anywhere from zero up to the maximum value as calculated above. This range of electron kinetic energy was found for any $\beta$ decay. It was as if the law of conservation of energy was being violated, and Bohr actually considered this possibility. Careful experiments indicated that linear momentum and angular momentum also did not seem to be conserved. Physicists were troubled at the prospect of giving up these laws, which had worked so well in all previous situations.

In 1930, Wolfgang Pauli proposed an alternate solution: perhaps a new particle that was very difficult to detect was emitted during $\beta$ decay in addition to the electron. This hypothesized particle could be carrying off the energy, momentum, and angular momentum required to maintain the conservation laws. This new particle was named the **neutrino**—meaning "little neutral one"—by the great Italian physicist Enrico Fermi (1901–1954; Fig. 41–8), who in 1934 worked out a detailed theory of $\beta$ decay. (It was Fermi who, in this theory, postulated the existence of the fourth force in nature which we call the *weak nuclear force*.) The neutrino has zero charge, spin of $\frac{1}{2}\hbar$, and was long thought to have zero mass, although today we are quite sure that it has a very tiny mass $(< 0.14\,\text{eV}/c^2)$. If its mass were zero, it would be much like a photon in that it is neutral and would travel at the speed of light. But the neutrino is very difficult to detect. In 1956, complex experiments produced further evidence for the existence of the neutrino; but by then, most physicists had already accepted its existence.

The symbol for the neutrino is the Greek letter nu $(\nu)$. The correct way of writing the decay of $^{14}_{6}$C is then

$$^{14}_{6}\text{C} \rightarrow {}^{14}_{7}\text{N} + \text{e}^- + \bar{\nu}.$$

The bar $(^-)$ over the neutrino symbol is to indicate that it is an "antineutrino."

**FIGURE 41–8** Enrico Fermi, as portrayed on a US postage stamp. Fermi contributed significantly to both *theoretical* and *experimental* physics, a feat almost unique in modern times:
theory: statistical theory of identical particles that obey the exclusion principle (= fermions); theory of the weak interaction and $\beta$ decay;
experiments: neutron physics; induced radioactivity and new elements; first nuclear reactor; first resonance of particle physics;
led and inspired a vast amount of other nuclear research.

(Why this is called an antineutrino rather than simply a neutrino is discussed in Chapter 43.)

In $\beta$ decay, including $\beta^+$ decay and EC, it is the weak nuclear force that plays the crucial role. The neutrino is unique in that it interacts with matter only via the weak force, which is why it is so hard to detect.

### $\beta^+$ Decay

Many isotopes decay by electron emission. They are always isotopes that have too many neutrons compared to the number of protons. That is, they are isotopes that lie above the stable isotopes plotted in Fig. 41–2. But what about unstable isotopes that have too few neutrons compared to their number of protons—those that fall below the stable isotopes of Fig. 41–2? These, it turns out, decay by emitting a **positron** instead of an electron. A positron (sometimes called an $e^+$ or $\beta^+$ particle) has the same mass as the electron, but it has a positive charge of $+1e$. Because it is so like an electron, except for its charge, the positron is called the **antiparticle**[†] to the electron. An example of a $\beta^+$ decay is that of $^{19}_{10}$Ne:

$$^{19}_{10}\text{Ne} \rightarrow {}^{19}_{9}\text{F} + \text{e}^+ + \nu,$$

where $e^+$ stands for a positron. Note that the $\nu$ emitted here is a neutrino, whereas that emitted in $\beta^-$ decay is called an antineutrino. Thus an antielectron (= positron) is emitted with a neutrino, whereas an antineutrino is emitted with an electron; this gives a certain balance as discussed in Chapter 43.

We can write $\beta^-$ and $\beta^+$ decay, in general, as follows:

$$^{A}_{Z}\text{N} \rightarrow {}^{A}_{Z+1}\text{N}' + \text{e}^- + \bar{\nu} \qquad [\beta^- \text{ decay}]$$

$$^{A}_{Z}\text{N} \rightarrow {}^{A}_{Z-1}\text{N}' + \text{e}^+ + \nu, \qquad [\beta^+ \text{ decay}]$$

where N is the parent nucleus and N′ is the daughter.

### Electron Capture

Besides $\beta^-$ and $\beta^+$ emission, there is a third related process. This is **electron capture** (abbreviated EC) and occurs when a nucleus absorbs one of its orbiting electrons. An example is $^{7}_{4}$Be, which as a result becomes $^{7}_{3}$Li. The process is written

$$^{7}_{4}\text{Be} + \text{e}^- \rightarrow {}^{7}_{3}\text{Li} + \nu,$$

or, in general,

$$^{A}_{Z}\text{N} + \text{e}^- \rightarrow {}^{A}_{Z-1}\text{N}' + \nu. \qquad [\text{electron capture}]$$

Usually it is an electron in the innermost (K) shell that is captured, in which case the process is called **K-capture**. The electron disappears in the process, and a proton in the nucleus becomes a neutron; a neutrino is emitted as a result. This process is inferred experimentally by detection of emitted X-rays (due to other electrons jumping down to fill the state of the captured $e^-$).

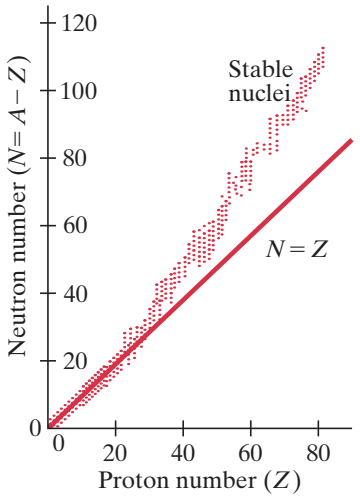

**FIGURE 41–2** (Repeated.) Number of neutrons versus number of protons for stable nuclides, which are represented by dots. The straight line represents $N = Z$.

## 41–6 Gamma Decay

Gamma rays are photons having very high energy. They have their origin in the decay of a nucleus, much like emission of photons by excited atoms. Like an atom, a nucleus itself can be in an excited state. When it jumps down to a lower energy state, or to the ground state, it emits a photon which we call a $\gamma$ ray. The possible states of a nucleus are much farther apart in energy than those of an atom: on the order of keV or MeV, as compared to a few eV for electrons in an atom. Hence, the emitted photons have energies that can range from a few keV to several MeV. For a given decay, the $\gamma$ ray always has the same energy. Since a $\gamma$ ray carries no charge, there is no change in the element as a result of a $\gamma$ decay.

[†]Discussed in Chapter 43. Briefly, an antiparticle has the same mass as its corresponding particle, but opposite charge. A particle and its antiparticle can quickly annihilate each other, releasing energy in the form of two $\gamma$ rays: $e^+ + e^- \rightarrow 2\gamma$.

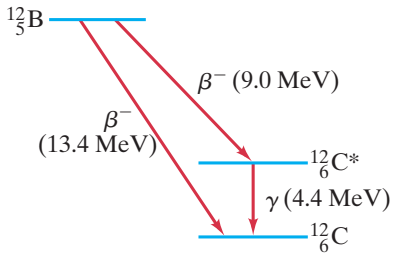

**FIGURE 41–9** Energy-level diagram showing how $^{12}_{5}$B can decay to the ground state of $^{12}_{6}$C by $\beta$ decay (total energy released = 13.4 MeV), or can instead $\beta$ decay to an excited state of $^{12}_{6}$C (indicated by *), which subsequently decays to its ground state by emitting a 4.4-MeV $\gamma$ ray.

How does a nucleus get into an excited state? It may occur because of a violent collision with another particle. More commonly, the nucleus remaining after a previous radioactive decay may be in an excited state. A typical example is shown in the energy-level diagram of Fig. 41–9. $^{12}_{5}$B can decay by $\beta$ decay directly to the ground state of $^{12}_{6}$C; or it can go by $\beta$ decay to an excited state of $^{12}_{6}$C, written $^{12}_{6}$C*, which itself decays by emission of a 4.4-MeV $\gamma$ ray to the ground state of $^{12}_{6}$C.

We can write $\gamma$ decay as

$$^{A}_{Z}\mathrm{N}^* \longrightarrow {}^{A}_{Z}\mathrm{N} + \gamma, \qquad [\gamma \text{ decay}]$$

where the asterisk means "excited state" of that nucleus.

What, you may wonder, is the difference between a $\gamma$ ray and an X-ray? They both are electromagnetic radiation (photons) and, though $\gamma$ rays usually have higher energy than X-rays, their range of energies overlap to some extent. The difference is not intrinsic. We use the term X-ray if the photon is produced by an electron–atom interaction, and $\gamma$ ray if the photon is produced in a nuclear process.

### Isomers; Internal Conversion

In some cases, a nucleus may remain in an excited state for some time before it emits a $\gamma$ ray. The nucleus is then said to be in a **metastable state** and is called an **isomer**.

An excited nucleus can sometimes return to the ground state by another process known as **internal conversion** with no $\gamma$ ray emitted. In this process, the excited nucleus interacts with one of the orbital electrons and ejects this electron from the atom with the same kinetic energy (minus the binding energy of the electron) that an emitted $\gamma$ ray would have had.

**TABLE 41–2 The Three Types of Radioactive Decay**

*$\alpha$ decay:*

$$^{A}_{Z}\mathrm{N} \longrightarrow {}^{A-4}_{Z-2}\mathrm{N}' + {}^{4}_{2}\mathrm{He}$$

*$\beta$ decay:*

$$^{A}_{Z}\mathrm{N} \longrightarrow {}^{A}_{Z+1}\mathrm{N}' + \mathrm{e}^- + \bar{\nu}$$

$$^{A}_{Z}\mathrm{N} \longrightarrow {}^{A}_{Z-1}\mathrm{N}' + \mathrm{e}^+ + \nu$$

$$^{A}_{Z}\mathrm{N} + \mathrm{e}^- \longrightarrow {}^{A}_{Z-1}\mathrm{N}' + \nu \; [\mathrm{EC}]^{\dagger}$$

*$\gamma$ decay:*

$$^{A}_{Z}\mathrm{N}^* \longrightarrow {}^{A}_{Z}\mathrm{N} + \gamma$$

†Electron capture.
*Indicates the excited state of a nucleus.

## 41–7 Conservation of Nucleon Number and Other Conservation Laws

In all three types of radioactive decay, the classical conservation laws hold. Energy, linear momentum, angular momentum, and electric charge are all conserved. These quantities are the same before the decay as after. But a new conservation law is also revealed, the **law of conservation of nucleon number**. According to this law, the total number of nucleons ($A$) remains constant in any process, although one type can change into the other type (protons into neutrons or vice versa). This law holds in all three types of decay. [In Chapter 43 we will generalize this and call it conservation of baryon number.]

Table 41–2 gives a summary of $\alpha$, $\beta$, and $\gamma$ decay.

## 41–8 Half-Life and Rate of Decay

A macroscopic sample of any radioactive isotope consists of a vast number of radioactive nuclei. These nuclei do not all decay at one time. Rather, they decay one by one over a period of time. This is a random process: we can not predict exactly when a given nucleus will decay. But we can determine, on a probabilistic basis, approximately how many nuclei in a sample will decay over a given time period, by assuming that each nucleus has the same probability of decaying in each second that it exists.

The number of decays $\Delta N$ that occur in a very short time interval $\Delta t$ is then proportional to $\Delta t$ and to the total number $N$ of radioactive nuclei present:

$$\Delta N = -\lambda N \, \Delta t \qquad \textbf{(41–4a)}$$

where the minus sign means $N$ is decreasing. We rewrite this to get the **rate of decay** (number of decays per second):

$$\frac{\Delta N}{\Delta t} = -\lambda N. \qquad \textbf{(41–4b)}$$

In these equations, $\lambda$ is a measurable constant called the **decay constant**, which is different for different isotopes. The greater $\lambda$ is, the greater the rate of decay, $\Delta N/\Delta t$,

PSE5_CH41_v1.8_23Jun-20

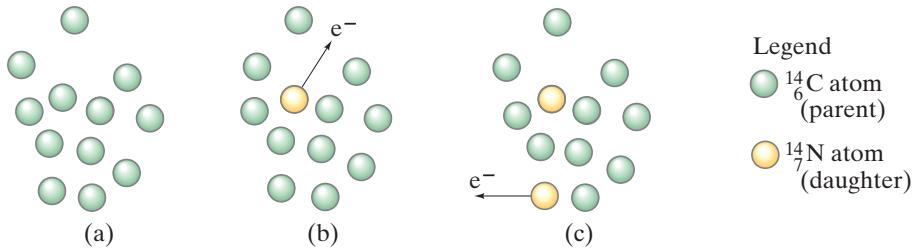

**FIGURE 41–10** Radioactive nuclei decay one by one. Hence, the number of parent nuclei in a sample is continually decreasing. When a $^{14}_{6}$C nucleus emits an electron, the nucleus becomes a $^{14}_{7}$N nucleus.

and the more "radioactive" that isotope is said to be. The number of decays that occur in the short time interval $\Delta t$ is designated $\Delta N$ because each decay that occurs corresponds to a decrease by one in the number $N$ of parent nuclei present. That is, radioactive decay is a "one-shot" process, Fig. 41–10. Once a particular parent nucleus decays into its daughter, it cannot do it again.

If we take the limit $\Delta t \to 0$ in Eq. 41–4, $\Delta N$ will be small compared to $N$, and we can write the equation in infinitesimal form as

$$dN = -\lambda N\, dt. \qquad \textbf{(41–5)}$$

We can determine $N$ as a function of $t$ by rearranging this equation to

$$\frac{dN}{N} = -\lambda\, dt$$

and then integrating from $t = 0$ to $t = t$:

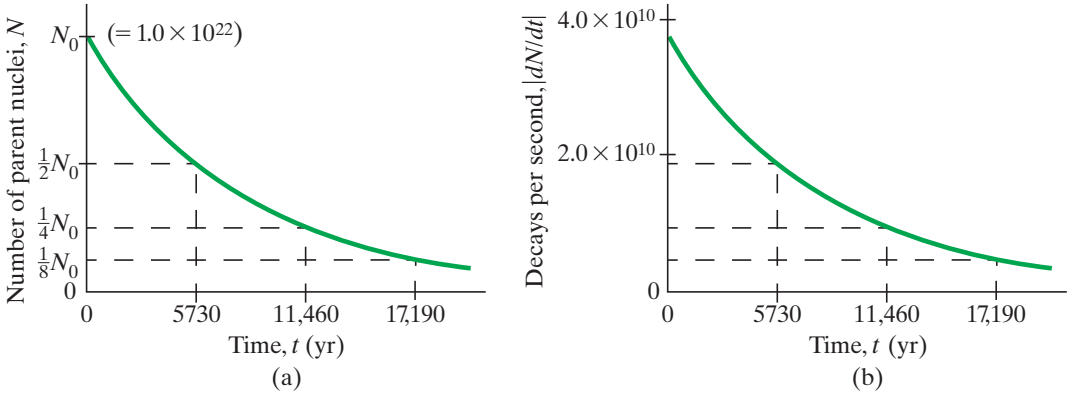
$$\int_{N_0}^{N} \frac{dN}{N} = -\int_0^t \lambda\, dt,$$

where $N_0$ is the number of parent nuclei present at $t = 0$ and $N$ is the number remaining at time $t$. The integration gives

$$\ln \frac{N}{N_0} = -\lambda t$$

or

$$N = N_0 e^{-\lambda t}. \qquad \textbf{(41–6)}$$



Equation 41–6 is called the **radioactive decay law**. It tells us that the number of radioactive nuclei in a given sample decreases exponentially in time. This is shown in Fig. 41–11a for the case of $^{14}_{6}$C whose decay constant is $\lambda = 3.83 \times 10^{-12}\ \text{s}^{-1}$.

The rate of decay in a pure sample, or number of decays per second, is

$$\left|\frac{dN}{dt}\right|,$$

also called the **activity** of the sample. We use absolute value signs to make activity a positive number ($dN/dt$ is negative because the number of parent nuclei $N$ is decreasing). The symbol $R$ is also used for activity, $R = |dN/dt|$.

**FIGURE 41–11** (a) The number $N$ of parent nuclei in a given sample of $^{14}_{6}$C decreases exponentially. We assume a sample that has $N_0 = 1.00 \times 10^{22}$ parent nuclei. (b) The number of decays per second also decreases exponentially. The half-life (Eq. 41–8) of $^{14}_{6}$C is 5730 yr, which means that the number of parent nuclei, $N$, and the rate of decay, $|dN/dt|$, decrease by half every 5730 yr.

From Eqs. 41–5 and 41–6,

$$\left|\frac{dN}{dt}\right| = \lambda N = \lambda N_0 e^{-\lambda t}. \tag{41–7a}$$

At $t = 0$, the activity is

$$\left|\frac{dN}{dt}\right|_0 = \lambda N_0. \tag{41–7b}$$

Hence, at any other time $t$ the activity is

$$\left|\frac{dN}{dt}\right| = \left|\frac{dN}{dt}\right|_0 e^{-\lambda t}, \tag{41–7c}$$

so the activity decreases exponentially in time at the same rate as for $N$ (Fig. 41–11b). Equation 41–7c is sometimes referred to as the **radioactive decay law** (so is Eq. 41–6), and can be written using $R$ to represent activity, $R = |dN/dt|$. The activity $R$ of a pure sample after a time $t$ is

$$R = \left|\frac{dN}{dt}\right| = R_0 e^{-\lambda t}. \tag{41–7d}$$

## Half-life

The rate of decay of any isotope is often specified by giving its half-life rather than the decay constant $\lambda$. The **half-life** of an isotope is defined as the time it takes for half the original amount of the parent isotope in a given sample to decay. For example, the half-life of $^{14}_{6}\text{C}$ is about 5730 years. If at some time a piece of petrified wood contains, say, $1.00 \times 10^{22}$ nuclei of $^{14}_{6}\text{C}$, then 5730 years later it will contain half as many, $0.50 \times 10^{22}$ parent nuclei. After another 5730 years it will contain $0.25 \times 10^{22}$ nuclei, and so on. This is characteristic of the exponential function, and is shown in Fig. 41–11a. Since the rate of decay $|dN/dt|$ is proportional to $N$, it too decreases by a factor of 2 every half-life, Fig. 41–11b.

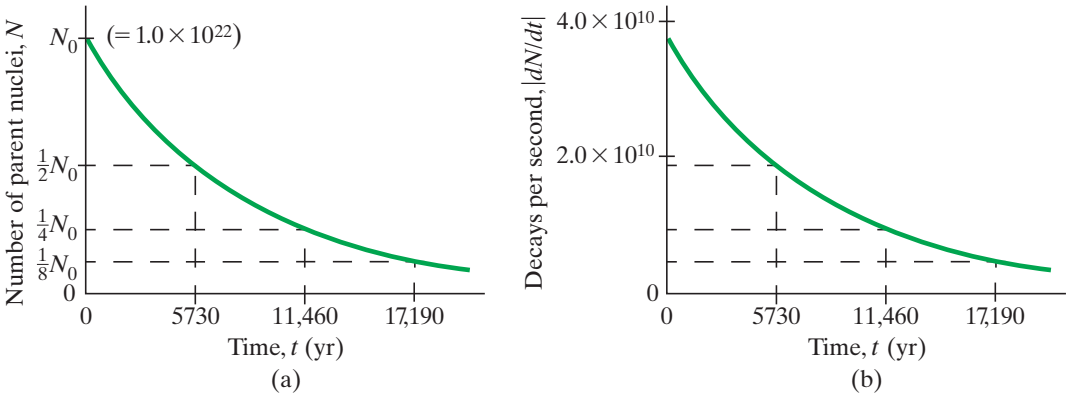


**FIGURE 41–11** (Repeated.) (a) The number $N$ of parent nuclei in a given sample of $^{14}_{6}\text{C}$ decreases exponentially. We assume a sample that has $N_0 = 1.00 \times 10^{22}$ parent nuclei. (b) The number of decays per second also decreases exponentially. The half-life of (Eq. 41–8) of $^{14}_{6}\text{C}$ is 5730 yr, which means that the number of parent nuclei, $N$, and the rate of decay, $|dN/dt|$, decrease by half every 5730 yr.

**EXERCISE D** The half-life of $^{22}_{11}\text{Na}$ is 2.6 years. How much $^{22}_{11}\text{Na}$ will be left of a pure 1.0-$\mu$g sample of $^{22}_{11}\text{Na}$ after 7.8 yr? (*a*) None. (*b*) $\frac{1}{8}\,\mu$g. (*c*) $\frac{1}{4}\,\mu$g. (*d*) $\frac{1}{2}\,\mu$g. (*e*) 0.693 $\mu$g.

**EXERCISE E** Return to the Chapter-Opening Question, page 1226, and answer it again now. Try to explain why you may have answered differently the first time.

The half-lives of known radioactive isotopes vary from very short $(\approx 10^{-22}\,\text{s})$ to more than $10^{23}$ yr $(> 10^{30}\,\text{s})$. The half-lives of many isotopes are given in Appendix G. The half-life (which we designate $T_{\frac{1}{2}}$) bears an inverse relationship

PSE5_CH41_v1.8_23Jun-20

to the decay constant. The longer the half-life of an isotope, the more slowly it decays, and hence $\lambda$ is smaller. Conversely, very active isotopes (large $\lambda$) have very short half-lives. The precise relation is obtained from Eq. 41–6 by setting $N = N_0/2$ at $t = T_{\frac{1}{2}}$:

$$\frac{N_0}{2} = N_0 e^{-\lambda T_{\frac{1}{2}}} \quad \text{or} \quad e^{\lambda T_{\frac{1}{2}}} = 2.$$

We take natural logs of both sides ("ln" and "$e$" are inverse operations, meaning $\ln(e^x) = x$) and find

$$\ln\left(e^{\lambda T_{\frac{1}{2}}}\right) = \ln 2, \quad \text{so} \quad \lambda T_{\frac{1}{2}} = \ln 2$$

and

$$T_{\frac{1}{2}} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda}. \tag{41–8}$$

We can then write Eq. 41–6 as

$$N = N_0 e^{-0.693 t/T_{\frac{1}{2}}}.$$

Sometimes the **mean life** $\tau$ of an isotope is quoted, which is defined as $\tau = 1/\lambda$ (see also Problem 86), so then Eq. 41–6 can be written

$$N = N_0 e^{-t/\tau}$$

just as for $RC$ and $LR$ circuits (Chapters 26 and 30, where $\tau$ is called the time constant). Since

$$\tau = \frac{1}{\lambda} = \frac{T_{\frac{1}{2}}}{0.693} \tag{41–9a}$$

the mean life and half-life differ by a factor 0.693, so confusing them can cause serious error. The radioactive decay law, Eq. 41–7d, can be written as

$$R = R_0 e^{-t/\tau}. \tag{41–9b}$$

**CAUTION**
*Do not confuse half-life and mean life*

**EXAMPLE 41–9** **Sample activity.** The isotope $^{14}_{6}\text{C}$ has a half-life of 5730 yr. If a sample contains $1.00 \times 10^{22}$ carbon-14 nuclei, what is the activity of the sample?

**APPROACH** We first use the half-life to find the decay constant (Eq. 41–8), and use that to find the activity, Eq. 41–7b or 41–5. The number of seconds in a year is $(60\,\text{s/min})(60\,\text{min/h})(24\,\text{h/d})\left(365\tfrac{1}{4}\,\text{d/yr}\right) = 3.156 \times 10^7\,\text{s}$.

**SOLUTION** The decay constant $\lambda$ from Eq. 41–8 is

$$\lambda = \frac{0.693}{T_{\frac{1}{2}}} = \frac{0.693}{(5730\,\text{yr})(3.156 \times 10^7\,\text{s/yr})} = 3.83 \times 10^{-12}\,\text{s}^{-1}.$$

From Eq. 41–7b, the activity or rate of decay is

$$\left|\frac{dN}{dt}\right|_0 = \lambda N_0 = (3.83 \times 10^{-12}\,\text{s}^{-1})(1.00 \times 10^{22}) = 3.83 \times 10^{10}\,\text{decays/s}.$$

Notice that the graph of Fig. 41–11b starts at this value, corresponding to the original value of $N_0 = 1.0 \times 10^{22}$ nuclei in Fig. 41–11a.

**NOTE** The unit "decays/s" is often written simply as $\text{s}^{-1}$ since "decays" is not a unit but refers only to the number. This simple unit of activity is called the becquerel: 1 Bq = 1 decay/s, as discussed in Chapter 42.

**EXERCISE F** Determine the decay constant for radium $(T_{\frac{1}{2}} = 1600\,\text{yr})$.

**CONCEPTUAL EXAMPLE 41–10** **Safety: Activity versus half-life.** One might think that a short half-life material is safer than a long half-life material because it will not last as long. Is that true?

**RESPONSE** No. A shorter half-life means the activity is higher and thus more "radioactive" and can cause more biological damage. In contrast, a longer half-life for the same sample size $N$ means a lower activity but we have to worry about it for longer and find safe storage until it reaches a safe (low) level of activity.

**EXAMPLE 41–11** **A sample of radioactive $^{13}_{7}$N.** A laboratory has 1.49 $\mu$g of pure $^{13}_{7}$N, which has a half-life of 10.0 min (600 s). (*a*) How many nuclei are present initially? (*b*) What is the activity (rate of decay) initially? (*c*) What is the activity after 1.00 h? (*d*) After approximately how long will the activity drop to less than one per second $(= 1\,\text{s}^{-1})$?

**APPROACH** We use the definition of the mole and Avogadro's number (Sections 17–7 and 17–9) to find the number of nuclei. For (*b*) we get $\lambda$ from the given half-life and use Eq. 41–7b for the activity. For (*c*) and (*d*) we use Eq. 41–7c.

**SOLUTION** (*a*) The atomic mass is 13.0, so 13.0 g will contain $6.02 \times 10^{23}$ nuclei (Avogadro's number). We have only $1.49 \times 10^{-6}$ g, so the number of nuclei $N_0$ that we have initially is given by the ratio

$$\frac{N_0}{6.02 \times 10^{23}} = \frac{1.49 \times 10^{-6}\,\text{g}}{13.0\,\text{g}}.$$

Solving, we find $N_0 = 6.90 \times 10^{16}$ nuclei.

(*b*) From Eq. 41–8,

$$\lambda = 0.693/T_{\frac{1}{2}} = (0.693)/(600\,\text{s}) = 1.155 \times 10^{-3}\,\text{s}^{-1}.$$

Then, at $t = 0$ (Eq. 41–7b),

$$\left|\frac{dN}{dt}\right|_0 = \lambda N_0 = (1.155 \times 10^{-3}\,\text{s}^{-1})(6.90 \times 10^{16}) = 7.97 \times 10^{13}\,\text{decays/s}.$$

(*c*) After $1.00\,\text{h} = 3600\,\text{s}$, the magnitude of the activity (the rate of decay) will be (Eq. 41–7c)

$$\left|\frac{dN}{dt}\right| = \left|\frac{dN}{dt}\right|_0 e^{-\lambda t}$$
$$= (7.97 \times 10^{13}\,\text{s}^{-1})\, e^{-(1.155\times10^{-3}\,\text{s}^{-1})(3600\,\text{s})} = 1.25 \times 10^{12}\,\text{s}^{-1}.$$

(*d*) We want to determine the time $t$ when $|dN/dt| = 1.00\,\text{s}^{-1}$. From Eq. 41–7c, we have

$$e^{-\lambda t} = \frac{|dN/dt|}{|dN/dt|_0} = \frac{1.00\,\text{s}^{-1}}{7.97 \times 10^{13}\,\text{s}^{-1}} = 1.25 \times 10^{-14}.$$

We take the natural log (ln) of both sides $(\ln e^{-\lambda t} = -\lambda t)$ and divide by $\lambda$ to find

$$t = -\frac{\ln(1.25 \times 10^{-14})}{\lambda} = 2.77 \times 10^{4}\,\text{s} = 7.70\,\text{h}.$$

***Easy Alternate Solution to (c)*** 1.00 h = 60.0 minutes is 6 half-lives, so the activity will decrease to $(\frac{1}{2})(\frac{1}{2})(\frac{1}{2})(\frac{1}{2})(\frac{1}{2})(\frac{1}{2}) = (\frac{1}{2})^6 = \frac{1}{64}$ of its original value, or $(7.97 \times 10^{13})/(64) = 1.25 \times 10^{12}$ per second.

# 41–9 Decay Series

It is often the case that one radioactive isotope decays to another isotope that is also radioactive. Sometimes this daughter decays to yet a third isotope which also is radioactive. Such successive decays are said to form a **decay series**. An important example is illustrated in Fig. 41–12. As can be seen, $^{238}_{92}\text{U}$ decays by $\alpha$ emission to $^{234}_{90}\text{Th}$, which in turn decays by $\beta$ decay to $^{234}_{91}\text{Pa}$. The series continues as shown, with several possible branches near the bottom, ending at the stable lead isotope, $^{206}_{82}\text{Pb}$. The two last decays can be

$$^{206}_{81}\text{Tl} \rightarrow {}^{206}_{82}\text{Pb} + e^- + \bar{\nu}, \qquad (T_{\frac{1}{2}} = 4.2\,\text{min})$$

or

$$^{210}_{84}\text{Po} \rightarrow {}^{206}_{82}\text{Pb} + \alpha. \qquad (T_{\frac{1}{2}} = 138\,\text{days})$$

Other radioactive series also exist.

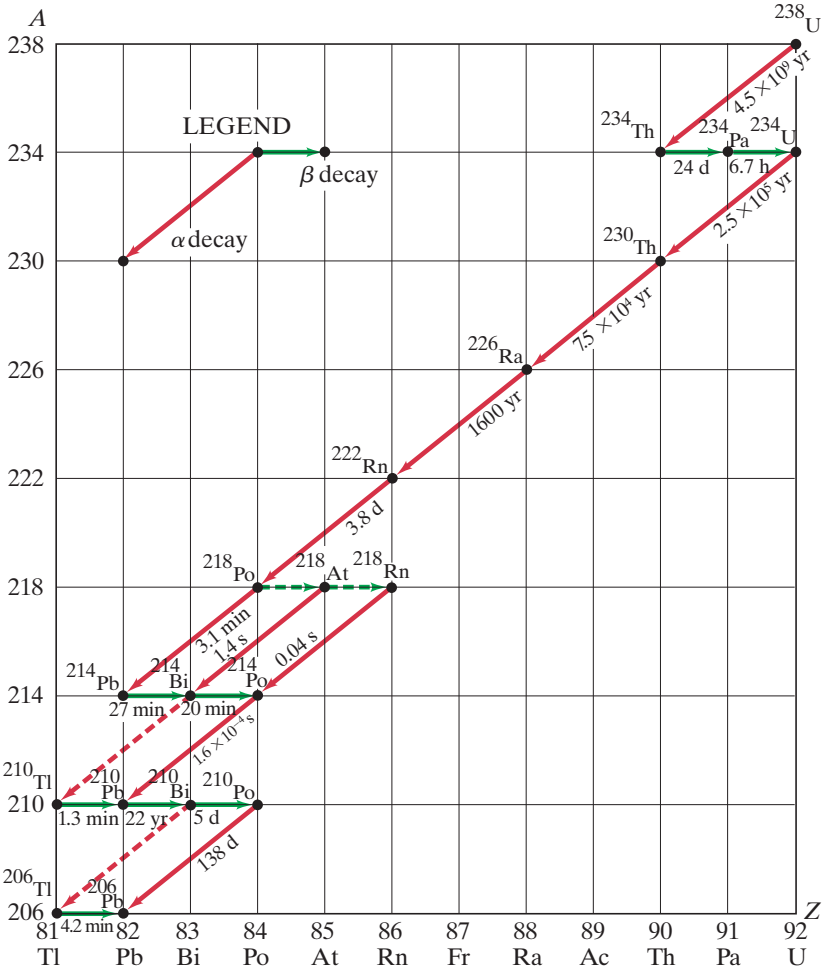

**FIGURE 41–12** Decay series beginning with $^{238}_{92}\text{U}$. Nuclei in the series are specified by a dot representing $A$ and $Z$ values. Half-lives are given in seconds (s), minutes (min), hours (h), days (d), or years (yr). Note that a horizontal arrow represents $\beta$ decay ($A$ does not change), whereas a diagonal line represents $\alpha$ decay ($A$ changes by 4, $Z$ changes by 2). For the four nuclides shown that can decay by both $\alpha$ and $\beta$ decay, the more prominent decay (in these four cases, $> 99.9\%$) is shown as a solid arrow and the less common decay ($< 0.1\%$) as a dashed arrow.

Because of such decay series, certain radioactive elements are found in nature that otherwise would not be. When the solar system (including Earth) was formed about 5 billion years ago, it is believed that nearly all nuclides were present, having been formed (by fusion and neutron capture, Sections 42–4 and 44–2) in a nearby supernova explosion (Section 44–2). Many isotopes with short half-lives decayed quickly and no longer are detected in nature today. But long-lived isotopes, such as $^{238}_{92}\text{U}$ with a half-life of $4.5 \times 10^9$ yr, still do exist in nature today. Indeed, about half of the original $^{238}_{92}\text{U}$ still remains. We might expect, however, that radium $\left(^{226}_{88}\text{Ra}\right)$, with a half-life of 1600 yr, would have disappeared from the Earth long ago. Indeed, the original $^{226}_{88}\text{Ra}$ nuclei must by now have all decayed.

However, because $^{238}_{92}\text{U}$ decays (in several steps) to $^{226}_{88}\text{Ra}$, the supply of $^{226}_{88}\text{Ra}$ is continually replenished, which is why it is still found on Earth today. The same can be said for many other radioactive nuclides.

**CONCEPTUAL EXAMPLE 41–12** **Decay chain.** In the decay chain of Fig. 41–12, if we look at the decay of $^{234}_{92}\text{U}$, we see four successive nuclides with half-lives of 250,000 yr, 75,000 yr, 1600 yr, and a little under 4 days. Each decay in the chain has an alpha particle of a characteristic energy, and so we can monitor the radioactive decay rate of each nuclide. Given a sample that was pure $^{234}_{92}\text{U}$ a million years ago, which alpha decay would you expect to have the highest activity rate in the sample?

**RESPONSE** The first instinct is to say that the process with the shortest half-life would show the highest activity. Surprisingly, perhaps, the activities of the four nuclides in this sample are all the same. The reason is that in each case the decay of the parent acts as a bottleneck to the decay of the daughter. Compared to the 1600-yr half-life of $^{226}_{88}\text{Ra}$, for example, its daughter $^{222}_{86}\text{Rn}$ decays almost immediately, but it cannot decay until it is made. (This is like an automobile assembly line: if worker A takes 20 minutes to do a task and then worker B takes only 1 minute to do the next task, worker B still does only one car every 20 minutes.)

## 41–10 Radioactive Dating

Radioactive decay has many interesting applications. One is the technique of *radioactive dating* by which the age of ancient materials can be determined.

**PHYSICS APPLIED**
*Carbon-14 dating*

The age of any object made from once-living matter, such as wood, can be determined using the natural radioactivity of $^{14}_{6}\text{C}$. All living plants absorb carbon dioxide ($CO_2$) from the air and use it to synthesize organic molecules. The vast majority of these carbon atoms are $^{12}_{6}\text{C}$, but a small fraction, about $1.3 \times 10^{-12}$, is the radioactive isotope $^{14}_{6}\text{C}$. The ratio of $^{14}_{6}\text{C}$ to $^{12}_{6}\text{C}$ in the atmosphere has remained roughly constant over many thousands of years, in spite of the fact that $^{14}_{6}\text{C}$ decays with a half-life of about 5730 yr. This is because energetic nuclei in the cosmic radiation, which impinges on the Earth from outer space, strike nuclei of atoms in the atmosphere and break those nuclei into pieces, releasing free neutrons. Those neutrons can collide with nitrogen nuclei in the atmosphere to produce the nuclear transformation $\text{n} + {}^{14}_{7}\text{N} \rightarrow {}^{14}_{6}\text{C} + \text{p}$. That is, a neutron strikes and is absorbed by a $^{14}_{7}\text{N}$ nucleus, and a proton is knocked out in the process. The remaining nucleus is $^{14}_{6}\text{C}$. This continual production of $^{14}_{6}\text{C}$ in the atmosphere roughly balances the loss of $^{14}_{6}\text{C}$ by radioactive decay.

As long as a plant or tree is alive, it continually uses the carbon from carbon dioxide in the air to build new tissue and to replace old. Animals eat plants, so they too are continually receiving a fresh supply of carbon for their tissues. Organisms cannot distinguish[†] $^{14}_{6}\text{C}$ from $^{12}_{6}\text{C}$, and because the ratio of $^{14}_{6}\text{C}$ to $^{12}_{6}\text{C}$ in the atmosphere remains nearly constant, the ratio of the two isotopes within the living organism remains nearly constant as well. When an organism dies, carbon dioxide is no longer taken in and utilized. Because the $^{14}_{6}\text{C}$ decays radioactively, the ratio of $^{14}_{6}\text{C}$ to $^{12}_{6}\text{C}$ in a dead organism decreases over time. The half-life of $^{14}_{6}\text{C}$ is about 5730 yr, so the $^{14}_{6}\text{C}/^{12}_{6}\text{C}$ ratio decreases by half every 5730 yr. If, for example, the $^{14}_{6}\text{C}/^{12}_{6}\text{C}$ ratio of an ancient wooden tool is half of what it is in living trees, then the object must have been made from a tree that was felled about 5730 years ago.

Actually, corrections must be made for the fact that the $^{14}_{6}\text{C}/^{12}_{6}\text{C}$ ratio in the atmosphere has not remained precisely constant over time. The determination of what this ratio has been over the centuries has required techniques such as comparing the expected ratio to the actual ratio for objects whose age is known, such as very old trees whose annual rings can be counted reasonably accurately.

[†]Organisms operate almost exclusively via chemical reactions—which involve only the outer orbital electrons of the atom; extra neutrons in the nucleus have essentially no effect.

PSE5_CH41_v1.8_23Jun-20

**EXAMPLE 41–13** **An ancient animal.** The mass of carbon in an animal bone fragment found in an archeological site is 200 g. If the bone registers an activity of 16 decays/s, what is its age?

PHYSICS APPLIED
*Archeological dating*

**APPROACH** First we determine how many $^{14}_{6}\text{C}$ atoms there were in our 200-g sample when the animal was alive, given the known fraction of $^{14}_{6}\text{C}$ to $^{12}_{6}\text{C}$, $1.3 \times 10^{-12}$. Then we use Eq. 41–7b to find the activity back then, and Eq. 41–7c to find out how long ago that was by solving for the time $t$.

**SOLUTION** The 200 g of carbon is nearly all $^{12}_{6}\text{C}$; 12.0 g of $^{12}_{6}\text{C}$ contains $6.02 \times 10^{23}$ atoms, so 200 g contains

$$\left(\frac{6.02 \times 10^{23}\ \text{atoms/mol}}{12\ \text{g/mol}}\right)(200\ \text{g}) \;=\; 1.00 \times 10^{25}\ \text{atoms}.$$

When the animal was alive, the ratio of $^{14}_{6}\text{C}$ to $^{12}_{6}\text{C}$ in the bone was $1.3 \times 10^{-12}$. The number of $^{14}_{6}\text{C}$ nuclei at that time was

$$N_0 \;=\; (1.00 \times 10^{25}\ \text{atoms})(1.3 \times 10^{-12}) \;=\; 1.3 \times 10^{13}\ \text{atoms}.$$

From Eq. 41–7b, with $\lambda = 3.83 \times 10^{-12}\ \text{s}^{-1}$ for $^{14}_{6}\text{C}$ (Example 41–9), the magnitude of the activity when the animal was still alive $(t = 0)$ was

$$\left|\frac{dN}{dt}\right|_0 \;=\; \lambda N_0 \;=\; (3.83 \times 10^{-12}\ \text{s}^{-1})(1.3 \times 10^{13}) \;=\; 50\ \text{s}^{-1}.$$

From Eq. 41–7c,

$$\left|\frac{dN}{dt}\right| \;=\; \left|\frac{dN}{dt}\right|_0 e^{-\lambda t},$$

where $|dN/dt|$, its activity now, is given as $16\ \text{s}^{-1}$. Then

$$16\ \text{s}^{-1} \;=\; (50\ \text{s}^{-1})e^{\lambda t}$$

or

$$e^{-\lambda t} \;=\; \frac{50}{16}.$$

We take the natural log (ln) of both sides (and divide by $\lambda$) to get

$$t \;=\; \frac{1}{\lambda}\ln\left(\frac{50}{16}\right) \;=\; \frac{1}{3.83 \times 10^{-12}\ \text{s}^{-1}}\ln\left(\frac{50}{16}\right)$$

$$\;=\; 2.98 \times 10^{11}\ \text{s} \;=\; 9400\ \text{yr},$$

which is the time elapsed since the death of the animal.

## Geological Time Scale Dating

Carbon dating is useful only for determining the age of objects less than about 60,000 years old. The amount of $^{14}_{6}\text{C}$ remaining in objects older than that is usually too small to measure accurately, although new techniques are allowing detection of even smaller amounts of $^{14}_{6}\text{C}$, pushing the time frame further back. On the other hand, radioactive isotopes with longer half-lives can be used in certain circumstances to obtain the age of older objects. For example, the decay of $^{238}_{92}\text{U}$, because of its long half-life of $4.5 \times 10^{9}$ years, is useful in determining the ages of rocks on a geologic time scale. When molten material on Earth long ago solidified into rock as the temperature dropped, different compounds solidified according to the melting points, and thus different compounds separated to some extent. Uranium present in a material became fixed in position and the daughter nuclei that result from the decay of uranium were also fixed in that position. Thus, by measuring the amount of $^{238}_{92}\text{U}$ remaining in the material relative to the amount of daughter nuclei, the time when the rock solidified can be determined.

PHYSICS APPLIED
*Geological dating*

**PHYSICS APPLIED**
*Oldest Earth rocks and earliest life*

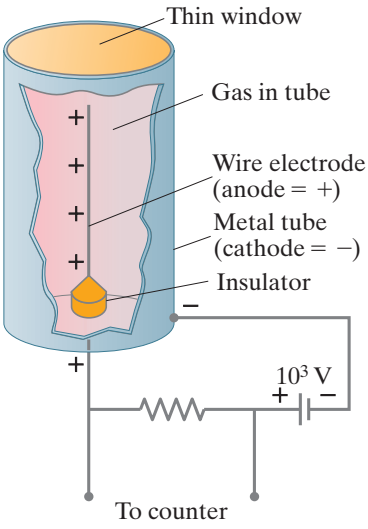
Radioactive dating methods using $^{238}_{92}U$ and other isotopes have shown the age of the oldest Earth rocks to be about $4 \times 10^9$ yr. The age of rocks in which the oldest fossilized organisms are embedded indicates that life appeared more than $3\frac{1}{2}$ billion years ago. The earliest fossilized remains of mammals are found in rocks 200 million years old, and humanlike creatures seem to have appeared more than 2 million years ago. Radioactive dating has been indispensable for the reconstruction of Earth's history.

# 41–11 Detection of Particles

Individual particles such as electrons, protons, $\alpha$ particles, neutrons, and $\gamma$ rays are not detected directly by our senses. Consequently, a variety of instruments have been developed to detect them.

## Counters

One of the most common detectors is the **Geiger counter**. As shown in Fig. 41–13, it consists of a cylindrical metal tube filled with a certain type of gas. A long wire runs down the center and is kept at a high positive voltage $(\approx 10^3\,\text{V})$ with respect to the outer cylinder. The voltage is just slightly less than that required to ionize the gas atoms. When a charged particle enters through the thin "window" at one end of the tube, it ionizes a few atoms of the gas. The freed electrons are attracted toward the positive wire, and as they are accelerated they strike and ionize additional atoms. An "avalanche" of electrons is quickly produced, and when it reaches the wire anode, it produces a voltage pulse. The pulse, after being amplified, can be sent to an electronic counter, which counts how many particles have been detected. Or the pulses can be sent to a loudspeaker and each detection of a particle is heard as a "click." Only a fraction of the radiation emitted by a sample is detected by any detector.



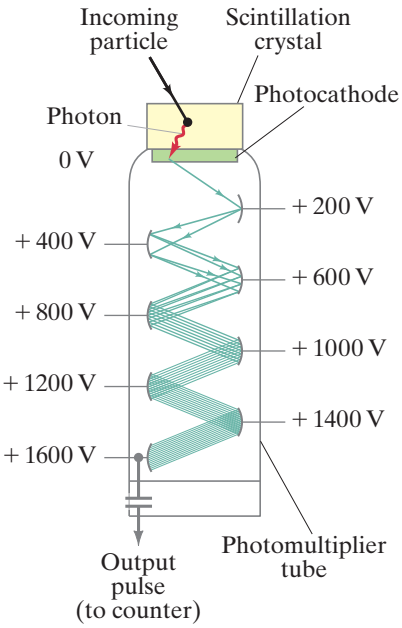


**FIGURE 41–13** Diagram of a Geiger counter.

A **scintillation counter** makes use of a solid, liquid, or gas known as a **scintillator** or **phosphor**. The atoms of a scintillator are easily excited when struck by an incoming particle and emit visible light when they return to their ground states. Typical scintillators are crystals of NaI and certain plastics. One face of a solid scintillator is cemented to a photomultiplier tube, and the whole is wrapped with opaque material to keep it light-tight (in the dark) or is placed within a light-tight container. The **photomultiplier** (PM) **tube** converts the energy of the scintillator-emitted photon(s) into an electric signal. A PM tube is a vacuum tube containing several electrodes (typically 8 to 14), called *dynodes*, which are maintained at successively higher voltages as shown in Fig. 41–14. At its top surface is a photoelectric surface, called the *photocathode*, whose work function (Section 37–2) is low enough that an electron is easily released when struck by a photon from the scintillator. Such an electron is accelerated toward the positive voltage of the first dynode. When it strikes the first dynode, the electron has acquired sufficient kinetic energy so that it can eject two to five more electrons. These, in turn, are accelerated toward the higher voltage second dynode, and a multiplication process begins. The number of electrons striking the last dynode may be $10^6$ or more. Thus the passage of a particle through the scintillator results in an electric signal at the output of the PM tube that can be sent to an electronic counter just as for a Geiger tube. Solid scintillators are much more dense than the gas of a Geiger counter, and so are much more efficient detectors—especially for $\gamma$ rays, which interact less with matter than do $\alpha$ or $\beta$ particles. Scintillators that can measure the total energy deposited are much used today and are called **calorimeters**.

**FIGURE 41–14** Scintillation counter with a photomultiplier tube.

In tracer work (Section 42–8), **liquid scintillators** are often used. Radioactive samples taken at different times or from different parts of an organism are placed directly in small bottles containing the liquid scintillator. This is particularly convenient for detection of $\beta$ rays from $^3_1H$ and $^{14}_6C$, which have very low energies

and have difficulty passing through the outer covering of a crystal scintillator or Geiger tube. A PM tube is still used to produce the electric signal from the liquid scintillator.

A **semiconductor detector** consists of a reverse-biased *pn* junction diode (Sections 40–8 and 40–9). A charged particle passing through the junction can excite electrons into the conduction band, leaving holes in the valence band. The freed charges produce a short electric current pulse that can be counted as for Geiger and scintillation counters.

Hospital workers and others who work around radiation may carry *film badges* which detect the accumulation of radiation exposure. The film inside is periodically replaced and developed, the darkness of the developed film being related to total exposure (see Section 42–6).

## Visualization

The devices discussed so far are used for counting the number of particles (or decays of a radioactive isotope). There are also devices that allow the track of charged particles to be *seen*. Very important are semiconductor detectors. **Silicon wafer semiconductors** have their surface etched into separate tiny pixels, each providing particle position information. They are much used in elementary particle physics (Chapter 43) to track the positions of particles produced and to determine their point of origin and/or their momentum (with the help of a magnetic field). The pixel arrangement can be CCD or CMOS (Section 33–5), the latter able to incorporate electronics inside, allowing fast readout.

One of the oldest tracking devices is the **photographic emulsion**, which can be small and portable, used now particularly for cosmic-ray studies from balloons. A charged particle passing through an emulsion ionizes the atoms along its path. These points undergo a chemical change, and when the emulsion is developed (like film) the particle's path is revealed.

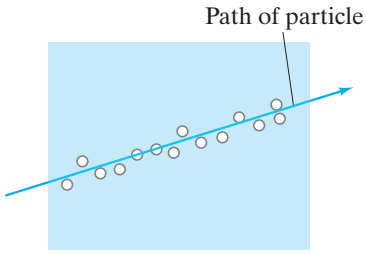
In a **cloud chamber**, used in the early days of nuclear physics, a gas is cooled to a temperature slightly below its usual condensation point ("supercooled"). Tiny droplets form around ions produced when a charged particle passes through (Fig. 41–15). Light scattering from these droplets reveals the track of the particle.

The **bubble chamber**, invented in 1952 by D. A. Glaser (1926–2013), makes use of a superheated liquid kept close to its normal boiling point. Bubbles characteristic of boiling form around ions produced by the passage of a charged particle, revealing paths of particles that recently passed through. Because a bubble chamber uses a liquid, often liquid hydrogen, many more interactions can occur than in a cloud chamber. A magnetic field applied across the chamber makes charged particle paths curve (Chapter 27) and allows the momentum of charged particles to be determined from the radius of curvature of their paths.

A **multiwire**[†] **chamber** consists of a set of closely spaced fine wires immersed in a gas (Fig. 41–16). Many wires are grounded, and the others between are kept at very high voltage. A charged particle passing through produces ions in the gas. Freed electrons drift toward the nearest high voltage wire, creating an "avalanche" of many more ions, and producing an electric pulse or signal at that wire. The positions of the particles are determined electronically by the position of the wire and by the time it takes the pulses to reach "readout" electronics at the ends of the wires. The paths of the particles are reconstructed electronically by computers which can "draw" a picture of the tracks, as shown in Fig. 43–15, Chapter 43. An external magnetic field curves the paths, allowing the momentum of the particles to be measured.

Many detectors are also **calorimeters** which measure the energy of the particles.

[†]Also called *wire drift chamber* or *wire proportional chamber*.



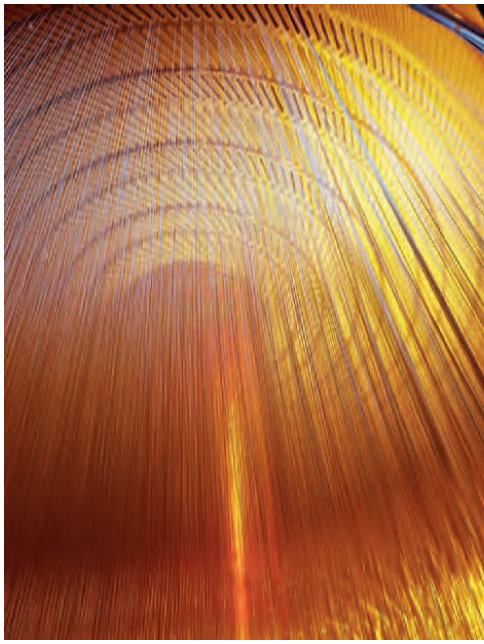


**FIGURE 41–15** In a cloud chamber or bubble chamber, droplets or bubbles are formed around ions produced by the passage of a charged particle.

**FIGURE 41–16** Multiwire chamber inside the Collider Detector at Fermilab (CDF). Figure 43–15 in Chapter 43 was done with this detector.

# Summary

**Nuclear physics** is the study of atomic nuclei. Nuclei contain **protons** and **neutrons**, which are collectively known as **nucleons**. The total number of nucleons, $A$, is the nucleus's **atomic mass number**. The number of protons, $Z$, is the **atomic number**. The number of neutrons equals $A - Z$. **Isotopes** are nuclei with the same $Z$, but with different numbers of neutrons. For an element $X$, an isotope of given $Z$ and $A$ is represented by

$$^{A}_{Z}\mathrm{X}.$$

The nuclear radius is approximately proportional to $A^{\frac{1}{3}}$, indicating that all nuclei have about the same density. Nuclear masses are specified in **unified atomic mass units** (u), where the mass of $^{12}_{6}\mathrm{C}$ (including its 6 electrons) is defined as exactly 12.000000 u. In terms of the energy equivalent (because $E = mc^2$),

$$1\,\mathrm{u} = 931.5\,\mathrm{MeV}/c^2 = 1.6605 \times 10^{-27}\,\mathrm{kg}.$$

The mass of a stable nucleus is less than the sum of the masses of its constituent nucleons. The difference in mass (times $c^2$) is the **total binding energy**. It represents the energy needed to break the nucleus into its constituent nucleons. The **binding energy per nucleon** averages about 8 MeV per nucleon, and is lowest for low mass and high mass nuclei.

Unstable nuclei undergo **radioactive decay**; they change into other nuclei with the emission of an $\alpha$, $\beta$, or $\gamma$ particle. An $\alpha$ particle is a $^{4}_{2}\mathrm{He}$ nucleus; a $\beta$ particle is an electron or positron; and a $\gamma$ ray is a high-energy photon. In $\beta$ decay, a **neutrino** is also emitted. The transformation of **parent** nuclei into **daughter** nuclei is called **transmutation** of the elements. Radioactive decay occurs spontaneously only when the mass of the products is less than the mass of the parent nucleus. The loss in mass appears as kinetic energy of the products.

Alpha decay occurs via the purely quantum mechanical process of **tunneling** through a barrier.

Nuclei are held together by the **strong nuclear force**. The **weak nuclear force** makes itself apparent in $\beta$ decay. These two forces, plus the gravitational and electromagnetic forces, are the four known types of force.

Electric charge, linear and angular momentum, mass–energy, and **nucleon number** are **conserved** in all decays.

Radioactive decay is a statistical process. For a given type of radioactive nucleus, the number of nuclei that decay ($\Delta N$) in a time $\Delta t$ is proportional to the number $N$ of parent nuclei present:

$$\Delta N = -\lambda N\,\Delta t; \qquad \textbf{(41–4a)}$$

the minus sign means $N$ *decreases* in time.

The proportionality constant $\lambda$ is called the **decay constant** and is characteristic of the given nucleus. The number $N$ of nuclei remaining after a time $t$ decreases exponentially

$$N = N_0\,e^{-\lambda t}, \qquad \textbf{(41–6)}$$

as does the **activity**, $R = |dN/dt|$:

$$\left|\frac{dN}{dt}\right| = \left|\frac{dN}{dt}\right|_0 e^{-\lambda t}. \qquad \textbf{(41–7c)}$$

The **half-life,** $T_{\frac{1}{2}}$, is the time required for half the nuclei of a radioactive sample to decay. It is related to the decay constant by

$$T_{\frac{1}{2}} = \frac{0.693}{\lambda}. \qquad \textbf{(41–8)}$$

**Radioactive dating** is the use of radioactive decay to determine the age of old objects, such as once-living biological material ($^{14}_{6}\mathrm{C}$) or geological formations ($^{238}_{92}\mathrm{U}$).

Particle **detectors** include **Geiger counters**, **scintillators** with attached **photomultiplier tubes**, and **semiconductor detectors**. Detectors that can image particle tracks include **semiconductors**, photographic **emulsions**, **bubble chambers**, and **wire drift chambers**.

# Questions

1. What do different isotopes of a given element have in common? How are they different?
2. Identify the element that has 88 nucleons and 50 neutrons.
3. What are the elements represented by the X in the following: (*a*) $^{232}_{92}\mathrm{X}$; (*b*) $^{18}_{7}\mathrm{X}$; (*c*) $^{1}_{1}\mathrm{X}$; (*d*) $^{86}_{38}\mathrm{X}$; (*e*) $^{252}_{97}\mathrm{X}$?
4. How many protons and how many neutrons do each of the isotopes in Question 3 have?
5. Why are the atomic masses of many elements (see the Periodic Table) not close to whole numbers?
6. How do we know there is such a thing as the strong nuclear force?
7. What are the similarities and the differences between the strong nuclear force and the electric force?
8. What is the experimental evidence in favor of radioactivity being a nuclear process?
9. The isotope $^{64}_{29}\mathrm{Cu}$ is unusual in that it can decay by $\gamma$, $\beta^-$, and $\beta^+$ emission. What is the resulting nuclide for each case?
10. A $^{238}_{92}\mathrm{U}$ nucleus decays via $\alpha$ decay to a nucleus containing how many neutrons?
11. Why are nuclei much more likely to emit an $\alpha$ particle than separate protons and neutrons?
12. Describe, in as many ways as you can, the difference between $\alpha$, $\beta$, and $\gamma$ rays.
13. What element is formed by the radioactive decay of (*a*) $^{24}_{11}\mathrm{Na}$ $(\beta^-)$; (*b*) $^{22}_{11}\mathrm{Na}$ $(\beta^+)$; (*c*) $^{210}_{84}\mathrm{Po}$ $(\alpha)$?
14. What element is formed by the decay of (*a*) $^{32}_{15}\mathrm{P}$ $(\beta^-)$; (*b*) $^{35}_{16}\mathrm{S}$ $(\beta^-)$; (*c*) $^{211}_{83}\mathrm{Bi}$ $(\alpha)$?
15. Fill in the missing particle or nucleus:
    (*a*) $^{45}_{20}\mathrm{Ca} \rightarrow\ ?\ +\ \mathrm{e}^-\ +\ \bar{\nu}$
    (*b*) $^{58}_{29}\mathrm{Cu}^* \rightarrow\ ?\ +\ \gamma$
    (*c*) $^{46}_{24}\mathrm{Cr} \rightarrow\ ^{46}_{23}\mathrm{V}\ +\ ?$
    (*d*) $^{234}_{94}\mathrm{Pu} \rightarrow\ ?\ +\ \alpha$
    (*e*) $^{239}_{93}\mathrm{Np} \rightarrow\ ^{239}_{94}\mathrm{Pu}\ +\ ?$
16. Immediately after a $^{238}_{92}\mathrm{U}$ nucleus decays to $^{234}_{90}\mathrm{Th} + ^{4}_{2}\mathrm{He}$, the daughter thorium nucleus may still have 92 electrons circling it. Since thorium normally holds only 90 electrons, what do you suppose happens to the two extra ones?

17. When a nucleus undergoes either $\beta^-$ or $\beta^+$ decay, what happens to the energy levels of the atomic electrons? What is likely to happen to these electrons following the decay?
18. The alpha particles from a given alpha-emitting nuclide are generally monoenergetic; that is, they all have the same kinetic energy. But the beta particles from a beta-emitting nuclide have a spectrum of energies. Explain the difference between these two cases.
19. Do isotopes that undergo electron capture generally lie above or below the stable nuclides in Fig. 41–2?
20. Can hydrogen or deuterium emit an $\alpha$ particle? Explain.
21. Why are many artificially produced radioactive isotopes rare in nature?
22. An isotope has a half-life of one month. After two months, will a given sample of this isotope have completely decayed? If not, how much remains?
23. Why are none of the elements with $Z > 92$ stable?
24. A proton strikes a ${}^{6}_{3}\text{Li}$ nucleus. As a result, an $\alpha$ particle and another particle are released. What is the other particle?
25. Can ${}^{14}_{6}\text{C}$ dating be used to measure the age of stone walls and tablets of ancient civilizations? Explain.
26. Explain the absence of $\beta^+$ emitters in the radioactive decay series of Fig. 41–12.
27. As ${}^{222}_{86}\text{Rn}$ decays into ${}^{206}_{82}\text{Pb}$, how many alpha and beta particles are emitted? Does it matter which path in the decay series is chosen? Why or why not?
28. A ${}^{238}\text{U}$ nucleus (initially at rest) decays into a ${}^{234}\text{Th}$ nucleus and an alpha particle. Which has the greater (i) momentum, (ii) velocity, (iii) kinetic energy? Explain.
    (*a*) The ${}^{234}\text{Th}$ nucleus.
    (*b*) The alpha particle.
    (*c*) Both the same.
29. Describe how the potential energy curve for an $\alpha$ particle in an $\alpha$-emitting nucleus differs from that for a stable nucleus.
30. Suppose we discovered that several thousand years ago cosmic rays had bombarded the Earth's atmosphere a lot more than we had thought. Compared to previous calculations of the carbon-dated age of organic matter, we would now calculate it to be older, younger, or the same age as previously calculated? Explain.
31. (*a*) Under what circumstances could a fermium nucleus decay into an einsteinium nucleus? (*b*) What about the reverse, an Es nucleus decaying into Fm?
32. In both internal conversion and $\beta$ decay, an electron is emitted. How could you determine which decay process occurred?
33. Carbon dating is useful only for determining the age of objects less than about _____ years old. (*a*) 4.5 million, or (*b*) 1.2 million, or (*c*) 600,000, or (*d*) 60,000, or (*e*) 6000.

# MisConceptual Questions

1. Elements of the Periodic Table are distinguished by
    (*a*) the number of protons in the nucleus.
    (*b*) the number of neutrons in the nucleus.
    (*c*) the number of electrons in the atom.
    (*d*) Both (*a*) and (*b*).
    (*e*) (*a*), (*b*), and (*c*).
2. A nucleus has
    (*a*) more energy than its component neutrons and protons have.
    (*b*) less energy than its component neutrons and protons have.
    (*c*) the same energy as its component neutrons and protons have.
    (*d*) more energy than its component neutrons and protons have when the nucleus is at rest but less energy than when it is moving.
3. Which of the following will generally create a more stable nucleus?
    (*a*) Having more nucleons.
    (*b*) Having more protons than neutrons.
    (*c*) Having a larger binding energy per nucleon.
    (*d*) Having the same number of electrons as protons.
    (*e*) Having a larger total binding energy.
4. There are 82 protons in a lead nucleus. Why doesn't the lead nucleus burst apart?
    (*a*) Coulomb repulsive force doesn't act inside the nucleus.
    (*b*) Gravity overpowers the Coulomb repulsive force inside the nucleus.
    (*c*) The negatively charged neutrons balance the positively charged protons.
    (*d*) Protons lose their positive charge inside the nucleus.
    (*e*) The strong nuclear force holds the nucleus together.
5. The half-life of a radioactive nucleus is
    (*a*) half the time it takes for the entire substance to fully decay.
    (*b*) the time it takes for half of the substance to decay.
    (*c*) the same as the decay constant.
    (*d*) Both (*a*) and (*b*) (they are the same).
    (*e*) All of the above.
6. As a radioactive sample decays,
    (*a*) the half-life increases.
    (*b*) the half-life decreases.
    (*c*) the activity remains the same.
    (*d*) the number of radioactive nuclei increases.
    (*e*) None of the above.
7. If the half-life of a radioactive sample is 10 years, then it should take _____ years for the sample to decay completely.
    (*a*) 10
    (*b*) 20
    (*c*) 40
    (*d*) Cannot be determined.
8. After three half-lives, what fraction of the original radioactive material is left?
    (*a*) None.
    (*b*) $\frac{1}{16}$.
    (*c*) $\frac{1}{8}$.
    (*d*) $\frac{1}{4}$.
    (*e*) $\frac{3}{4}$.
    (*f*) $\frac{7}{8}$.
    (*g*) $\frac{1}{3}$.

**9.** Technicium $^{98}_{43}$Tc has a half-life of $4.2 \times 10^6$ yr. Strontium $^{90}_{38}$Sr has a half-life of 28.79 yr. Which statements are true?
(*a*) The decay constant of Sr is greater than the decay constant of Tc.
(*b*) The activity of 100 g of Sr is less than the activity of 100 g of Tc.
(*c*) The long half-life of Tc means that it decays by alpha decay.
(*d*) A Tc atom has a higher probability of decaying in 1 yr than a Sr atom.

**10.** A material having which decay constant would have the shortest half-life?
(*a*) 100/second.
(*b*) 5/year.
(*c*) 8/century.
(*d*) $10^9$/day.

**11.** Radon has a half-life of about 1600 years. The Earth is several billion years old, so why do we still find radon on this planet?
(*a*) Ice-age temperatures preserved some of it.
(*b*) Heavier unstable isotopes decay into it.
(*c*) It is created in lightning strikes.
(*d*) It is replenished by cosmic rays.
(*e*) Its half-life has increased over time.
(*f*) Its half-life has decreased over time.

**12.** What has greater mass?
(*a*) A neutron and a proton that are far from each other (unbound).
(*b*) A neutron and a proton that are bound together in a hydrogen (deuterium) nucleus.
(*c*) Both the same.

# Problems

[See Appendix G for masses]

## 41–1 Nuclear Properties

**1.** (I) A rho meson has a mass of $775\ \text{MeV}/c^2$. What is this in atomic mass units?

**2.** (I) What is the approximate radius of an $\alpha$ particle $\left(^4_2\text{He}\right)$?

**3.** (I) By what % is the radius of $^{214}_{82}$Pb greater than the radius of $^{206}_{82}$Pb?

**4.** (II) (*a*) What is the approximate radius of a $^{120}_{50}$Sn nucleus? (*b*) Approximately what is the value of $A$ for a nucleus whose radius is $3.7 \times 10^{-15}$ m?

**5.** (II) What is the mass of a bare $\alpha$ particle (without electrons) in $\text{MeV}/c^2$?

**6.** (II) Suppose two alpha particles were held together so they were just "touching" (use Eq. 41–1). Estimate the electrostatic repulsive force each would exert on the other. What would be the acceleration of an alpha particle subjected to this force?

**7.** (II) (*a*) What would be the radius of the Earth if it had its actual mass but had the density of nuclei? (*b*) By what factor would the radius of a $^{238}_{92}$U nucleus increase if it had the Earth's density?

**8.** (II) What stable nucleus has approximately half the radius of a uranium nucleus? [*Hint*: Find $A$ and use Appendix G to get $Z$.]

**9.** (II) If an alpha particle were released from rest near the surface of a $^{263}_{104}$Rf nucleus, what would its kinetic energy be when far away?

**10.** (II) (*a*) What is the fraction of the hydrogen atom's mass $(^1_1\text{H})$ that is in the nucleus? (*b*) What is the fraction of the hydrogen atom's volume that is occupied by the nucleus?

**11.** (II) Approximately how many nucleons are there in a 1.0-g object? Does it matter what the object is made of? Why or why not?

**12.** (II) How much kinetic energy, in MeV, must an $\alpha$ particle have to just "touch" the surface of a $^{232}_{90}$Th nucleus?

## 41–2 Binding Energy

**13.** (I) Estimate the total binding energy for $^{63}_{29}$Cu, using Fig. 41–1.

**14.** (I) Use Fig. 41–1 to estimate the total binding energy of (*a*) $^{238}_{92}$U, and (*b*) $^{84}_{36}$Kr.

**15.** (II) Calculate the binding energy per nucleon for a $^{18}_{8}$O nucleus, using Appendix G.

**16.** (II) Use Appendix G to calculate the binding energy of $^2_1$H (deuterium).

**17.** (II) Determine the binding energy of the last neutron in a $^{31}_{15}$P nucleus.

**18.** (II) Calculate the total binding energy, and the binding energy per nucleon, for (*a*) $^7_4$Be, (*b*) $^{197}_{79}$Au. Use Appendix G.

**19.** (II) Compare the average binding energy of a nucleon in $^{31}_{15}$P to that in $^{32}_{15}$P, using Appendix G.

**20.** (III) How much energy is required to remove (*a*) a proton, (*b*) a neutron, from $^{16}_{8}$O? Explain the difference in your answers.

**21.** (III) (*a*) Show that the nucleus $^8_4$Be (mass = 8.005305 u) is unstable and will decay into two $\alpha$ particles. (*b*) Is $^{12}_6$C stable against decay into three $\alpha$ particles? Show why or why not.

## 41–3 to 41–7 Radioactive Decay

**22.** (I) The $^7_3$Li nucleus has an excited state 0.48 MeV above the ground state. What wavelength gamma photon is emitted when the nucleus decays from the excited state to the ground state?

**23.** (I) Calculate the energy released when tritium, $^3_1$H, decays by $\beta^-$ emission.

**24.** (II) Show that the decay $^{11}_6\text{C} \rightarrow {}^{10}_5\text{B} + \text{p}$ is not possible because energy would not be conserved.

**25.** (II) What is the maximum kinetic energy of an electron emitted in the $\beta$ decay of a free neutron?

**26.** (II) Give the result of a calculation that shows whether or not the following decays are possible:
(*a*) $^{233}_{92}\text{U} \rightarrow {}^{232}_{92}\text{U} + \text{n}$;
(*b*) $^{14}_{7}\text{N} \rightarrow {}^{13}_{7}\text{N} + \text{n}$;
(*c*) $^{40}_{19}\text{K} \rightarrow {}^{39}_{19}\text{K} + \text{n}$.

**27.** (II) $^{24}_{11}$Na is radioactive. (*a*) Is it a $\beta^-$ or $\beta^+$ emitter? (*b*) Write down the decay reaction, and estimate the maximum kinetic energy of the emitted $\beta$.

**27'.** (II) When $^{23}_{10}\text{Ne}$ (mass = 22.9944 u) decays to $^{23}_{11}\text{Na}$ (mass = 22.9898 u), what is the maximum kinetic energy of the emitted electron? What is its minimum energy? What is the energy of the neutrino in each case? Ignore recoil of the daughter nucleus.

**28.** (II) A $^{238}_{92}\text{U}$ nucleus emits an $\alpha$ particle with kinetic energy = 4.20 MeV. (*a*) What is the daughter nucleus, and (*b*) what is the approximate atomic mass (in u) of the daughter atom? Ignore recoil of the daughter nucleus.

**29.** (II) Calculate the maximum kinetic energy of the $\beta$ particle emitted during the decay of $^{60}_{27}\text{Co}$.

**30.** (II) How much energy is released in electron capture by beryllium: $^{7}_{4}\text{Be} + e^- \rightarrow {}^{7}_{3}\text{Li} + \nu$?

**31.** (II) The isotope $^{218}_{84}\text{Po}$ can decay by either $\alpha$ or $\beta^-$ emission. What is the energy release in each case? The mass of $^{218}_{84}\text{Po}$ is 218.008973 u.

**32.** (II) The nuclide $^{32}_{15}\text{P}$ decays by emitting an electron whose maximum kinetic energy can be 1.71 MeV. (*a*) What is the daughter nucleus? (*b*) Calculate the daughter's atomic mass (in u).

**33.** (II) A photon with a wavelength of $1.05 \times 10^{-13}$ m is emitted from an atom. Calculate its energy and explain whether it is a $\gamma$ ray from the nucleus or a photon from the atom.

**34.** (II) How much recoil energy does a $^{40}_{19}\text{K}$ nucleus get when it emits a 1.46-MeV gamma ray?

**35.** (II) Determine the maximum kinetic energy of $\beta^+$ particles released when $^{13}_{7}\text{N}$ decays to $^{13}_{6}\text{C}$. What is the maximum energy the neutrino can have? What is the minimum energy of each?

**36.** (III) Show that when a nucleus decays by $\beta^+$ decay, the total energy released is equal to

$$(M_\text{P} - M_\text{D} - 2m_\text{e})c^2,$$

where $M_\text{P}$ and $M_\text{D}$ are the masses of the parent and daughter atoms (neutral), and $m_\text{e}$ is the mass of an electron or positron.

**37.** (III) When $^{238}_{92}\text{U}$ decays, the $\alpha$ particle emitted has 4.20 MeV of kinetic energy. Calculate the recoil kinetic energy of the daughter nucleus and the $Q$-value of the decay.

**38.** (III) What is the energy of the $\alpha$ particle emitted in the decay $^{226}_{88}\text{Ra} \rightarrow {}^{222}_{86}\text{Rn} + \alpha$? Take into account the recoil of the daughter nucleus.

## 41–8 to 41–11 Half-Life, Decay Rates, Decay Series, Dating

**39.** (I) (*a*) What is the decay constant of $^{238}_{92}\text{U}$ whose half-life is $4.5 \times 10^9$ yr? (*b*) The decay constant of a given nucleus is $3.8 \times 10^{-5}\ \text{s}^{-1}$. What is its half-life?

**40.** (I) A radioactive material produces 1120 decays per minute at one time, and 4.2 h later produces 140 decays per minute. What is its half-life?

**41.** (I) What fraction of a sample of $^{68}_{32}\text{Ge}$, whose half-life is about 9 months, will remain after 2.2 yr?

**42.** (I) What is the activity of a sample of $^{14}_{6}\text{C}$ that contains $5.6 \times 10^{20}$ nuclei?

**43.** (I) What fraction of a radioactive sample is left after exactly 5 half-lives?

**44.** (II) The iodine isotope $^{131}_{53}\text{I}$ is used in hospitals for diagnosis of thyroid function. If 846 $\mu$g are ingested by a patient, determine the activity (*a*) immediately, (*b*) 1.50 h later when the thyroid is being tested, and (*c*) 3.0 months later. Use Appendix G.

**45.** (II) A sample of $^{60}_{27}\text{Co}$ and a sample of $^{131}_{53}\text{I}$ both have $N_0$ atoms at $t = 0$. How long will it take until both have the same activity? (Use Appendix G for half-life data.)

**46.** (II) How many nuclei of $^{238}_{92}\text{U}$ remain in a rock if the activity registers 370 decays per second?

**47.** (II) In a series of decays, the nuclide $^{235}_{92}\text{U}$ becomes $^{207}_{82}\text{Pb}$. How many $\alpha$ and $\beta^-$ particles are emitted in this series?

**48.** (II) $^{124}_{55}\text{Cs}$ has a half-life of 30.8 s. (*a*) If we have 9.6 $\mu$g initially, how many Cs nuclei are present? (*b*) How many are present 2.6 min later? (*c*) What is the activity at this time? (*d*) After how much time will the activity drop to less than about 1 per second?

**49.** (II) Calculate the mass of a sample of pure $^{40}_{19}\text{K}$ with an initial decay rate of $1.6 \times 10^5\ \text{s}^{-1}$. The half-life of $^{40}_{19}\text{K}$ is $1.248 \times 10^9$ yr.

**50.** (II) Calculate the activity of a pure 7.8-$\mu$g sample of $^{32}_{15}\text{P}$ $\left(T_{\frac{1}{2}} = 1.23 \times 10^6\ \text{s}\right)$.

**51.** (II) A sample of $^{233}_{92}\text{U}$ $\left(T_{\frac{1}{2}} = 1.59 \times 10^5\ \text{yr}\right)$ contains $3.50 \times 10^{18}$ nuclei. (*a*) What is the decay constant? (*b*) Approximately how many disintegrations will occur per minute?

**52.** (II) The activity of a sample drops by a factor of 6.0 in 9.8 minutes. What is its half-life?

**53.** (II) A 315-g sample of pure carbon contains 1.3 parts in $10^{12}$ (atoms) of $^{14}_{6}\text{C}$. How many disintegrations occur per second?

**54.** (II) A sample of $^{238}_{92}\text{U}$ is decaying at a rate of $4.75 \times 10^2$ decays/s. What is the mass of the sample?

**55.** (II) **Rubidium–strontium dating.** The rubidium isotope $^{87}_{37}\text{Rb}$, a $\beta$ emitter with a half-life of $4.75 \times 10^{10}$ yr, is used to determine the age of rocks and fossils. Rocks containing fossils of ancient animals contain a ratio of $^{87}_{38}\text{Sr}$ to $^{87}_{37}\text{Rb}$ of 0.0260. Assuming that there was no $^{87}_{38}\text{Sr}$ present when the rocks were formed, estimate the age of these fossils.

**56.** (II) Two of the naturally occurring radioactive decay sequences start with $^{232}_{90}\text{Th}$ and with $^{235}_{92}\text{U}$. The first five decays of these two sequences are:

$$\alpha, \beta, \beta, \alpha, \alpha$$

and

$$\alpha, \beta, \alpha, \beta, \alpha.$$

Determine the resulting intermediate daughter nuclei in each case.

**57.** (II) An ancient wooden club is found that contains 67 g of carbon and has an activity of 7.0 decays per second. Determine its age assuming that in living trees the ratio of $^{14}\text{C}/^{12}\text{C}$ atoms is about $1.3 \times 10^{-12}$.

**58.** (II) Use Fig. 41–12 and calculate the relative decay rates for $\alpha$ decay of $^{218}_{84}\text{Po}$ and $^{214}_{84}\text{Po}$.

**59.** (II) The activity of a radioactive source decreases by 5.5% in 35.0 hours. What is the half-life of this source?

**60.** (III) $^{7}_{4}\text{Be}$ decays with a half-life of about 53 d. It is produced in the upper atmosphere, and filters down onto the Earth's surface. If a plant leaf is detected to have 320 decays/s of $^{7}_{4}\text{Be}$, (*a*) how long do we have to wait for the decay rate to drop to 25 per second? (*b*) Estimate the initial mass of $^{7}_{4}\text{Be}$ on the leaf.

**61.** (III) At $t = 0$, a pure sample of radioactive nuclei contains $N_0$ nuclei whose decay constant is $\lambda$. Determine a formula for the number of daughter nuclei, $N_\text{D}$, as a function of time; assume the daughter is stable and that $N_\text{D} = 0$ at $t = 0$.

# General Problems

**62.** Which radioactive isotope of lead is being produced if the measured activity of a sample drops to 1.050% of its original activity in 4.00 h?

**63.** An old wooden tool is found to contain only 6.2% of the $^{14}_{6}C$ that an equal mass of fresh wood would. How old is the tool?

**64.** A neutron star consists of neutrons at approximately nuclear density. Estimate, for a 15-km-diameter neutron star, (*a*) its mass number, (*b*) its mass (kg), and (*c*) the acceleration of gravity at its surface.

**65.** **Tritium dating**. The $^{3}_{1}H$ isotope of hydrogen, which is called *tritium* (because it contains three nucleons), has a half-life of 12.3 yr. It can be used to measure the age of objects up to about 100 yr. It is produced in the upper atmosphere by cosmic rays and brought to Earth by rain. As an application, determine approximately the age of a bottle of wine whose $^{3}_{1}H$ radiation is about $\frac{1}{10}$ that present in new wine.

**66.** Some elementary particle theories (Section 43–11) suggest that the proton may be unstable, with a half-life $\geq 10^{33}$ yr. (*a*) How long would you expect to wait for one proton in your body to decay (approximate your body as all water)? (*b*) Of the roughly 7 billion people on Earth, about how many would have a proton in their body decay in a 70 yr lifetime?

**67.** The original experiments which established that an atom has a heavy, positive nucleus were done by shooting alpha particles through gold foil. The alpha particles had a kinetic energy of 7.7 MeV. What is the closest they could get to the center of a gold nucleus? How does this compare with the size of the nucleus?

**68.** How long must you wait (in half-lives) for a radioactive sample to drop to 1.50% of its original activity?

**69.** If the potassium isotope $^{40}_{19}K$ gives 48 decays/s in a liter of milk, estimate how much $^{40}_{19}K$ and regular $^{39}_{19}K$ are in a liter of milk. Use Appendix G.

**70.** Strontium-90 is produced as a nuclear fission product of uranium in both reactors and atomic bombs. Look at its location in the Periodic Table to see what other elements it might be similar to chemically, and tell why you think it might be dangerous to ingest. It has too many neutrons to be stable, and it decays with a half-life of about 29 yr. How long will we have to wait for the amount of $^{90}_{38}Sr$ on the Earth's surface to reach 1% of its current level, assuming no new material is scattered about? Write down the decay reaction, including the daughter nucleus. The daughter is radioactive: write down its decay.

**71.** The activity of a sample of $^{35}_{16}S$ $\left(T_{\frac{1}{2}} = 87.37 \text{ days}\right)$ is $3.94 \times 10^4$ decays per second. What is the mass of the sample?

**72.** The nuclide $^{191}_{76}Os$ decays with $\beta^-$ energy of 0.14 MeV accompanied by $\gamma$ rays of energy 0.042 MeV and 0.129 MeV. (*a*) What is the daughter nucleus? (*b*) Draw an energy-level diagram showing the ground states of the parent and daughter and excited states of the daughter. (*c*) To which of the daughter states does $\beta^-$ decay of $^{191}_{76}Os$ occur?

**73.** Determine the activities of (*a*) 1.0 g of $^{32}_{15}P$ $\left(T_{\frac{1}{2}} = 14.3 \text{ days}\right)$ and (*b*) 1.0 g of $^{232}_{90}Th$ $\left(T_{\frac{1}{2}} = 1.40 \times 10^{10} \text{ yr}\right)$.

**74.** Use Fig. 41–1 to estimate the total binding energy for copper and then estimate the energy, in joules, needed to break a 3.0-g copper penny into its constituent nucleons.

**75.** Instead of giving atomic masses for nuclides as in Appendix G, some Tables give the **mass excess**, $\Delta$, defined as $\Delta = M - A$, where $A$ is the atomic mass number and $M$ is the mass in u. Determine the mass excess, in u and in MeV/$c^2$, for: (*a*) $^{4}_{2}He$; (*b*) $^{12}_{6}C$; (*c*) $^{86}_{38}Sr$; (*d*) $^{235}_{92}U$. (*e*) From a glance at Appendix G, can you make a generalization about the sign of $\Delta$ as a function of $Z$ or $A$? [Note: The quantity $A - M$ is called the **mass defect**.]

**76.** When water is placed near an intense neutron source, the neutrons can be slowed down to almost zero speed by collisions with the water molecules, and are eventually captured by a hydrogen nucleus to form the stable isotope called **deuterium**, $^{2}_{1}H$, giving off a gamma ray. What is the energy of the gamma ray?

**77.** The practical limit for carbon-14 dating is about 60,000 years. If a bone contains 1.0 kg of carbon, and the animal died 60,000 years ago, what is the activity today?

**78.** Using Section 41–2 and Appendix G, determine the energy required to remove one neutron from $^{4}_{2}He$. How many times greater is this energy than the binding energy of the last neutron in $^{13}_{6}C$?

**79.** (*a*) If all of the atoms of the Earth were to collapse and simply become nuclei, what would be the Earth's new radius? (*b*) If all of the atoms of the Sun were to collapse and simply become nuclei, what would be the Sun's new radius?

**80.** (*a*) An 84-gram sample of natural carbon contains the usual fraction of $^{14}_{6}C$. Estimate roughly how long it will take before there is only one $^{14}_{6}C$ nucleus left. (*b*) How does the answer in (*a*) change if the sample is 340 grams? What does this tell you about the limits of carbon dating?

**81.** If the mass of the proton were just a little closer to the mass of the neutron, the following reaction would be possible even at low collision energies:

$$e^- + p \rightarrow n + \nu.$$

(*a*) Why would this situation be catastrophic? (See last paragraph of Chapter 44.) (*b*) By what percentage would the proton's mass have to be increased to make this reaction possible?

**82.** What is the ratio of the kinetic energies for an alpha particle and a beta particle if both make tracks with the same radius of curvature in a magnetic field, oriented perpendicular to the paths of the particles?

**83.** A 1.00-g sample of natural samarium emits $\alpha$ particles at a rate of 120 $s^{-1}$ due to the presence of $^{147}_{62}Sm$. The natural abundance of $^{147}_{62}Sm$ is 15%. Calculate the half-life for this decay process.

**84.** Almost all of naturally occurring uranium is $^{238}_{92}U$ with a half-life of $4.468 \times 10^9$ yr. Most of the rest of natural uranium is $^{235}_{92}U$ with a half-life of $7.04 \times 10^8$ yr. Today a sample contains 0.720% $^{235}_{92}U$. (*a*) What was this percentage 1.0 billion years ago? (*b*) What percentage of uranium will be $^{235}_{92}U$ 100 million years from now?

**85.** In 1991, the frozen remains of a Neolithic-age man, nicknamed Otzi, were found in the Italian Alps by hikers. The body was well preserved, as were his bow, arrows, knife, axe, other tools, and clothing. The date of his death can be determined using carbon-14 dating. (*a*) What is the decay constant for $^{14}_{6}\text{C}$? (*b*) How many $^{14}_{6}\text{C}$ atoms per gram of $^{12}_{6}\text{C}$ are there in a living organism? (*c*) What is the activity per gram in naturally occurring carbon for a living organism? (*d*) For Otzi, the activity per gram of carbon was measured to be 0.121. How long ago did he live?

**86.** (*a*) Show that the **mean life** of a radioactive nuclide, defined as

$$\tau = \frac{\int_0^\infty t\,N(t)\,dt}{\int_0^\infty N(t)\,dt},$$

is $\tau = 1/\lambda$. (*b*) What fraction of the original number of nuclei remains after one mean life?

**87.** A banana contains about 400 mg of potassium, of which a small fraction is the radioactive isotope $^{40}_{19}\text{K}$ (see Appendix G). Estimate the activity of an average banana due to $^{40}_{19}\text{K}$.

**88.** (*a*) In $\alpha$ decay, of, say, a $^{226}_{88}\text{Ra}$ nucleus, show that the nucleus carries away a fraction $1/\left(1+\frac{1}{4}A_\text{D}\right)$ of the total energy available, where $A_\text{D}$ is the mass number of the daughter nucleus. [*Hint*: Use conservation of momentum as well as conservation of energy.] (*b*) Approximately what percentage of the energy available is thus carried off by the $\alpha$ particle when $^{226}_{88}\text{Ra}$ decays?

**89.** Decay series, such as that shown in Fig. 41–12, can be classified into four families, depending on whether the mass numbers have the form $4n$, $4n+1$, $4n+2$, or $4n+3$, where $n$ is an integer. Justify this statement and show that for a nuclide in any family, all its daughters will be in the same family.

**90.** Show, using the decays given in Section 41–5, that the neutrino has either spin $\frac{1}{2}$ or $\frac{3}{2}$. (*a*) Calculate the kinetic energy of the $\alpha$ particle emitted when $^{236}_{92}\text{U}$ decays. (*b*) Use Eq. 41–1 to estimate the radius of an $\alpha$ particle and a $^{232}_{90}\text{Th}$ nucleus. Use this to estimate (*c*) the maximum height of the Coulomb barrier, and (*d*) its width AB in Fig. 41–7.

**91.** Using the uncertainty principle and the radius of a nucleus, estimate the minimum possible kinetic energy of a nucleon in, say, iron. Ignore relativistic corrections. [*Hint*: A particle can have a momentum at least as large as its momentum uncertainty.]

**92.** In Fig. 41–17, a nucleus decays and emits a particle that enters a region with a uniform magnetic field of 0.012 T directed into the page. The path of the detected particle is shown. (*a*) What type of radioactive decay is this? (*b*) If the radius of the circular arc is 4.7 mm, what is the velocity of the particle?

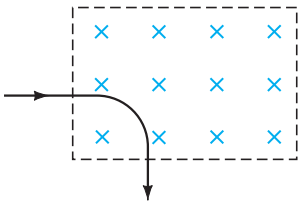

**FIGURE 41–17** Problem 92.

**93.** A nucleus of mass 256 u, initially at rest, emits an $\alpha$ particle with a kinetic energy of 4.5 MeV. What is the kinetic energy of the recoiling daughter nucleus?

**94.** Some radioactive isotopes have half-lives that are greater than the age of the universe (like gadolinium or samarium). The only way to determine these half-lives is to monitor the decay rate of a sample that contains these isotopes. For example, suppose we find an asteroid that currently contains about 15,000 kg of $^{152}_{64}\text{Gd}$ (gadolinium) and we detect an activity of 1 decay/s. What is the half-life of gadolinium (in years)?

**95.** A laboratory has a 2.20-$\mu$g sample of radioactive $^{13}_{7}\text{N}$ whose decay constant $\lambda = 1.16\times10^{-3}\,\text{s}^{-1}$. Calculate the initial number of nuclei, $N_0$, present in the sample. Use the radioactive decay law, $N = N_0 e^{-\lambda t}$, to determine the number of nuclei $N$ present at time $t$ for $t = 0$ to 30 minutes (1800 s) in steps of 0.5 min (30 s). Make a graph of $N$ versus $t$ and from the graph determine the half-life of the sample.

## ANSWERS TO EXERCISES

**A:** 0.042130 u.
**B:** 7.98 MeV/nucleon.
**C:** (*b*).
**D:** (*b*) $\frac{1}{8}\,\mu$g.
**E:** (*a*).
**F:** $1.37\times10^{-11}\,\text{s}^{-1}$.

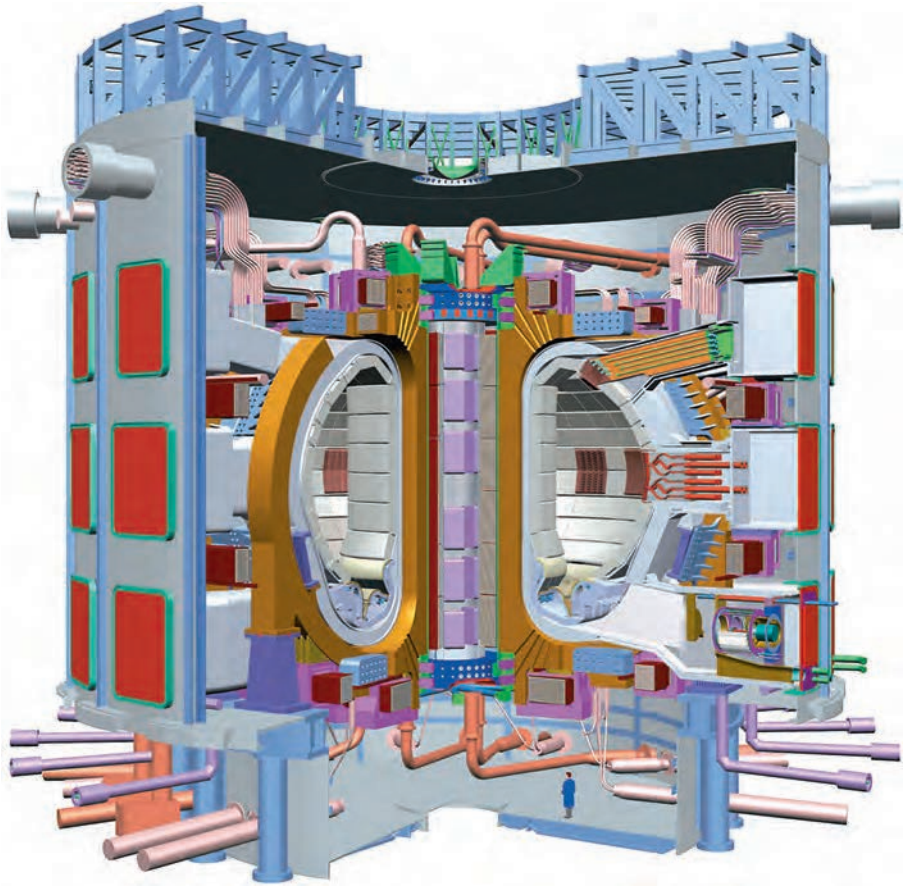

Diagram of ITER (International Thermonuclear Experimental Reactor), which will hopefully begin operation in the mid-2020s. Inside its cavity, over 12 m in diameter, a plasma of electrons and light nuclei will be heated to high temperatures that rival the Sun. Confining a plasma by magnetic fields has proved difficult, and intense research is needed if the fusion of smaller nuclei is to fulfill its promise as a source of abundant and relatively clean power.

This Chapter covers the basic physics topics of nuclear reactions, nuclear fission, nuclear fusion, and how we obtain nuclear energy. We also examine the health aspects of radiation dosimetry, therapy, and imaging by CAT, PET, SPET, and MRI.

CHAPTER 42

# Nuclear Energy; Effects and Uses of Radiation

## CONTENTS

42 – 1 Nuclear Reactions and the Transmutation of Elements
42 – 2 Cross Section
42 – 3 Nuclear Fission; Nuclear Reactors
42 – 4 Nuclear Fusion
42 – 5 Passage of Radiation Through Matter; Biological Damage
42 – 6 Measurement of Radiation—Dosimetry
*42 – 7 Radiation Therapy
*42 – 8 Tracers in Research and Medicine
*42 – 9 Emission Tomography: PET and SPECT
*42–10 Nuclear Magnetic Resonance (NMR) and Magnetic Resonance Imaging (MRI)

## CHAPTER-OPENING QUESTIONS—Guess now!

**1.** The Sun is powered by
- **(a)** nuclear alpha decay.
- **(b)** nuclear beta decay.
- **(c)** nuclear gamma decay.
- **(d)** nuclear fission.
- **(e)** nuclear fusion.

**2.** Which radiation induces the most biological damage for a given amount of energy deposited in tissue?
- **(a)** Alpha particles.
- **(b)** Gamma radiation.
- **(c)** Beta radiation.
- **(d)** They all do the same damage for the same deposited energy.
- **(e)** It depends on the type of tissue.

We continue our study of nuclear physics in this Chapter. We begin with a discussion of nuclear reactions, and then we examine the important huge energy-releasing processes of fission and fusion. We also deal with the effects of nuclear radiation passing through matter, particularly biological matter, and how radiation is used medically for therapy, diagnosis, and imaging techniques.

# 42–1 Nuclear Reactions and the Transmutation of Elements

When a nucleus undergoes $\alpha$ or $\beta$ decay, the daughter nucleus is a different element from the parent. The transformation of one element into another, called **transmutation**, also occurs via nuclear reactions. A **nuclear reaction** is said to occur when a nucleus is struck by another nucleus, or by a simpler particle such as a $\gamma$ ray, neutron, or proton, and an interaction takes place. Ernest Rutherford was the first to report seeing a nuclear reaction. In 1919 he observed that some of the $\alpha$ particles passing through nitrogen gas were absorbed and protons emitted. He concluded that nitrogen nuclei had been transformed into oxygen nuclei via the reaction

$$^4_2\text{He} + {}^{14}_7\text{N} \rightarrow {}^{17}_8\text{O} + {}^1_1\text{H},$$

where $^4_2$He is an $\alpha$ particle, and $^1_1$H is a proton.

Since then, a great many nuclear reactions have been observed. Indeed, many of the radioactive isotopes used in the laboratory are made by means of nuclear reactions. Nuclear reactions can be made to occur in the laboratory, but they also occur regularly in nature. In Chapter 41 we saw an example: $^{14}_6$C is continually being made in the atmosphere via the reaction $\text{n} + {}^{14}_7\text{N} \rightarrow {}^{14}_6\text{C} + \text{p}$.

Nuclear reactions are sometimes written in a shortened form: for example,

$$\text{n} + {}^{14}_7\text{N} \rightarrow {}^{14}_6\text{C} + \text{p}$$

can be written

$$^{14}_7\text{N}\ (\text{n}, \text{p})\ {}^{14}_6\text{C}.$$

The symbols outside the parentheses on the left and right represent the initial and final nuclei, respectively. The symbols inside the parentheses represent the bombarding particle (first) and the emitted small particle (second).

In any nuclear reaction, both electric charge and nucleon number are conserved. These conservation laws are often useful, as the following Example shows.

**CONCEPTUAL EXAMPLE 42–1** **Deuterium reaction.** A neutron is observed to strike an $^{16}_8$O nucleus, and a deuteron is given off. (A **deuteron**, or **deuterium**, is the isotope of hydrogen containing one proton and one neutron, $^2_1$H; it is sometimes given the symbol d or D.) What is the nucleus that results?

**RESPONSE** We have the reaction $\text{n} + {}^{16}_8\text{O} \rightarrow ? + {}^2_1\text{H}$. The total number of nucleons initially is $1 + 16 = 17$, and the total charge is $0 + 8 = 8$. The same totals apply after the reaction. The $^2_1$H carries off 2 nucleons and 1 charge, so the unknown product nucleus must have $Z = 7$ and $A = 15$. From the Periodic Table, we find that it is nitrogen that has $Z = 7$, so the nucleus produced is $^{15}_7$N.

**EXERCISE A** Determine the resulting nucleus in the reaction $\text{n} + {}^{137}_{56}\text{Ba} \rightarrow ? + \gamma$.

Energy and momentum are also conserved in nuclear reactions, and can be used to determine whether or not a given reaction can occur. For example, if the total mass of the final products is less than the total mass of the initial particles, this decrease in mass (recall $\Delta E = \Delta m\, c^2$) is converted to kinetic energy ($K$) of the outgoing particles. But if the total mass of the products is greater than the total mass of the initial reactants, the reaction requires energy. The reaction will then not occur unless the bombarding particle has sufficient kinetic energy. Consider a nuclear reaction of the general form

$$\text{a} + \text{X} \rightarrow \text{Y} + \text{b}, \qquad \textbf{(42–1)}$$

where particle a is a moving projectile particle (or small nucleus) that strikes nucleus X, producing nucleus Y and particle b (typically, p, n, $\alpha$, $\gamma$).

We define the **reaction energy**, or ***Q*-value**, in terms of the masses involved, as

$$Q = (M_a + M_X - M_b - M_Y)c^2. \quad \textbf{(42–2a)}$$

For a $\gamma$ ray, $M = 0$. If energy is released by the reaction, $Q > 0$. If energy is required, $Q < 0$.

Because energy is conserved, $Q$ has to be equal to the change in kinetic energy (final minus initial):

$$Q = K_b + K_Y - K_a - K_X. \quad \textbf{(42–2b)}$$

If X is a target nucleus at rest (or nearly so) struck by incoming particle a, then $K_X = 0$. For $Q > 0$, the reaction is said to be *exothermic* or *exoergic*; energy is released in the reaction, so the total kinetic energy is greater after the reaction than before. If $Q$ is negative $(Q < 0)$, the reaction is said to be *endothermic* or *endoergic*: the final total kinetic energy is less than the initial kinetic energy, and an energy input is required to make the reaction happen. The energy input comes from the kinetic energy of the initial colliding particles (a and X).

**EXAMPLE 42–2** **A slow-neutron reaction.** The nuclear reaction

$$n + {}^{10}_{5}B \rightarrow {}^{7}_{3}Li + {}^{4}_{2}He$$

is observed to occur even when very slow-moving neutrons (mass $M_n = 1.0087$ u) strike boron atoms at rest. For a particular reaction in which $K_n \approx 0$, the outgoing helium $(M_{He} = 4.0026\ \text{u})$ is observed to have a speed of $9.30 \times 10^6$ m/s. Determine (*a*) the kinetic energy of the lithium $(M_{Li} = 7.0160\ \text{u})$, and (*b*) the *Q*-value of the reaction.

**APPROACH** Since the neutron and boron are both essentially at rest, the total momentum before the reaction is zero; momentum is conserved and so must be zero afterward as well. Thus,

$$M_{Li} v_{Li} = M_{He} v_{He}.$$

We solve this for $v_{Li}$ and substitute it into the equation for kinetic energy. In (*b*) we use Eq. 42–2b.

**SOLUTION** (*a*) We can use classical kinetic energy with little error, rather than relativistic formulas, because $v_{He} = 9.30 \times 10^6$ m/s is not close to the speed of light *c*, and $v_{Li}$ will be even less because $M_{Li} > M_{He}$. Thus we can write the kinetic energy of the lithium atom, using the momentum equation just above, as

$$K_{Li} = \frac{1}{2} M_{Li} v_{Li}^2 = \frac{1}{2} M_{Li} \left( \frac{M_{He} v_{He}}{M_{Li}} \right)^2 = \frac{M_{He}^2 v_{He}^2}{2 M_{Li}}.$$

We put in numbers, changing the mass in u to kg and recall that $1.60 \times 10^{-13}$ J = 1 MeV:

$$K_{Li} = \frac{(4.0026\ \text{u})^2 (1.66 \times 10^{-27}\ \text{kg/u})^2 (9.30 \times 10^6\ \text{m/s})^2}{2 (7.0160\ \text{u}) (1.66 \times 10^{-27}\ \text{kg/u})}$$

$$= 1.64 \times 10^{-13}\ \text{J} = 1.02\ \text{MeV}.$$

(*b*) We are given the data $K_a = K_X = 0$ in Eq. 42–2b, so $Q = K_{Li} + K_{He}$, where

$$K_{He} = \tfrac{1}{2} M_{He} v_{He}^2$$

$$= \tfrac{1}{2} (4.0026\ \text{u}) (1.66 \times 10^{-27}\ \text{kg/u}) (9.30 \times 10^6\ \text{m/s})^2$$

$$= 2.87 \times 10^{-13}\ \text{J} = 1.80\ \text{MeV}.$$

Hence, $Q = 1.02\ \text{MeV} + 1.80\ \text{MeV} = 2.82\ \text{MeV}$.

PSE5_CH42_v1.6_23Jun-20

**EXAMPLE 42–3** **Will the reaction "go"?** Can the reaction

$$p + {}^{13}_{6}C \rightarrow {}^{13}_{7}N + n$$

occur when ${}^{13}_{6}C$ is bombarded by 2.0-MeV protons?

**APPROACH** The reaction will "go" if the reaction is exothermic $(Q > 0)$ and even if $Q < 0$ if the input momentum and kinetic energy are sufficient. First we calculate $Q$ from the difference between final and initial masses using Eq. 42–2a, and look up the masses in Appendix G.

**SOLUTION** The total masses before and after the reaction are:

| Before | | After | |
|---|---|---|---|
| $M({}^{13}_{6}C)$ | 13.003355 | $M({}^{13}_{7}N)$ | 13.005739 |
| $M({}^{1}_{1}H)$ | 1.007825 | $M(n)$ | 1.008665 |
| | 14.011180 | | 14.014404 |

(We must use the mass of the ${}^{1}_{1}H$ atom rather than that of the bare proton because the masses of ${}^{13}_{6}C$ and ${}^{13}_{7}N$ include the electrons, and we must include an equal number of electron masses on each side of the equation since none are created or destroyed.) The products have an excess mass of

$$(14.014404 - 14.011180)\,u = 0.003224\,u \times 931.5\,MeV/u = 3.00\,MeV.$$

Thus $Q = -3.00\,MeV$, and the reaction is endothermic. This reaction requires energy, and the 2.0-MeV protons do not have enough to make it go.

**NOTE** The incoming proton in this Example would need more than 3.00 MeV of kinetic energy to make this reaction go; 3.00 MeV would be enough to conserve energy, but a proton of this energy would produce the ${}^{13}_{7}N$ and n with no kinetic energy and hence no momentum. Since an incident 3.0-MeV proton has momentum, conservation of momentum would be violated. A calculation using conservation of energy *and* of momentum, as we did in Examples 41–7 and 42–2, shows that the minimum proton energy, called the **threshold energy**, is 3.23 MeV in this case (= Problem 15).

## Neutron Physics

The artificial transmutation of elements took a great leap forward in the 1930s when Enrico Fermi realized that neutrons would be the most effective projectiles for causing nuclear reactions and in particular for producing new elements. Because neutrons have no net electric charge, they are not repelled by positively charged nuclei as are protons or alpha particles. Hence the probability of a neutron reaching the nucleus and causing a reaction is much greater than for charged projectiles,[†] particularly at low energies. Between 1934 and 1936, Fermi and his co-workers in Rome produced many previously unknown isotopes by bombarding different elements with neutrons. Fermi realized that if the heaviest known element, uranium, is bombarded with neutrons, it might be possible to produce new elements with atomic numbers greater than that of uranium. After several years of hard work, it was suspected that two new elements had been produced, neptunium $(Z = 93)$ and plutonium $(Z = 94)$. The full confirmation that such "transuranic" elements could be produced came several years later at the University of California, Berkeley. The reactions are shown in Fig. 42–1.

It was soon shown that what Fermi had actually observed when he bombarded uranium was an even stranger process—one that was destined to play an extraordinary role in the world at large. We discuss it in Section 42–3.

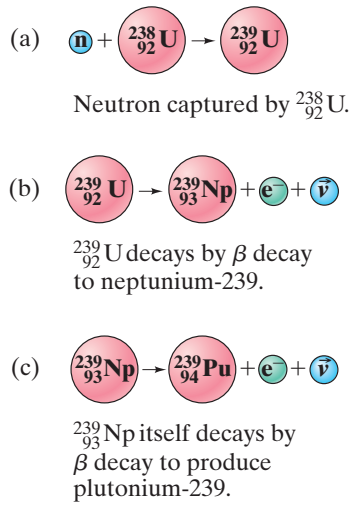

**FIGURE 42–1** Neptunium and plutonium are produced in this series of reactions, after bombardment of ${}^{238}_{92}U$ by neutrons.

[†]That is, positively charged particles. Electrons rarely cause nuclear reactions because they do not interact via the strong nuclear force.

## 42–2 Cross Section

Some reactions have a higher probability of occurring than others. The reaction probability is specified by a quantity called the collision **cross section**. Although the size of a nucleus, like that of an atom, is not a clearly defined quantity since the edges are not distinct like those of a tennis ball or baseball, we can nonetheless define a *cross section* for nuclei undergoing collisions by using an analogy. Suppose that projectile particles strike a stationary target of total area $A$ and thickness $\ell$, as shown in Fig. 42–2. Assume also that the target is made up of identical objects (such as marbles or nuclei), each of which has a cross-sectional area $\sigma$, and we assume the incoming projectiles are small by comparison. We assume that the target objects are fairly far apart and the thickness $\ell$ is so small that we don't have to worry about overlapping. This is often a reasonable assumption because nuclei have diameters on the order of $10^{-14}$ m but are at least $10^{-10}$ m (atomic size) apart even in solids. If there are $n$ nuclei per unit volume, the total cross-sectional area of all these tiny targets is

$$A' = nA\ell\sigma$$

since $nA\ell = (n)(\text{volume})$ is the total number of targets and $\sigma$ is the cross-sectional area of each. If $A' \ll A$, most of the incident projectile particles will pass through the target without colliding. If $R_0$ is the rate at which the projectile particles strike the target (number/second), the rate at which collisions occur, $R$, is

$$R = R_0\frac{A'}{A} = R_0\frac{nA\ell\sigma}{A}$$

so

$$R = R_0 n\ell\sigma.$$

Thus, by measuring the collision rate, $R$, we can determine $\sigma$:

$$\sigma = \frac{R}{R_0 n\ell}. \qquad \textbf{(42–3)}$$

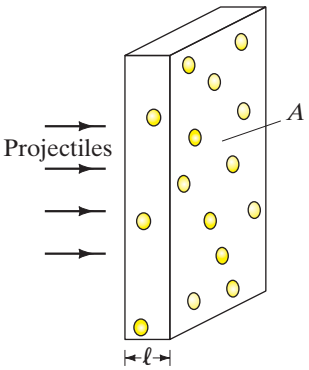

**FIGURE 42–2** Projectile particles strike a target of area $A$ and thickness $\ell$ made up of $n$ nuclei per unit volume.

If nuclei were simple billiard balls, and $R$ the number of particles that are deflected per second, $\sigma$ would represent the real cross-sectional area of each ball. But nuclei are complicated objects that cannot be considered to have distinct boundaries. Furthermore, collisions can be either elastic or inelastic, and reactions can occur in which the nature of the particles can change. By measuring $R$ for each possible process, we can determine an **effective cross section**, $\sigma$, for each process. None of these cross sections is necessarily related to a geometric cross-sectional area. Rather, $\sigma$ is an "effective" target area. It is a *measure of the probability of a collision or of a particular reaction occurring* per target nucleus, independent of the dimensions of the entire target. The concept of cross section is useful because $\sigma$ depends only on the properties of the interacting particles, whereas $R$ depends on the thickness and area of the physical (macroscopic) target, on the number of particles in the incident beam, and so on.

When a given pair of particles interact, we define their **elastic cross section** $\sigma_{\text{el}}$ using Eq. 42–3, where $R$ for a given experimental setup is the rate of elastic collisions (or **elastic scattering**), by which we mean collisions for which the final particles are the same as the initial particles (a = b, X = Y in Eq. 42–1) and $Q = 0$. Similarly, the inelastic cross section, $\sigma_{\text{inel}}$, is related to the rate of inelastic collisions, or **inelastic scattering**, which involves the same final and initial particles but $Q \neq 0$, usually because excited states are involved. For each reaction in which the final particles are different than the initial particles, there is a particular cross section. For protons (p) incident on ${}^{13}_{6}\text{C}$, for example, we could have various reactions, such as $\text{p} + {}^{13}_{6}\text{C} \rightarrow {}^{13}_{7}\text{N} + \text{n}$ or $\text{p} + {}^{13}_{6}\text{C} \rightarrow {}^{10}_{5}\text{B} + {}^{4}_{2}\text{He}$, and so on. The sum of all the separate reaction cross sections (for a given pair of initial particles) is called the **total reaction cross section**, $\sigma_{\text{R}}$. The **total cross section**, $\sigma_{\text{T}}$, is

$$\sigma_{\text{T}} = \sigma_{\text{el}} + \sigma_{\text{inel}} + \sigma_{\text{R}}$$

and is a measure of all possible interactions or collisions starting with given initial particles. Said another way, $\sigma_{\text{T}}$ is a measure of how many of the incident particles interact in some way and hence are eliminated from the incident beam.

PSE5_CH42_v1.6_23Jun-20

We can also define **differential cross sections**, which represent the probability of the deflected (or emitted) particles leaving at particular angles.

It is said that when one of the first nuclear cross sections was measured, a physicist, surprised that it was as large as it was $(\approx 10^{-28}\,\text{m}^2)$, remarked, "it's as big as a barn." Ever since then nuclear cross sections have been measured in "barns," where 1 barn $(\text{bn}) = 10^{-28}\,\text{m}^2$.

The value of $\sigma$ for a given reaction depends on, among other things, the incident kinetic energy. Typical nuclear cross sections are on the order of barns, but they can vary from millibarns to kilobarns or more. Figure 42–3 shows the cross section for neutron capture in cadmium $\left(\text{n} + {}^{114}_{48}\text{Cd} \rightarrow {}^{115}_{48}\text{Cd} + \gamma\right)$ as a function of neutron kinetic energy. Neutron cross sections for most materials are greater at low energies, as in Fig. 42–3. To produce nuclear reactions at a high rate it is therefore desirable that the bombarding neutrons have low energy. Neutrons that have been slowed down and have reached equilibrium with matter at room temperature $\left(\frac{3}{2}kT \approx 0.04\,\text{eV} \text{ at } T = 300\,\text{K}\right)$ are called **thermal neutrons**.

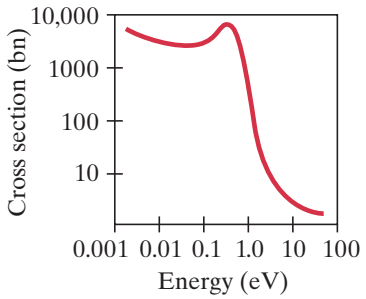

**FIGURE 42–3** The neutron cross section for cadmium-114 as a function of incoming neutron kinetic energy. It is extraordinarily large for $K \lesssim 1\,\text{eV}$. Note that both scales are logarithmic.

**EXAMPLE 42–4** **Using cross section.** The reaction

$$\text{p} + {}^{56}_{26}\text{Fe} \rightarrow {}^{56}_{27}\text{Co} + \text{n}$$

has a cross section of 0.65 bn for a particular incident proton energy. Suppose the iron target has an area of $1.5\,\text{cm}^2$, and is $2.0\,\mu\text{m}$ thick. The density of iron is $7.8 \times 10^3\,\text{kg/m}^3$. If the protons are incident at a rate of $2.0 \times 10^{13}$ particles/s, calculate the rate at which neutrons are produced.

**APPROACH** We use Eq. 42–3 in the form: $R = R_0 n\ell\sigma$.

**SOLUTION** We are given $R_0 = 2.0 \times 10^{13}$ particles/s, $\ell = 2.0 \times 10^{-6}\,\text{m}$, and $\sigma = 0.65$ bn. Recalling from Chapter 17 that one mole (mass = 56 g for iron) contains $6.02 \times 10^{23}$ atoms, then the number of iron atoms per unit volume is

$$n = \left(6.02 \times 10^{23}\,\text{atoms/mole}\right)\frac{\left(7.8 \times 10^3\,\text{kg/m}^3\right)}{\left(56 \times 10^{-3}\,\text{kg/mole}\right)} = 8.4 \times 10^{28}\,\text{atoms/m}^3.$$

Then we find that the rate at which neutrons are produced is

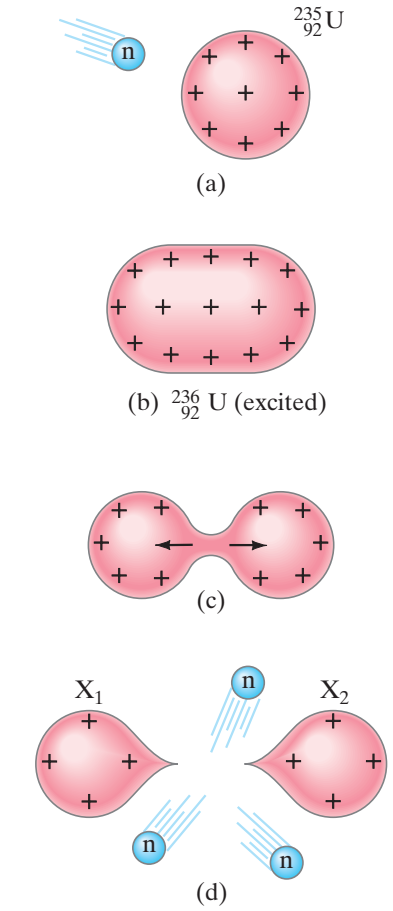
$$\begin{aligned} R &= R_0 n\ell\sigma \\ &= \left(2.0 \times 10^{13}\text{particles/s}\right)\left(8.4 \times 10^{28}\text{atoms/m}^3\right)\left(2.0 \times 10^{-6}\text{m}\right)\left(0.65 \times 10^{-28}\text{m}^2\right) \\ &= 2.2 \times 10^{8}\text{particles/s}. \end{aligned}$$

# 42–3 Nuclear Fission; Nuclear Reactors

In 1938, the German scientists Otto Hahn and Fritz Strassmann made an amazing discovery. Following up on Fermi's work, they found that uranium bombarded by neutrons sometimes produced smaller nuclei that were roughly half the size of the original uranium nucleus. Lise Meitner and Otto Frisch quickly realized what had happened: the uranium nucleus, after absorbing a neutron, actually had split into two roughly equal pieces. This was startling, for until then the known nuclear reactions involved knocking out only a tiny fragment (for example, n, p, or $\alpha$) from a nucleus.

## Nuclear Fission and Chain Reactions

This new phenomenon was named **nuclear fission** because of its resemblance to biological fission (cell division). It occurs much more readily for ${}^{235}_{92}\text{U}$ than for the more common ${}^{238}_{92}\text{U}$. The process can be visualized by imagining the uranium nucleus to be like a liquid drop. According to this **liquid-drop model**, the neutron absorbed by the ${}^{235}_{92}\text{U}$ nucleus gives the nucleus extra internal energy (like heating a drop of water).



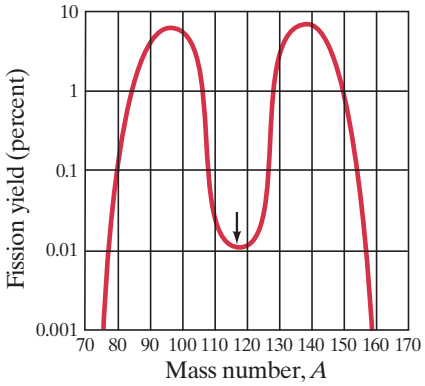


**FIGURE 42–4** Fission of a $^{235}_{92}$U nucleus after capture of a neutron, according to the liquid-drop model.

**FIGURE 42–5** Mass distribution of fission fragments from $^{235}_{92}$U + n. The small arrow indicates equal mass fragments $\left(\frac{1}{2} \times (236 - 2) = 117\right.$, assuming 2 neutrons are liberated$\left.\right)$. Note that the vertical scale is logarithmic.

This intermediate state, or **compound nucleus**, is $^{236}_{92}$U (because of the absorbed neutron). The extra energy of this nucleus—it is in an excited state—appears as increased motion of the individual nucleons, which causes the nucleus to take on abnormal elongated shapes, Fig. 42–4. When the nucleus elongates (in this model) into the shape shown in Fig. 42–4c, the attraction of the two ends via the short-range nuclear force is greatly weakened by the increased separation distance. Then the electric repulsive force becomes dominant, and the nucleus splits in two (Fig.42–4d). The two resulting nuclei, $X_1$ and $X_2$, are called **fission fragments**, and in the process a number of neutrons (typically two or three) are also given off. The reaction can be written

$$\text{n} + {}^{235}_{92}\text{U} \rightarrow {}^{236}_{92}\text{U} \rightarrow \text{X}_1 + \text{X}_2 + \text{neutrons}. \qquad \textbf{(42–4)}$$

The compound nucleus, $^{236}_{92}$U, exists for less than $10^{-12}$ s, so the process occurs very quickly. The two fission fragments, $X_1$ and $X_2$, rarely split the original uranium precisely half and half, but more often as about 40%–60%. A typical fission reaction is

$$\text{n} + {}^{235}_{92}\text{U} \rightarrow {}^{141}_{56}\text{Ba} + {}^{92}_{36}\text{Kr} + 3\text{n}, \qquad \textbf{(42–5)}$$

although many others also occur. Indeed Figure 42–5 shows the measured distribution of $^{235}_{92}$U fission fragments according to mass. Only rarely (about 1 in $10^4$) does a fission result in equal mass fragments (arrow in Fig. 42–5).

**CONCEPTUAL EXAMPLE 42–5** **Counting nucleons.** Identify the element X in the fission reaction $\text{n} + {}^{235}_{92}\text{U} \rightarrow {}^{A}_{Z}\text{X} + {}^{93}_{38}\text{Sr} + 2\text{n}$.

**RESPONSE** The number of nucleons is conserved (Section 41–7). The uranium nucleus with 235 nucleons plus the incoming neutron make $235 + 1 = 236$ nucleons. So there must be 236 nucleons after the reaction. The Sr has 93 nucleons, and the two neutrons make 95 nucleons, so X has $A = 236 - 95 = 141$. Electric charge is also conserved: before the reaction, the total charge is $92e$. After the reaction the total charge is $(Z + 38)e$ and must equal $92e$. Thus $Z = 92 - 38 = 54$. The element with $Z = 54$ is xenon (see Appendix G or the Periodic Table inside the back cover), so the isotope is $^{141}_{54}$Xe.

**EXERCISE B** In the fission reaction $\text{n} + {}^{235}_{92}\text{U} \rightarrow {}^{137}_{53}\text{I} + {}^{96}_{39}\text{Y} + \text{neutrons}$, how many neutrons are released?

A tremendous amount of energy is released in a fission reaction because the mass of $^{235}_{92}$U is considerably greater than the total mass of the fission fragments plus released neutrons. This can be seen from the binding-energy-per-nucleon curve of Fig. 41–1; the binding energy per nucleon for uranium is about 7.6 MeV/nucleon, but for fission fragments that have intermediate mass (in the center portion of the graph, $A \approx 100$), the average binding energy per nucleon is about 8.5 MeV/nucleon. Since the fission fragments are more tightly bound, the sum of their masses is less than the mass of the uranium. The difference in mass, or energy, between the original uranium nucleus and the fission fragments is about $8.5 - 7.6 = 0.9$ MeV per nucleon. Because there are 236 nucleons involved in each fission, the total energy released per fission is

$$(0.9\,\text{MeV/nucleon})\,(236\,\text{nucleons}) \approx 200\,\text{MeV}. \qquad \textbf{(42–6)}$$

This is an enormous amount of energy for one single nuclear fission. At a practical level, the energy from one fission is tiny. But if many such fissions could occur in a short time, an enormous amount of energy at the macroscopic level would be available. A number of physicists, including Fermi, recognized that the neutrons released in each fission (Eqs. 42–4 and 42–5) could be used to create a **chain reaction**. That is, one neutron initially causes one fission of a uranium

PSE5_CH42_v1.6_23Jun-20

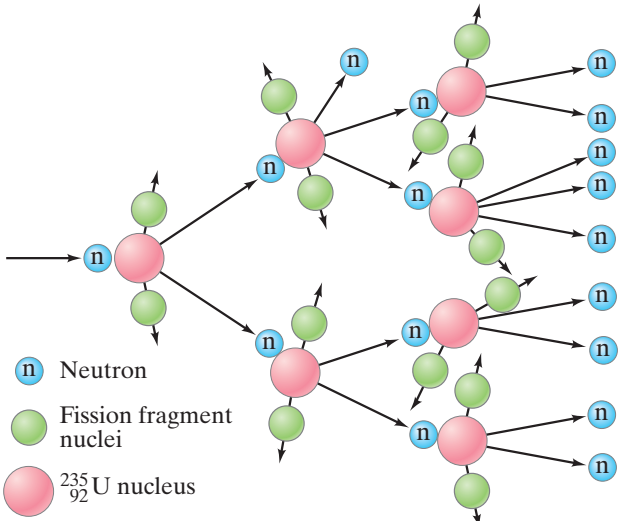

**FIGURE 42–6** Chain reaction.

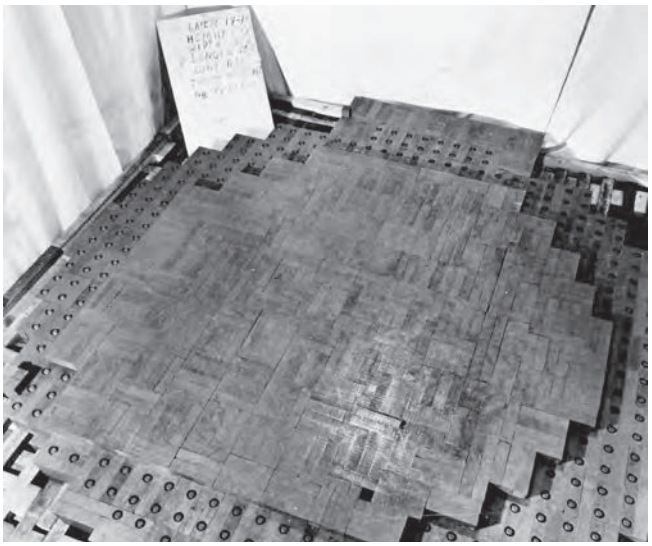

**FIGURE 42–7** This is the only photograph of the first nuclear reactor, built by Fermi under the grandstand of Stagg Field at the University of Chicago. It is shown here under construction as a layer of graphite (used as moderator) was being placed over a layer of natural uranium. On December 2, 1942, Fermi slowly withdrew the cadmium control rods and the reactor went critical. This first self-sustaining chain reaction was announced to Washington, via telephone, by Arthur Compton who witnessed the event and reported: "The Italian navigator has just landed in the new world."

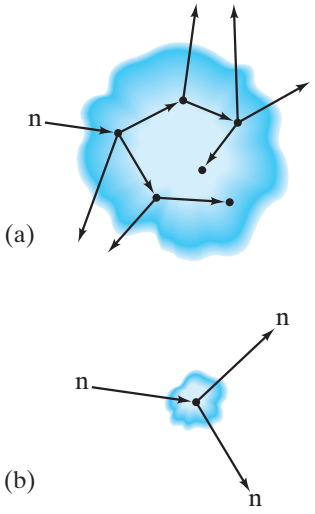
nucleus; the two or three neutrons released can go on to cause additional fissions, so the process multiplies as shown schematically in Fig. 42–6.

If a **self-sustaining chain reaction** was actually possible in practice, the enormous energy available in fission could be released on a larger scale. Fermi and his co-workers (at the University of Chicago) showed it was possible by constructing the first **nuclear reactor** in 1942 (Fig. 42–7).



## Nuclear Reactors

Several difficulties have to be overcome to make any nuclear reactor function. First, the probability that a $^{235}_{92}$U nucleus will absorb a neutron is large only for slow neutrons, but the neutrons emitted during a fission (which are needed to sustain a chain reaction) are moving very fast. A substance known as a **moderator** must be used to slow down the neutrons. The most effective moderator will consist of atoms whose mass is as close as possible to that of the neutrons. (To see why this is true, recall from Chapter 9 that a billiard ball striking an equal mass ball at rest can itself be stopped in one collision; but a billiard ball striking a heavy object bounces off with nearly unchanged speed.) The best moderator would thus contain $^{1}_{1}$H atoms. Unfortunately, $^{1}_{1}$H tends to absorb neutrons. But the isotope of hydrogen called *deuterium*, $^{2}_{1}$H, does not absorb many neutrons and is thus an almost ideal moderator. Either $^{1}_{1}$H or $^{2}_{1}$H can be used in the form of water. In the latter case, it is **heavy water**, in which the hydrogen atoms have been replaced by deuterium. Another common moderator is *graphite*, which consists of $^{12}_{6}$C atoms.

A second problem is that the neutrons produced in one fission may be absorbed and produce other nuclear reactions with other nuclei in the reactor, rather than produce further fissions. In a "light-water" reactor, the $^{1}_{1}$H nuclei absorb neutrons, as does $^{238}_{92}$U to form $^{239}_{92}$U in the reaction $n + {}^{238}_{92}U \rightarrow {}^{239}_{92}U + \gamma$. Naturally occurring uranium[†] contains 99.3% $^{238}_{92}$U and only 0.7% fissionable $^{235}_{92}$U. To increase the probability of fission of $^{235}_{92}$U nuclei, natural uranium can be **enriched** to increase the percentage of $^{235}_{92}$U by using processes such as diffusion or centrifugation. Enrichment is not usually necessary for reactors using heavy water as the moderator, because heavy water doesn't absorb neutrons.[‡]

The third problem is that some neutrons will escape through the surface of the reactor core before they can cause further fissions (Fig. 42–8). Thus the mass of fuel must be sufficiently large for a self-sustaining chain reaction to take place. The minimum mass of uranium needed is called the **critical mass**.

**FIGURE 42–8** If the amount of uranium exceeds the critical mass, as in (a), a sustained chain reaction is possible. If the mass is less than critical, as in (b), too many neutrons escape before additional fissions occur, and the chain reaction is not sustained.

[†]$^{238}_{92}$U will fission, but only with fast neutrons ($^{238}_{92}$U is more stable than $^{235}_{92}$U). The probability of absorbing a fast neutron and producing a fission is too low to produce a self-sustaining chain reaction.

[‡]Other types of power or research reactors need 3% to 20% of $^{235}_{92}$U. Atom bombs need greater enrichment: $\geq 80\%$.

The value of the critical mass depends on the moderator, the fuel ($^{239}_{94}$Pu may be used instead of $^{235}_{92}$U), and how much the fuel is enriched, if at all. Typical values are on the order of a few kilograms (that is, neither grams nor thousands of kilograms). Critical mass depends also on the average number of neutrons released per fission: 2.5 for $^{235}_{92}$U, 2.9 for $^{239}_{94}$Pu and so the critical mass for $^{239}_{94}$Pu is smaller.

To have a self-sustaining chain reaction, on average at least one neutron produced in each fission must go on to produce another fission. The average number of neutrons per fission that do go on to produce further fissions is called the **neutron multiplication factor**, $f$. For a self-sustaining chain reaction, we must have $f \geq 1$. If $f < 1$, the reactor is "subcritical." If $f > 1$, it is "supercritical" (and could become dangerously explosive). Reactors are equipped with movable **control rods** (good neutron absorbers like cadmium or boron), whose function is to absorb neutrons and maintain the reactor at just barely "critical," $f = 1$.

The release of neutrons and subsequent fissions occur so quickly that manipulation of the control rods to maintain $f = 1$ would not be possible if it weren't for a small percentage ($\approx 1\%$) of so-called **delayed neutrons**. They come from the decay of neutron-rich fission fragments (or their daughters) having lifetimes on the order of seconds—sufficient to allow enough reaction time to operate the control rods and maintain $f = 1$.

Nuclear reactors have been built for use in research and to produce electric power. Fission produces many neutrons and a "research reactor" is basically an intense source of neutrons. These neutrons can be used as projectiles in nuclear reactions to produce nuclides not found in nature, including isotopes used as tracers and for therapy. A "power reactor" is used to produce electric power. The energy released in the fission process appears as heat, which is used to boil water and produce steam to drive a turbine connected to an electric generator (Fig. 42–9). The **core** of a nuclear reactor consists of the fuel and a moderator (water in most U.S. commercial reactors). The fuel is usually uranium enriched so that it contains 2 to 4 percent $^{235}_{92}$U. Water at high pressure or other liquid (such as liquid sodium) is allowed to flow through the core. The thermal energy it absorbs is used to produce steam in the heat exchanger, so the fissionable fuel acts as the heat input for a heat engine (Chapter 20).

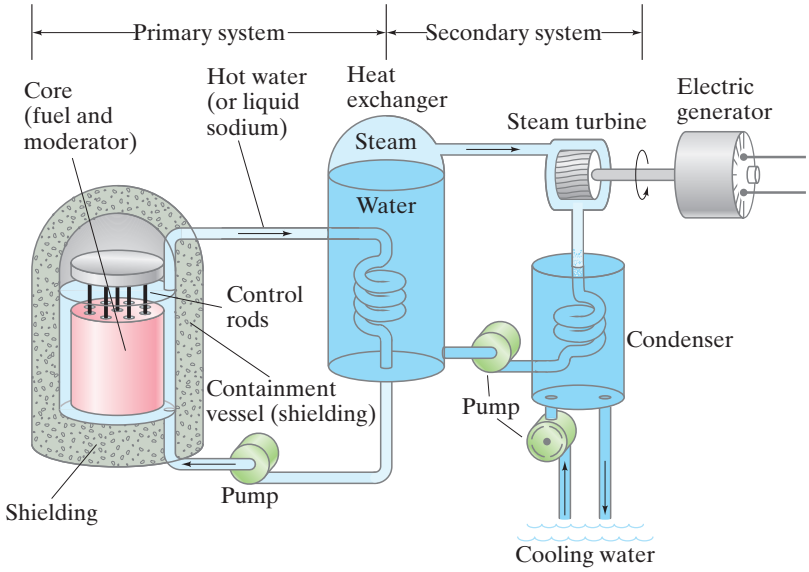


**FIGURE 42–9** A nuclear reactor. The heat generated by the fission process in the fuel rods is carried off by hot water or liquid sodium and is used to boil water to steam in the heat exchanger. The steam drives a turbine to generate electricity and is then cooled in the condenser (to reduce pressure on the back side of the turbine blades).

There are problems associated with nuclear power plants. Besides the usual thermal pollution associated with any heat engine (Section 20–11), there is the serious problem of disposal of the radioactive fission fragments produced in the reactor, plus radioactive nuclides produced by neutrons interacting with the structural parts of the reactor. Fission fragments, like their uranium or plutonium parents, have about 50% more neutrons than protons. Nuclei with atomic number in the typical range for fission fragments ($Z \approx 30$ to 60) are stable only if they have more nearly equal numbers of protons and neutrons (see Fig. 41–2). Hence the highly neutron-rich fission fragments are very unstable and decay radioactively. The accidental release

PSE5_CH42_v1.6_23Jun-20

of highly radioactive fission fragments into the atmosphere poses a serious threat to human health (Section 42–5), as does possible leakage of the radioactive wastes when they are disposed of. The accidents at Three Mile Island, Pennsylvania (1979), at Chernobyl, Russia (1986), and at Fukushima, Japan (2011), have illustrated some of the dangers and have shown that nuclear plants must be located, constructed, maintained, and operated with great care and precision (Fig. 42–10).

Finally, the lifetime of nuclear power plants is limited to 30-some years, due to buildup of radioactivity and the fact that the structural materials themselves are weakened by the intense conditions inside. The cost of "decommissioning" a power plant is very great.

So-called **breeder reactors** were proposed as a solution to the problem of limited supplies of fissionable uranium, $^{235}_{92}\text{U}$. A breeder reactor is one in which some of the neutrons produced in the fission of $^{235}_{92}\text{U}$ are absorbed by $^{238}_{92}\text{U}$, and $^{239}_{94}\text{Pu}$ is produced via the set of reactions shown in Fig. 42–1. $^{239}_{94}\text{Pu}$ is fissionable with slow neutrons, so after separation it can be used as a fuel in a nuclear reactor. Thus a breeder reactor "breeds" new fuel† $\left(^{239}_{94}\text{Pu}\right)$ from otherwise useless $^{238}_{92}\text{U}$. Natural uranium is 99.3 percent $^{238}_{92}\text{U}$, which in a breeder becomes useful fissionable $^{239}_{94}\text{Pu}$, thus increasing the supply of fissionable fuel by more than a factor of 100. But breeder reactors have the same problems as other reactors, plus other serious problems. Not only is plutonium a serious health hazard in itself (radioactive with a half-life of 24,000 years), but plutonium produced in a reactor can readily be used in a bomb, increasing the danger of nuclear proliferation and theft of fuel to produce a bomb.

Nuclear power presents risks. Other large-scale energy-conversion methods, such as conventional oil and coal-burning steam plants, also present health and environmental hazards; some of them were discussed in Section 20–11, and include air pollution, oil spills, and the release of $CO_2$ gas which can trap heat as in a greenhouse to raise the Earth's temperature. The solution to the world's needs for energy is not only technological, but also economic and political. A major factor surely is to "conserve"—to minimize our energy use. "Reduce, reuse, recycle."

**FIGURE 42–10** Smoke rising from Fukushina, Japan, after the terrible nuclear power plant meltdown in 2011.

**EXAMPLE 42–6** **Uranium fuel amount.** Estimate the minimum amount of $^{235}_{92}\text{U}$ that needs to undergo fission in order to run a 1000-MW power reactor per year of continuous operation. Assume an efficiency (Chapter 20) of about 33%.

**APPROACH** At 33% efficiency, we need $3 \times 1000\,\text{MW} = 3000 \times 10^6\,\text{J/s}$ input. Each fission releases about 200 MeV (Eq. 42–6), so we divide the energy for a year by 200 MeV to get the number of fissions needed per year. Then we multiply by the mass of one uranium atom.

**SOLUTION** For 1000-MW output, the total power generation needs to be 3000 MW, of which 2000 MW is dumped as "waste" heat. Thus the total energy release in 1 yr $\left(3 \times 10^7\,\text{s}\right)$ from fission needs to be about

$$\left(3 \times 10^9\,\text{J/s}\right)\left(3 \times 10^7\,\text{s}\right) \approx 10^{17}\,\text{J}.$$

If each fission releases 200 MeV of energy, the number of fissions required for a year is

$$\frac{\left(10^{17}\,\text{J}\right)}{\left(2 \times 10^8\,\text{eV/fission}\right)\left(1.6 \times 10^{-19}\,\text{J/eV}\right)} \approx 3 \times 10^{27}\,\text{fissions}.$$

The mass of a single uranium atom is about $(235\,\text{u})\left(1.66 \times 10^{-27}\,\text{kg/u}\right) \approx 4 \times 10^{-25}\,\text{kg}$, so the total uranium mass needed is

$$\left(4 \times 10^{-25}\,\text{kg/fission}\right)\left(3 \times 10^{27}\,\text{fissions}\right) \approx 1000\,\text{kg},$$

or about a ton of $^{235}_{92}\text{U}$.

**NOTE** Because $^{235}_{92}\text{U}$ makes up only 0.7% of natural uranium, the yearly requirement for uranium is on the order of a hundred tons. This is orders of magnitude less than coal, both in mass and volume. Coal releases $2.8 \times 10^7\,\text{J/kg}$, whereas $^{235}_{92}\text{U}$ can release $10^{17}\,\text{J}$ per ton, as we just calculated, or $10^{17}\,\text{J}/10^3\,\text{kg} = 10^{14}\,\text{J/kg}$. For natural uranium, the figure is 100 times less, $10^{12}\,\text{J/kg}$.

**PHYSICS APPLIED**
*Energy in coal vs. uranium*

†A breeder reactor does *not* produce more fuel than it uses.

**FIGURE 42–11** J. Robert Oppenheimer, on the left, with General Leslie Groves, who was the administrative head of Los Alamos during World War II. The photograph was taken at the Trinity site in the New Mexico desert, where the first atomic bomb was exploded.

**FIGURE 42–12** Photo taken a month after the bomb was dropped on Nagasaki. The shacks were constructed afterwards from debris in the ruins. The bombs dropped on Hiroshima and Nagasaki were each equivalent to about 20,000 tons of the common explosive TNT $(\sim 10^{14}\,\text{J})$.

**EXERCISE C** A nuclear-powered submarine needs 6000-kW input power. How many $^{235}_{92}\text{U}$ fissions is this per second?

### Atom Bomb

The first use of fission, however, was not to produce electric power. Instead, it was first used as a fission bomb (called the "atomic bomb"). In early 1940, with Europe already at war, Germany's leader, Adolf Hitler, banned the sale of uranium from the Czech mines he had recently taken over. Research into the fission process suddenly was enshrouded in secrecy. Physicists in the United States were alarmed. A group of them approached Einstein—a man whose name was a household word—to send a letter to President Franklin Roosevelt about the possibilities of using nuclear fission for a bomb far more powerful than any previously known, and inform him that Germany might already have begun development of such a bomb. Roosevelt responded by authorizing the program known as the Manhattan Project, to see if a bomb could be built. Work began in earnest after Fermi's demonstration in 1942 that a sustained chain reaction was possible. A new secret laboratory was developed on an isolated mesa in New Mexico known as Los Alamos. Under the direction of J. Robert Oppenheimer (1904–1967; Fig. 42–11), it became the home of famous scientists from all over Europe and the United States.

To build a bomb that was subcritical during transport but that could be made supercritical (to produce a chain reaction) at just the right moment, two pieces of uranium were used, each less than the critical mass but together greater than the critical mass. The two masses, kept separate until the moment of detonation, were then forced together quickly by a kind of gun, and a chain reaction of explosive proportions occurred. A second bomb design detonated conventional explosives (TNT) surrounding a plutonium sphere to compress it by implosion to double its density, making it more than critical and causing a nuclear explosion. The first fission bomb was tested in the New Mexico desert in July 1945. It was successful. In early August, a fission bomb using uranium was dropped on Hiroshima and a second, using plutonium, was dropped on Nagasaki (Fig. 42–12), both in Japan. World War II ended shortly thereafter.

Besides its destructive power, a fission bomb produces many highly radioactive fission fragments, as does a nuclear reactor. When a fission bomb explodes, these radioactive isotopes are released into the atmosphere as **radioactive fallout**.

Testing of nuclear bombs in the atmosphere after World War II was a cause of concern, because the movement of air masses spread the fallout all over the globe. Radioactive fallout eventually settles to the Earth, particularly in rainfall, and is absorbed by plants and grasses and enters the food chain. This is a far more serious problem than the same radioactivity on the exterior of our bodies, because $\alpha$ and $\beta$ particles are largely absorbed by clothing and the outer (dead) layer of skin. But inside our bodies as food, the isotopes are in contact with living cells. One particularly dangerous radioactive isotope is $^{90}_{38}\text{Sr}$, which is chemically much like calcium and becomes concentrated in bone, where it causes bone cancer and destroys bone marrow. The 1963 treaty signed by over 100 nations that bans nuclear weapons testing in the atmosphere was motivated because of the hazards of fallout.

## 42–4 Nuclear Fusion

The mass of every stable nucleus is less than the sum of the masses of its constituent protons and neutrons. For example, the mass of the helium isotope $^{4}_{2}\text{He}$ is less than the mass of two protons plus two neutrons, Example 41–3. If two protons and two neutrons were to come together to form a helium nucleus, there would be a loss of mass. This mass loss is manifested in the release of energy.

PSE5_CH42_v1.6_23Jun-20

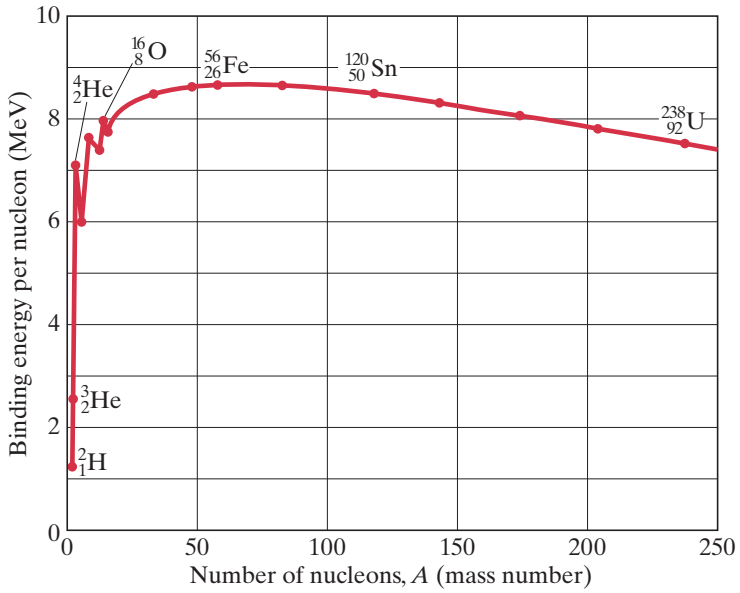

**FIGURE 42–13** Average binding energy per nucleon as a function of mass number $A$ for stable nuclei. Same as Fig. 41–1.

## Nuclear Fusion; Stars

The process of building up nuclei by bringing together individual protons and neutrons, or building larger nuclei by combining small nuclei, is called **nuclear fusion**. In Fig. 42–13 (same as Fig. 41–1), we can see why small nuclei can combine to form larger ones with the release of energy: it is because the binding energy per nucleon is less for light nuclei than it is for heavier nuclei (up to about $A \approx 60$). For two positively charged nuclei to get close enough to fuse, they must have very high kinetic energy to overcome the electric repulsion. Many of the elements in the universe can be explained as being formed through the process of nuclear fusion in stars (see Chapter 44) where the temperature is extremely high, corresponding to high kinetic energy (Eq. 18–4). Today fusion is still producing the prodigious amounts of light energy (EM waves) stars emit, including our Sun.

**EXAMPLE 42–7** **Fusion energy release.** One of the simplest fusion reactions involves the production of deuterium, $^{2}_{1}\text{H}$, from a neutron and a proton: $^{1}_{1}\text{H} + \text{n} \rightarrow {}^{2}_{1}\text{H} + \gamma$. How much energy is released in this reaction?

**APPROACH** The energy released equals the difference in mass (times $c^2$) between the initial and final masses.

**SOLUTION** From Appendix G, the initial mass is

$$1.007825\,\text{u} + 1.008665\,\text{u} = 2.016490\,\text{u},$$

and after the reaction the mass is that of the $^{2}_{1}\text{H}$, namely 2.014102 u (the $\gamma$ is massless). The mass difference is

$$2.016490\,\text{u} - 2.014102\,\text{u} = 0.002388\,\text{u},$$

so the energy released is

$$(\Delta m)c^2 = (0.002388\,\text{u})\,(931.5\,\text{MeV/u}) = 2.22\,\text{MeV},$$

and it is carried off as kinetic energy of the $^{2}_{1}\text{H}$ nucleus and the $\gamma$ ray.

The energy output of our Sun is believed to be due principally to the following sequence of fusion reactions:

$$^{1}_{1}\text{H} + {}^{1}_{1}\text{H} \rightarrow {}^{2}_{1}\text{H} + \text{e}^{+} + \nu \qquad (0.42\,\text{MeV}) \qquad \textbf{(42–7a)}$$

$$^{1}_{1}\text{H} + {}^{2}_{1}\text{H} \rightarrow {}^{3}_{2}\text{He} + \gamma \qquad (5.49\,\text{MeV}) \qquad \textbf{(42–7b)}$$

$$^{3}_{2}\text{He} + {}^{3}_{2}\text{He} \rightarrow {}^{4}_{2}\text{He} + {}^{1}_{1}\text{H} + {}^{1}_{1}\text{H} \qquad (12.86\,\text{MeV}) \qquad \textbf{(42–7c)}$$

*Proton–proton chain*

where the energy released ($Q$-value) for each reaction is given in parentheses.

(They include keeping track of atomic electrons as for $\beta$-decay, Section 41–5). These reactions are between nuclei, without electrons at these very high temperatures; the first reaction can be written as

$$\mathrm{p} + \mathrm{p} \rightarrow \mathrm{d} + \mathrm{e}^+ + \nu$$

where p = proton and d = deuteron. The net effect of this sequence, which is called the **proton–proton chain**, is for four protons to combine to form one $^4_2\mathrm{He}$ nucleus plus two positrons, two neutrinos, and two gamma rays:

$$4\,{}^1_1\mathrm{H} \rightarrow {}^4_2\mathrm{He} + 2\mathrm{e}^+ + 2\nu + 2\gamma. \qquad \textbf{(42–8)}$$

Note that it takes two of each of the first two reactions (Eqs. 42–7a and b) to produce the two $^3_2\mathrm{He}$ for the third reaction. Also, each of the two $\mathrm{e}^+$ formed (Eq. 42–7a) quickly annihilates with an electron to produce 2 $\gamma$ rays (Section 37–5) with total energy $2m_\mathrm{e}c^2 = 1.02\,\mathrm{MeV}$. So the total energy release for the net reaction, Eq. 42–8, is

$$2(0.42\,\mathrm{MeV}) + 2(1.02\,\mathrm{MeV}) + 2(5.49\,\mathrm{MeV}) + 12.86\,\mathrm{MeV} = 26.7\,\mathrm{MeV}.$$

The first reaction, the formation of deuterium from two protons (Eq. 42–7a), has a very low probability and so limits the rate at which the Sun produces energy. (Thank goodness; this is why the Sun and other stars have a long lifetime and are still shining brightly.)

**EXERCISE D** Return to the first Chapter-Opening Question, page 1256, and answer it again now. Try to explain why you may have answered it differently the first time.

**EXAMPLE 42–8** | **ESTIMATE** **Estimating fusion energy.** Estimate the energy released if the following reaction occurred:

$${}^2_1\mathrm{H} + {}^2_1\mathrm{H} \rightarrow {}^4_2\mathrm{He}.$$

**APPROACH** We use Fig. 42–13 for a quick estimate.

**SOLUTION** We see in Fig. 42–13 that each $^2_1\mathrm{H}$ has a binding energy of about $1\frac{1}{4}\,\mathrm{MeV/nucleon}$, which for 2 nuclei of mass 2 is $4\times(1\frac{1}{4}) \approx 5\,\mathrm{MeV}$. The $^4_2\mathrm{He}$ has a binding energy per nucleon (Fig. 42–13) of about 7 MeV for a total of $4\times 7\,\mathrm{MeV} \approx 28\,\mathrm{MeV}$. Hence the energy release is about $28\,\mathrm{MeV} - 5\,\mathrm{MeV} \approx 23\,\mathrm{MeV}$.

In stars hotter than the Sun, it is more likely that the energy output comes principally from the **carbon** (or **CNO**) **cycle**, which comprises the following sequence of reactions:

*Carbon cycle*

$$\begin{aligned}
{}^{12}_6\mathrm{C} + {}^1_1\mathrm{H} &\rightarrow {}^{13}_7\mathrm{N} + \gamma \\
{}^{13}_7\mathrm{N} &\rightarrow {}^{13}_6\mathrm{C} + \mathrm{e}^+ + \nu \\
{}^{13}_6\mathrm{C} + {}^1_1\mathrm{H} &\rightarrow {}^{14}_7\mathrm{N} + \gamma \\
{}^{14}_7\mathrm{N} + {}^1_1\mathrm{H} &\rightarrow {}^{15}_8\mathrm{O} + \gamma \\
{}^{15}_8\mathrm{O} &\rightarrow {}^{15}_7\mathrm{N} + \mathrm{e}^+ + \nu \\
{}^{15}_7\mathrm{N} + {}^1_1\mathrm{H} &\rightarrow {}^{12}_6\mathrm{C} + {}^4_2\mathrm{He}.
\end{aligned}$$

No net carbon is consumed in this cycle and the net effect is the same as the proton–proton chain, Eq. 42–8 (plus one extra $\gamma$). The theory of the proton–proton chain and of the carbon cycle as the source of energy for the Sun and stars was first worked out by Hans Bethe (1906–2005) in 1939.

PSE5_CH42_v1.6_23Jun-20

**CONCEPTUAL EXAMPLE 42–9** **Stellar fusion.** What is the heaviest element likely to be produced in fusion processes in stars?

**RESPONSE** Fusion is possible if the final products have more binding energy (less mass) than the reactants, because then there is a net release of energy. Since the binding energy curve in Fig. 42–13 (or Fig. 41–1) peaks near $A \approx 56$ to 58 which corresponds to iron or nickel, it would not be energetically favorable to produce elements heavier than that. Nevertheless, in the center of massive stars or in supernova explosions, there is enough initial kinetic energy available to drive endothermic reactions that produce heavier elements, as well.

**EXERCISE E** If the Sun is generating a constant amount of energy via fusion, the mass of the Sun must be (*a*) increasing, (*b*) decreasing, (*c*) constant, (*d*) irregular.

## Possible Fusion Reactors

PHYSICS APPLIED
*Fusion energy reactors*

The possibility of utilizing the energy released in fusion to make a power reactor is very attractive. The fusion reactions most likely to succeed in a reactor involve the isotopes of hydrogen, ${}^2_1\text{H}$ (deuterium) and ${}^3_1\text{H}$ (tritium), and are as follows, with the energy released given in parentheses:

$$ {}^2_1\text{H} + {}^2_1\text{H} \rightarrow {}^3_1\text{H} + {}^1_1\text{H} \qquad (4.03\ \text{MeV}) \qquad \textbf{(42–9a)} $$

$$ {}^2_1\text{H} + {}^2_1\text{H} \rightarrow {}^3_2\text{He} + \text{n} \qquad (3.27\ \text{MeV}) \qquad \textbf{(42–9b)} $$

$$ {}^2_1\text{H} + {}^3_1\text{H} \rightarrow {}^4_2\text{He} + \text{n}. \qquad (17.59\ \text{MeV}) \qquad \textbf{(42–9c)} $$

Comparing these energy yields with that for the fission of ${}^{235}_{92}\text{U}$, we can see that the energy released in fusion reactions can be greater for a given mass of fuel than in fission. Furthermore, as fuel, a fusion reactor could use deuterium, which is very plentiful in the water of the oceans (the natural abundance of ${}^2_1\text{H}$ is 0.0115% on average, or about 1 g of deuterium per 80 L of water). The simple proton–proton reaction of Eq. 42–7a, which could use a much more plentiful source of fuel, ${}^1_1\text{H}$, has such a small probability of occurring that it cannot be considered a possibility on Earth.

Although a useful fusion reactor has not yet been achieved, considerable progress has been made in overcoming the inherent difficulties. The problems are associated with the fact that all nuclei have a positive charge and repel each other. However, if they can be brought close enough together so that the short-range attractive strong nuclear force can come into play, it can pull the nuclei together and fusion can occur. For the nuclei to get close enough together, they must have large kinetic energy to overcome the electric repulsion. High kinetic energies are readily attainable with particle accelerators (Chapter 43), but the number of particles involved is too small. To produce realistic amounts of energy, we must deal with matter in bulk, for which high kinetic energy means higher temperatures. Indeed, very high temperatures are required for sustained fusion to occur, and fusion devices are often referred to as **thermonuclear devices**. The interiors of the Sun and other stars are very hot, many millions of degrees, so the nuclei are moving fast enough for fusion to take place, and the energy released keeps the temperature high so that further fusion reactions can occur. The Sun and the stars represent huge self-sustaining thermonuclear reactors that stay together because of their great gravitational mass. But on Earth, containment of the fast-moving nuclei at the high temperatures and densities required has proven difficult.

It was realized after World War II that the temperature produced within a fission (or "atomic") bomb was close to $10^8$ K. This suggested that a fission bomb could be used to ignite a fusion bomb (popularly known as a thermonuclear or hydrogen bomb) to release the vast energy of fusion. The uncontrollable release of fusion energy in an H-bomb (in 1952) was relatively less difficult to obtain. But to realize usable energy from fusion at a slow and controlled rate has turned out to be a serious challenge.

**EXAMPLE 42–10** **ESTIMATE** **Temperature needed for d–t fusion.** Estimate the temperature required for deuterium–tritium fusion (d–t) to occur.

**APPROACH** We assume the nuclei approach head-on, each with kinetic energy $K$, and that the nuclear force comes into play when the distance between their centers equals the sum of their nuclear radii. The electrostatic potential energy (Chapter 23) of the two particles at this distance equals the minimum total kinetic energy of the two particles when far apart. The average kinetic energy is related to Kelvin temperature by Eq. 18–4.

**SOLUTION** The radii of the two nuclei ($A_d = 2$ and $A_t = 3$) are given by Eq. 41–1: $r_d \approx 1.5\,\text{fm}$, $r_t \approx 1.7\,\text{fm}$, so $r_d + r_t = 3.2 \times 10^{-15}\,\text{m}$. We equate the kinetic energy of the two initial particles to the potential energy when at this distance:

$$2K \approx \frac{1}{4\pi\epsilon_0}\frac{e^2}{(r_d + r_t)}$$

$$\approx \left(9.0 \times 10^9 \frac{\text{N}\cdot\text{m}^2}{\text{C}^2}\right)\frac{(1.6 \times 10^{-19}\,\text{C})^2}{(3.2 \times 10^{-15}\,\text{m})(1.6 \times 10^{-19}\,\text{J/eV})} \approx 0.45\,\text{MeV}.$$

Thus, $K \approx 0.22\,\text{MeV}$, and if we ask that the average kinetic energy be this high, then from Eq. 18–4, $\frac{3}{2}kT = \overline{K}$, we have a temperature of

$$T = \frac{2\overline{K}}{3k} = \frac{2(0.22\,\text{MeV})(1.6 \times 10^{-13}\,\text{J/MeV})}{3(1.38 \times 10^{-23}\,\text{J/K})} \approx 2 \times 10^9\,\text{K}.$$

**NOTE** More careful calculations show that the temperature required for fusion is actually about an order of magnitude less than this rough estimate, partly because it is not necessary that the *average* kinetic energy be 0.22 MeV—a small percentage of nuclei with this much energy (in the high-energy tail of the Maxwell distribution, Fig. 18–3) would be sufficient. Reasonable estimates for a usable fusion reactor are in the range $T \gtrsim 1$ to $4 \times 10^8\,\text{K}$.

A high temperature is required for a fusion reactor. But there must also be a high density of nuclei to ensure a sufficiently high collision rate. A real difficulty with controlled fusion is to contain nuclei long enough and at a high enough density for sufficient reactions to occur so that a usable amount of energy is obtained. At the temperatures needed for fusion, the atoms are ionized, and the resulting collection of nuclei and electrons is referred to as a **plasma**. Ordinary materials vaporize at a few thousand degrees at most, and hence cannot be used to contain a high-temperature plasma. Two major containment techniques are *magnetic confinement* and *inertial confinement*.

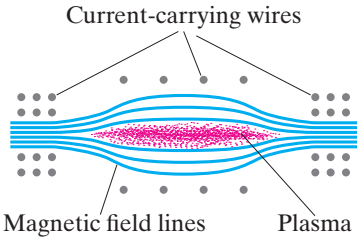

**FIGURE 42–14** "Magnetic bottle" used to confine a plasma.

In **magnetic confinement**, magnetic fields are used to try to contain the hot plasma. A simple approach is the "magnetic bottle" shown in Fig. 42–14. The paths of the charged particles in the plasma are bent by the magnetic field; where magnetic field lines are close together, the force on the particles reflects them back toward the center. Unfortunately, magnetic bottles develop "leaks" and the charged particles slip out before sufficient fusion takes place. The most promising design today is the **tokamak**, first developed in Russia. A tokamak (Fig. 42–15) is

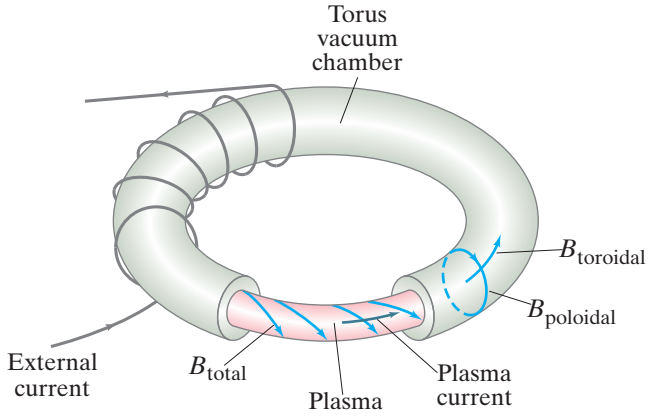

**FIGURE 42–15** Tokamak configuration, showing the total $\vec{\mathbf{B}}$ field due to external current plus current in the plasma itself.

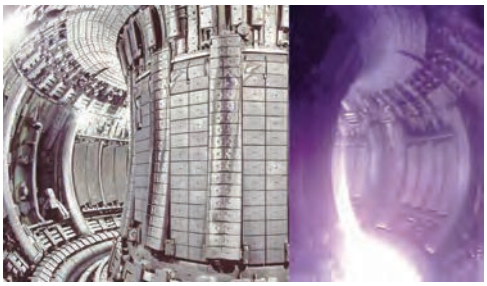
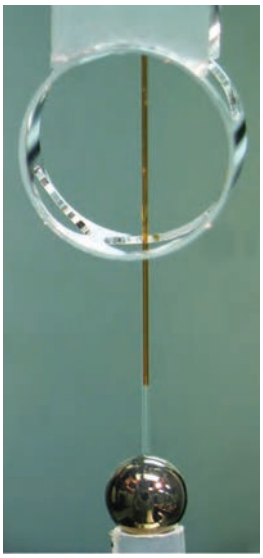
PSE5_CH42_v1.6_23Jun-20

toroid-shaped (a torus, which is like a donut) and involves complicated magnetic fields: current-carrying conductors produce a magnetic field directed along the axis of the toroid ("toroidal" field); an additional field is produced by currents within the plasma itself ("poloidal" field). The combination produces a helical field as shown in Fig. 42–15, confining the plasma, at least briefly, so it doesn't touch the vacuum chamber's metal walls (Fig. 42–16a).



In 1957, J. D. Lawson showed that the product of ion density $n$ $(= \text{ions/m}^3)$ and confinement time $\tau$ must exceed a minimum value of approximately

$$n\tau \gtrsim 3 \times 10^{20}\,\text{s/m}^3.$$



This **Lawson criterion** must be reached to produce **ignition**, meaning fusion that continues after all external heating is turned off. Practically, it is expected to be achieved with $n \approx 1$ to $3 \times 10^{20}\,\text{m}^{-3}$ and $\tau \approx 1$ to 3 s. To reach **break-even**, the point at which the energy output due to fusion is equal to the energy input to heat the plasma, requires an $n\tau$ about an order of magnitude less. The break-even point was very closely approached in the 1990s at the Tokamak Fusion Test Reactor (TFTR) at Princeton, and the very high temperature needed for ignition $(4 \times 10^8\,\text{K})$ was exceeded—although not both of these at the same time.

Magnetic confinement fusion research continues throughout the world. This research will help us in developing the huge multinational test device (European Union, India, Japan, South Korea, Russia, China, and the U.S.), called ITER (International Thermonuclear Experimental Reactor) situated in France. It is expected that ITER will produce temperatures above $10^8$ K for extended periods (minutes or hours) and to begin running in the 2020s, with an expected power output of about 500 MW, 10 times the input energy. ITER is planned to be the final research step before building a working reactor.

The second method for containing the fuel for fusion is **inertial confinement fusion** (ICF): a small pellet or capsule of deuterium and tritium (Fig. 42–16b) is struck simultaneously from hundreds of directions by very intense laser beams. The intense influx of energy heats and ionizes the pellet into a plasma, compressing it and heating it to temperatures at which fusion can occur $(> 10^8\,\text{K})$. The confinement time is on the order of $10^{-11}$ to $10^{-9}$ s, during which time the ions do not move appreciably because of their own inertia, and fusion can take place.

## 42–5 Passage of Radiation Through Matter; Biological Damage

When we speak of *radiation*, we include $\alpha$, $\beta$, $\gamma$, and X-rays, as well as protons, neutrons, and other particles such as pions (see Chapter 43). Because charged particles can ionize the atoms or molecules of any material they pass through, they are referred to as **ionizing radiation**. And because radiation produces ionization, it can cause considerable damage to materials, particularly to biological tissue.

Charged particles, such as $\alpha$ and $\beta$ rays and protons, cause ionization because of electric forces. That is, when they pass through a material, they can attract or repel electrons strongly enough to remove them from the atoms of the material. Since the $\alpha$ and $\beta$ rays emitted by radioactive substances have energies on the order of 1 MeV $(10^4$ to $10^7$ eV), whereas ionization of atoms and molecules requires on the order of 10 eV (Chapter 37), we see that a single $\alpha$ or $\beta$ particle can cause thousands of ionizations.

Neutral particles also give rise to ionization when they pass through materials. For example, X-ray and $\gamma$-ray photons can ionize atoms by knocking out electrons by means of the photoelectric and Compton effects (Chapter 37). Furthermore, if a $\gamma$ ray has sufficient energy (greater than 1.02 MeV), it can undergo pair production: an electron and a positron are produced (Section 37–5). The charged particles produced in all of these processes can themselves go on to produce further ionization. Neutrons, on the other hand, interact with matter mainly by collisions with nuclei, with which they interact strongly.

Often the nucleus is broken apart by such a collision, altering the molecule of which it was a part. The fragments produced can in turn cause ionization.

Radiation passing through matter can do considerable damage. Metals and other structural materials become brittle and their strength can be weakened if the radiation is very intense, as in nuclear reactor power plants and for space vehicles that must pass through areas of intense cosmic radiation.

### *Biological Damage

**PHYSICS APPLIED**
*Biological radiation damage*

The radiation damage produced in biological organisms is due primarily to ionization produced in cells. Several related processes can occur. Ions or radicals are produced that are highly reactive and take part in chemical reactions that interfere with the normal operation of the cell. All forms of radiation can ionize atoms by knocking out electrons. If these are bonding electrons, the molecule may break apart, or its structure may be altered so it does not perform its normal function or may perform a harmful function. In the case of proteins, the loss of one molecule is not serious if there are other copies of the protein in the cell and additional copies can be made from the gene that codes for it. However, large doses of radiation may damage so many molecules that new copies cannot be made quickly enough, and the cell dies.

Damage to the DNA is more serious, since a cell may have only one copy. Each alteration in the DNA can affect a gene and alter the molecule that gene codes for (Section 40–3), so that needed proteins or other molecules may not be made at all. Again the cell may die. The death of a single cell is not normally a problem, since the body can replace it with a new one. (There are exceptions, such as neurons, which are mostly not replaceable, so their loss is serious.) But if many cells die, the organism may not be able to recover. On the other hand, a cell may survive but be defective. It may go on dividing and produce many more defective cells, to the detriment of the whole organism. Thus radiation can cause cancer—the rapid uncontrolled production of cells.

The possible damage done by the medical use of X-rays and other radiation must be balanced against the medical benefits and prolongation of life as a result of their diagnostic use.

## 42–6 Measurement of Radiation—Dosimetry

Although the passage of ionizing radiation through the human body can cause considerable damage, radiation can also be used to treat certain diseases, particularly cancer, often by using very narrow beams directed at a cancerous tumor in order to destroy it (Section 42–7). It is therefore important to be able to quantify the amount, or **dose**, of radiation. This is the subject of **dosimetry**.

**PHYSICS APPLIED**
*Dosimetry*

The strength of a source can be specified at a given time by stating the **source activity**: how many nuclear decays (or disintegrations) occur per second. The traditional unit is the **curie** (Ci), defined as

$$1\ \text{Ci} = 3.70 \times 10^{10}\ \text{decays per second.}$$

(This number comes from the original definition as the activity of exactly one gram of radium.) Although the curie is still in common use, the SI unit for source activity is the **becquerel** (Bq), defined as

$$1\ \text{Bq} = 1\ \text{decay/s.}$$

**CAUTION**
*In the lab, activity will be less than written on the bottle—note the date*

Commercial suppliers of **radionuclides** (radioactive nuclides) used as tracers specify the activity at a given time. Because the activity decreases over time, more so for short-lived isotopes, it is important to take this decrease into account.

The magnitude of the source activity, $|dN/dt|$, is related to the number of radioactive nuclei present, $N$, and to the half-life, $T_{\frac{1}{2}}$, by (see Section 41–8):

$$\left|\frac{dN}{dt}\right| = \lambda N = \frac{0.693}{T_{\frac{1}{2}}} N.$$

PSE5_CH42_v1.6_23Jun-20

**EXAMPLE 42–11** **Radioactivity taken up by cells.** In a certain experiment, 0.016 $\mu$Ci of $^{32}_{15}$P is injected into a medium containing a culture of bacteria. After 1.0 h the cells are washed and a 70% efficient detector (counts 70% of emitted $\beta$ rays) records 720 counts per minute from the cells. What percentage of the original $^{32}_{15}$P was taken up by the cells?

**APPROACH** The half-life of $^{32}_{15}$P is about 14 days (Appendix F), so we can ignore any loss of activity over 1 hour. From the given activity, we find how many $\beta$ rays are emitted. We can compare 70% of this to the $(720/\text{min})/(60\,\text{s/min}) = 12$ per second detected.

**SOLUTION** The total number of decays per second originally was $(0.016 \times 10^{-6})(3.7 \times 10^{10}) = 590$. The counter could be expected to count 70% of this, or 410 per second. Since it counted $720/60 = 12$ per second, then $12/410 = 0.029$ or 2.9% was incorporated into the cells.

Another type of measurement is the exposure or **absorbed dose**—that is, the *effect* the radiation has on the absorbing material. The earliest unit of dosage was the **roentgen** (R), defined in terms of the amount of ionization produced by the radiation $(1\,\text{R} = 1.6 \times 10^{12}$ ion pairs per gram of dry air at standard conditions$)$. Today, 1 R is defined as the amount of X-ray or $\gamma$ radiation that deposits $0.878 \times 10^{-2}$ J of energy per kilogram of air. The roentgen was largely superseded by another unit of absorbed dose applicable to any type of radiation, the **rad**: *1 rad is that amount of radiation which deposits energy per unit mass of* $1.00 \times 10^{-2}$ *J/kg in any absorbing material.* (This is quite close to the roentgen for X- and $\gamma$ rays.) The proper SI unit for absorbed dose is the **gray** (Gy):

$$1\,\text{Gy} = 1\,\text{J/kg} = 100\,\text{rad}. \qquad \textbf{(42–10)}$$

The absorbed dose depends not only on the energy per particle and on the strength of a given source or of a radiation beam (number of particles per second), but also on the type of material that is absorbing the radiation. Bone, for example, absorbs more of X-ray or $\gamma$ radiation normally used than does flesh, so the same beam passing through a human body deposits a greater dose (in rads or grays) in bone than in flesh.

The gray and the rad are physical units of dose—the energy deposited per unit mass of material. They are, however, not the most meaningful units for measuring the biological damage produced by radiation because equal doses of different types of radiation cause differing amounts of damage. For example, 1 rad of $\alpha$ radiation does 10 to 20 times the amount of damage as 1 rad of $\beta$ or $\gamma$ rays. This difference arises largely because $\alpha$ rays (and other heavy particles such as protons and neutrons) move much more slowly than $\beta$ and $\gamma$ rays of equal energy due to their greater mass. Hence, ionizing collisions occur closer together, so more irreparable damage can be done. The **relative biological effectiveness** (RBE) of a given type of radiation is defined as the number of rads of X-ray or $\gamma$ radiation that produces the same biological damage as 1 rad of the given radiation. For example, 1 rad of slow neutrons does the same damage as 5 rads of X-rays. Table 42–1 gives the RBE for several types of radiation. The numbers are approximate because they depend somewhat on the energy of the particles and on the type of damage that is used as the criterion.

The **effective dose** can be given as the product of the dose in rads and the RBE, and this unit is known as the **rem** (which stands for *rad equivalent man*):

$$\text{effective dose (in rem)} = \text{dose (in rad)} \times \text{RBE}. \qquad \textbf{(42–11a)}$$

This unit is being replaced by the SI unit for "effective dose," the **sievert** (Sv):

$$\text{effective dose (Sv)} = \text{dose (Gy)} \times \text{RBE} \qquad \textbf{(42–11b)}$$

so

$$1\,\text{Sv} = 100\,\text{rem} \quad \text{or} \quad 1\,\text{rem} = 10\,\text{mSv}.$$

**TABLE 42–1 Relative Biological Effectiveness (RBE)**

| Type | RBE |
|---|---|
| X- and $\gamma$ rays | 1 |
| $\beta$ (electrons) | 1 |
| Protons | 2 |
| Slow neutrons | 5 |
| Fast neutrons | ≈10 |
| $\alpha$ particles and heavy ions | ≈20 |

By these definitions, 1 rem (or 1 Sv) of any type of radiation does approximately the same amount of biological damage. For example, 50 rem of fast neutrons does the same damage as 50 rem of $\gamma$ rays. But note that 50 rem of fast neutrons is only 5 rads, whereas 50 rem of $\gamma$ rays is 50 rads.

**EXERCISE F** Return to the second Chapter-Opening Question, page 1256, and answer it again now. Try to explain why you may have answered it differently the first time.

## Human Exposure to Radiation

**PHYSICS APPLIED**
*Radon*

We are constantly exposed to low-level radiation from natural sources: cosmic rays, natural radioactivity in rocks and soil, and naturally occurring radioactive isotopes in our food, such as $^{40}_{19}$K. **Radon**, $^{222}_{86}$Rn, is of considerable concern today. It is the product of radium decay and is an intermediate in the decay series from uranium (see Fig. 41–12). Most intermediates remain in the rocks where formed, but radon is a gas that can escape from rock (and from building material like concrete) to enter the air we breathe, and damage the interior of the lung.

**PHYSICS APPLIED**
*Human radiation exposure*

The **natural radioactive background** averages about 0.30 rem (300 mrem) per year per person in the U.S., although there are large variations. From medical X-rays and scans, the average person receives about 50 to 60 mrem per year, giving an average total dose of about 360 mrem (3.6 mSv) per person. U.S. government regulators suggest an upper limit of allowed radiation for an individual in the general populace at about 100 mrem (1 mSv) per year in addition to natural background. It is believed that even low doses of radiation increase the chances of cancer or genetic defects; there is *no safe level* or threshold of radiation exposure.

**PHYSICS APPLIED**
*Radiation worker exposure*
*Film badge*

The upper limit for people who work around radiation—in hospitals, in power plants, in research—has been set higher, a maximum of 20 mSv (2 rem) whole-body dose, averaged over some years (a maximum of 50 mSv (5 rem/yr) in any one year). To monitor exposure, those people who work around radiation generally carry some type of dosimeter, one common type being a **radiation film badge** which is a piece of film wrapped in light-tight material. The passage of ionizing radiation through the film changes it so that the film is darkened upon development, and thus indicates the received dose. Newer types include the *thermoluminescent dosimeter* (TLD). Dosimeters and badges do not protect the worker, but high levels detected suggest reassignment or modified work practices to reduce radiation exposure to acceptable levels.

**PHYSICS APPLIED**
*Radiation sickness*

Large doses of radiation can cause unpleasant symptoms such as nausea, fatigue, and loss of body hair, because of cellular damage. Such effects are sometimes referred to as **radiation sickness**. Very large doses can be fatal, although the time span of the dose is important. A brief dose of 10 Sv (1000 rem) is nearly always fatal. A 3-Sv (300-rem) dose in a short period of time is fatal in about 50% of patients within a month. However, the body possesses remarkable repair processes, so that a 3-Sv dose spread over several weeks is usually not fatal. It will, nonetheless, cause considerable damage to the body.

The effects of low doses over a long time are difficult to determine and are not well known as yet.

**CONCEPTUAL EXAMPLE 42–12** **Limiting the dose.** A worker in an environment with a radioactive source is warned that she is accumulating a dose too quickly and will have to lower her exposure by a factor of ten to continue working for the rest of the year. If the worker is able to work farther away from the source, how much farther away is necessary?

**RESPONSE** If the energy is radiated uniformly in all directions, then the intensity (dose/area) should decrease as the distance squared, just as it does for sound and light. If she can work four times farther away, the exposure lowers by a factor of sixteen, enough to make her safe.

PSE5_CH42_v1.6_23Jun-20

**EXAMPLE 42–13** **Whole-body dose.** What whole-body dose is received by a 70-kg laboratory worker exposed to a 40-mCi $^{60}_{27}$Co source, assuming the person's body has cross-sectional area 1.5 $m^2$ and is normally about 4.0 m from the source for 4.0 h per day? $^{60}_{27}$Co emits $\gamma$ rays of energy 1.33 MeV and 1.17 MeV in quick succession. Approximately 50% of the $\gamma$ rays interact in the body and deposit all their energy. (The rest pass through.)

**APPROACH** Of the given energy emitted, only a fraction passes through the worker, equal to *her* area divided by the total area (or $4\pi r^2$) over a full sphere of radius 4.0 m (Fig. 42–17).

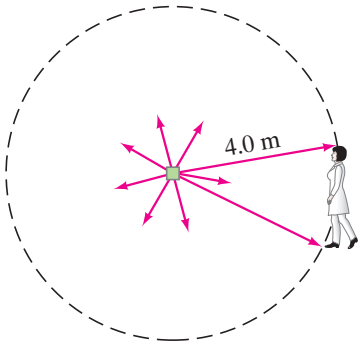

**FIGURE 42–17** Radiation spreads out in all directions. A person 4.0 m away intercepts only a fraction: her cross-sectional area divided by the area of a sphere of radius 4.0 m. Example 42–13.

**SOLUTION** The total $\gamma$-ray energy per decay is $(1.33 + 1.17)$ MeV $= 2.50$ MeV, so the total energy emitted by the source per second is

$$(0.040\ \text{Ci})\left(3.7 \times 10^{10}\ \text{decays/Ci} \cdot \text{s}\right)(2.50\ \text{MeV}) \;=\; 3.7 \times 10^{9}\ \text{MeV/s}.$$

The proportion of this energy intercepted by the body is its 1.5-$m^2$ area divided by the area of a sphere of radius 4.0 m (Fig. 42–17):

$$\frac{1.5\ \text{m}^2}{4\pi r^2} \;=\; \frac{1.5\ \text{m}^2}{4\pi\,(4.0\ \text{m})^2} \;=\; 7.5 \times 10^{-3}.$$

So the rate energy is deposited in the body (remembering that only 50% of the $\gamma$ rays interact in the body) is

$$E = \left(\tfrac{1}{2}\right)\left(7.5 \times 10^{-3}\right)\left(3.7 \times 10^{9}\ \text{MeV/s}\right)\left(1.6 \times 10^{-13}\ \text{J/MeV}\right) \;=\; 2.2 \times 10^{-6}\ \text{J/s}.$$

Since $1\ \text{Gy} = 1\ \text{J/kg}$, the whole-body dose rate for this 70-kg person is $\left(2.2 \times 10^{-6}\ \text{J/s}\right)/(70\ \text{kg}) = 3.1 \times 10^{-8}\ \text{Gy/s}$. In 4.0 h, this amounts to a dose of

$$(4.0\ \text{h})\,(3600\ \text{s/h})\left(3.1 \times 10^{-8}\ \text{Gy/s}\right) \;=\; 4.5 \times 10^{-4}\ \text{Gy}.$$

RBE $\approx 1$ for gammas, so the effective dose is 450 $\mu$Sv (Eqs. 42–11b and 42–10) or:

$$(100\ \text{rad/Gy})\left(4.5 \times 10^{-4}\ \text{Gy}\right)(1\ \text{rem/rad}) \;=\; 45\ \text{mrem} \;=\; 0.45\ \text{mSv}.$$

**NOTE** This 45-mrem effective dose is almost 50% of the normal allowed dose for a whole year $(100\ \text{mrem/yr})$, or 1% of the maximum one-year allowance for radiation workers. This worker should not receive such a large dose every day and should seek ways to reduce it (shield the source, vary the work, work farther from the source, work less time this close to source, etc.).

We have assumed that the intensity of radiation decreases as the square of the distance. It actually falls off faster than $1/r^2$ because of absorption in the air, so our answers are a slight overestimate of dose received.

PHYSICS APPLIED
*Radon exposure*

**EXAMPLE 42–14** **Radon exposure.** In the U.S., yearly deaths from radon exposure (the second leading cause of lung cancer) are estimated to be on the order of 20,000 and maybe much more. The Environmental Protection Agency recommends taking action to reduce the radon concentration in living areas if it exceeds 4 pCi/L of air. In some areas 50% of houses exceed this level from naturally occurring radon in the soil. Estimate (*a*) the number of decays/s in 1.0 $m^3$ of air and (*b*) the mass of radon that emits 4.0 pCi of $^{222}_{86}Rn$ radiation.

**APPROACH** We can use the definition of the curie to determine how many decays per second correspond to 4 pCi, then Eq. 41–7b to determine how many nuclei of radon it takes to have this activity $\left|dN/dt\right|$.

**SOLUTION** (*a*) We saw at the start of this Section that $1\text{ Ci} = 3.70 \times 10^{10}$ decays/s. Thus

$$\left|\frac{dN}{dt}\right| = 4.0\text{ pCi} = (4.0 \times 10^{-12}\text{ Ci})(3.70 \times 10^{10}\text{ decays/s/Ci})$$
$$= 0.148\text{ s}^{-1}$$

per liter of air. In $1\text{ m}^3$ of air $(1\text{ m}^3 = 10^6\text{ cm}^3 = 10^3\text{ L})$ there would be $(0.148\text{ s}^{-1})(1000) \approx 150$ decays/s.

(*b*) From Eqs. 41–7a and 41–8

$$\frac{dN}{dt} = \lambda N = \frac{0.693}{T_{\frac{1}{2}}} N.$$

Appendix G tells us $T_{\frac{1}{2}} = 3.8235$ days for radon, so

$$N = \left|\frac{dN}{dt}\right| \frac{T_{\frac{1}{2}}}{0.693}$$
$$= (0.148\text{ s}^{-1}) \frac{(3.8235\text{ days})(8.64 \times 10^4\text{ s/day})}{0.693}$$
$$= 7.06 \times 10^4\text{ atoms of radon-222.}$$

The molar mass (222 u) and Avogadro's number are used to find the mass:

$$m = \frac{(7.06 \times 10^4\text{ atoms})(222\text{ g/mol})}{6.02 \times 10^{23}\text{ atoms/mol}} = 2.6 \times 10^{-17}\text{ g}$$

or 26 attograms in 1 L of air at the limit of 4 pCi/L. This $2.6 \times 10^{-17}$ g/L is $2.6 \times 10^{-14}$ grams of radon per $m^3$ of air.

**NOTE** Each radon atom emits 4 $\alpha$ particles and 4 $\beta$ particles, each one capable of causing many harmful ionizations, before the sequence of decays reaches a stable element.

PHYSICS APPLIED
*Radiation therapy*

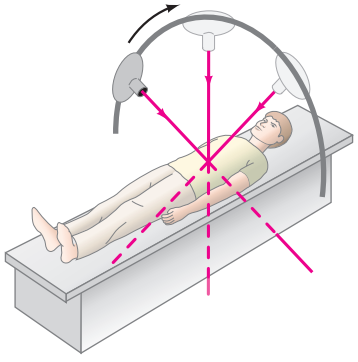

**FIGURE 42–18** Radiation source rotates so that the beam always passes through the diseased tissue, but minimizes the dose in the rest of the body.

## *42–7 Radiation Therapy

The medical application of radioactivity and radiation to human beings involves two basic aspects: (1) **radiation therapy**—the treatment of disease (mainly cancer)—which we discuss in this Section; and (2) the *diagnosis* of disease, which we discuss in the following Sections of this Chapter.

Radiation can cause cancer. It can also be used to treat it. Rapidly growing cancer cells are especially susceptible to destruction by radiation. Nonetheless, large doses are needed to kill the cancer cells, and some of the surrounding normal cells are inevitably killed as well. It is for this reason that cancer patients receiving radiation therapy often suffer side effects characteristic of radiation sickness. To minimize the destruction of normal cells, a narrow beam of $\gamma$ or X-rays is often used when a cancerous tumor is well localized. The beam is directed at the tumor, and the source (or body) is rotated so that the beam passes through various parts of the body to keep the dose at any one place as low as possible—except at the tumor and its immediate surroundings, where the beam passes at all times (Fig. 42–18).

The radiation may be from a radioactive source such as $^{60}_{27}$Co, or it may be from an X-ray machine that produces photons in the range 200 keV to 5 MeV. Protons, neutrons, electrons, and pions, which are produced in particle accelerators (Section 43–1), are also being used in cancer therapy.

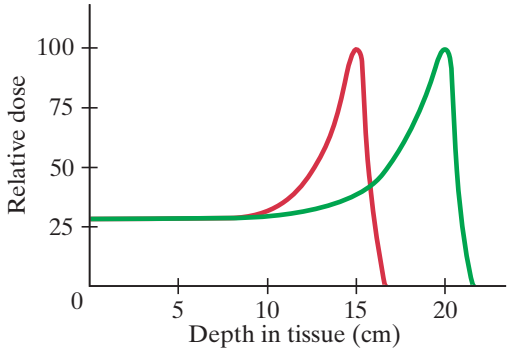

**FIGURE 42–19** Energy deposited in tissue as a function of depth for 170-MeV protons (red curve) and 190-MeV protons (green). The peak of each curve is often called the Bragg peak.

Protons used to kill tumors have a special property that makes them particularly useful. As shown in Fig. 42–19, when protons enter tissue, most of their energy is deposited at the end of their path. The protons' initial kinetic energy can be chosen so that most of the energy is deposited at the depth of the tumor itself, to destroy it. The incoming protons deposit only a small amount of energy in the tissue in front of the tumor, and none at all behind the tumor, thus having less negative effect on healthy tissue than X- or $\gamma$ rays. Because tumors have physical size, even several centimeters in diameter, a range of proton energies is often used. Heavier ions, such as $\alpha$ particles or carbon ions, are similarly useful. This **proton therapy** technique is more than a half century old, but the necessity of having a large accelerator has meant that few hospitals have used the technique until now.

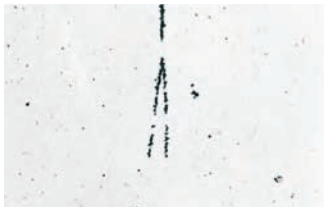
**PHYSICS APPLIED**
*Proton therapy*

Another form of treatment is to insert a tiny radioactive source directly inside a tumor, which will eventually kill the majority of the cells. A similar technique is used to treat cancer of the thyroid with the radioactive isotope $^{131}_{53}$I. The thyroid gland concentrates iodine present in the bloodstream, particularly in any area where abnormal growth is taking place. Its intense radioactivity can destroy the defective cells.

Another application of radiation is for sterilizing bandages, surgical equipment, and even packaged foods such as ground beef, chicken, and produce, because bacteria and viruses can be killed or deactivated by large doses of radiation.

## *42–8 Tracers in Research and Medicine

Radioactive isotopes are used in biological and medical research as **tracers**. A given compound is artificially synthesized incorporating a radioactive isotope such as $^{14}_{6}$C or $^{3}_{1}$H. Such "tagged" molecules can then be traced as they move through an organism or as they undergo chemical reactions. The presence of these tagged molecules (or parts of them, if they undergo chemical change) can be detected by a Geiger or scintillation counter, which detects emitted radiation (see Section 41–11). How food molecules are digested, and to what parts of the body they are diverted, can be traced in this way.



Radioactive tracers have been used to determine how amino acids and other essential compounds are synthesized by organisms. The permeability of cell walls to various molecules and ions can be determined using radioactive tracers: the tagged molecule or ion is injected into the extracellular fluid, and the radioactivity present inside and outside the cells is measured as a function of time.

In a technique known as **autoradiography**, the position of the radioactive isotopes is detected on film. For example, the distribution of carbohydrates produced in the leaves of plants from absorbed $CO_2$ can be observed by keeping the plant in an atmosphere where the carbon atom in the $CO_2$ is $^{14}_{6}$C. After a time, a leaf is placed firmly on a photographic plate and the emitted radiation darkens the film most strongly where the isotope is most strongly concentrated (Fig. 42–20a).

**FIGURE 42–20** (a) Autoradiograph of a leaf exposed for 30 s to $^{14}CO_2$. Only the tissue where the $CO_2$ has been taken up, to be used in photosynthesis (Example 37–7), has become radioactive. The non-metabolizing tissue of the veins is free of $^{14}_{6}$C and does not blacken the X-ray sheet. (b) Autoradiograph of chromosomal DNA. The dashed arrays of film grains show the Y-shaped growing point of replicating DNA.

(a)

(b)

Autoradiography using labeled nucleotides (components of DNA) has revealed much about the details of DNA replication (Fig. 42–20b). Today gamma cameras are used in a similar way.

**PHYSICS APPLIED**
*Medical diagnosis*

For medical diagnosis, the radionuclide commonly used today is $^{99m}_{43}$Tc, a long-lived excited state of technetium-99 (the "m" in the symbol stands for "metastable" state). It is formed when $^{99}_{42}$Mo decays. The great usefulness of $^{99m}_{43}$Tc derives from its convenient half-life of 6 h (short, but not too short) and the fact that it can combine with a large variety of compounds. The compound to be labeled with the radionuclide is so chosen because it concentrates in the organ or region of the anatomy to be studied. Detectors outside the body then record, or image, the distribution of the radioactively labeled compound. The detection could be done by a single detector (Fig. 42–21a) which is moved across the body, measuring the intensity of radioactivity at a large number of points. The image represents the relative intensity of radioactivity at each point. The relative radioactivity is a diagnostic tool. For example, high or low radioactivity may represent overactivity or underactivity of an organ or part of an organ, or in another case may represent a lesion or tumor. More complex **gamma cameras** make use of many detectors which simultaneously record the radioactivity at many points. The measured intensities can be displayed on a TV or computer monitor. The image is sometimes called a scintigram (after scintillator), Fig. 42–21b. Gamma cameras are relatively inexpensive, but their resolution is limited—by non-perfect collimation.[†] Yet they allow "dynamic" studies: images that change in time, like a movie.

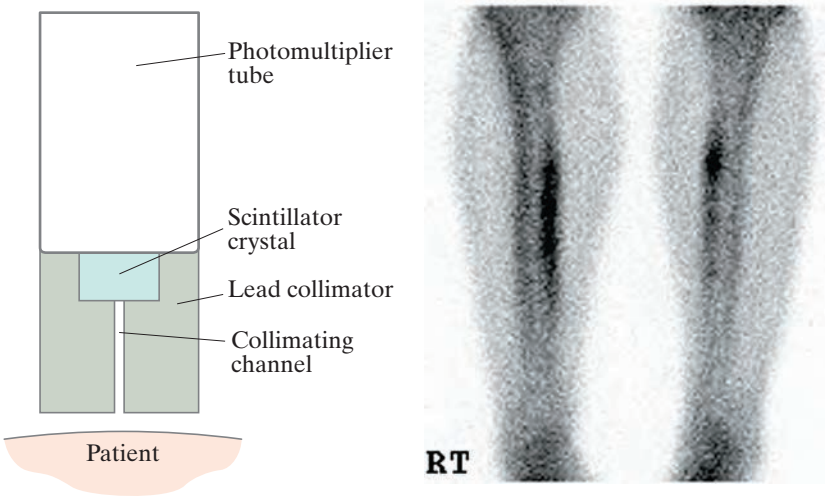


**FIGURE 42–21** (a) Collimated gamma-ray detector for scanning (moving) over a patient. The collimator selects $\gamma$ rays that come in a (nearly) straight line from the patient. Without the collimator, $\gamma$ rays from all parts of the body could strike the scintillator, producing a poor image. Detectors today usually have many collimator tubes and are called *gamma cameras*. (b) Gamma camera image (scintigram), of both legs of a patient with shin splints, detecting $\gamma$s from $^{99m}_{43}$Tc.

## *42–9 Emission Tomography: PET and SPECT

**PHYSICS APPLIED**
*Medical imaging*

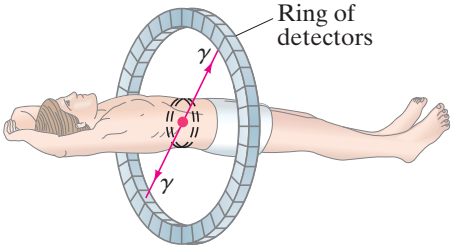
The images formed using the standard techniques of nuclear medicine, as briefly discussed in the previous Section, are produced from radioactive tracer sources within the *volume* of the body. It is also possible to image the radioactive emissions from a single plane or slice through the body using the computed tomography techniques discussed in Section 35–11. A gamma camera measures the radioactive intensity from the tracer at many points and angles around the patient. The data are processed in much the same way as for X-ray CT scans (Section 35–11).

**PHYSICS APPLIED**
*Emission tomography (SPECT, PET)*

This technique is referred to as **single photon emission computed tomography** (SPECT), or simply SPET (single photon emission tomography).

[†]To "collimate" means to "make parallel," usually by blocking non-parallel rays with a narrow tube inside lead, as in Fig. 42–21a.

Another important technique is **positron emission tomography** (PET), which makes use of positron emitters such as $^{11}_{6}\text{C}$, $^{13}_{7}\text{N}$, $^{15}_{8}\text{O}$, and $^{18}_{9}\text{F}$ whose half-lives are short. These isotopes are incorporated into molecules that, when inhaled or injected, accumulate in the organ or region of the body to be studied. When such a nuclide undergoes $\beta^+$ decays, the emitted positron travels at most a few millimeters before it collides with a normal electron. In this collision, the positron and electron are annihilated, producing two $\gamma$ rays $(e^+ + e^- \rightarrow 2\gamma)$, each having an energy of 511 keV $(= m_e c^2)$. The two $\gamma$ rays fly off in opposite directions $(180° \pm 0.25°)$ since they must have almost exactly equal and opposite momenta to conserve momentum (the momenta of the initial $e^+$ and $e^-$ are essentially zero compared to the momenta afterward of the $\gamma$ rays). Because the photons travel along the same line in opposite directions, their detection in coincidence by rings of detectors surrounding the patient (Fig. 42–22) readily establishes the line along which the emission took place. If the difference in time of arrival of the two photons could be determined accurately, the actual position of the emitting nuclide along that line could be calculated. Present-day electronics can measure times to at best $\pm 300$ ps, so at the $\gamma$ ray's speed $(c = 3 \times 10^8 \text{ m/s})$, the actual position could be determined to an accuracy on the order of about $d = vt \approx (3 \times 10^8 \text{ m/s})(300 \times 10^{-12} \text{ s}) \approx 10 \text{ cm}$, which is not very useful. Although there may be future potential for *time-of-flight* measurements to determine position, today computed tomography techniques are used instead, similar to those for X-ray CT, which can reconstruct PET images with a resolution on the order of 2–5 mm. One big advantage of PET is that no collimators are needed (as for detection of a single photon—see Fig. 42–21a). Thus, fewer photons are "wasted" and lower doses can be administered to the patient with PET.



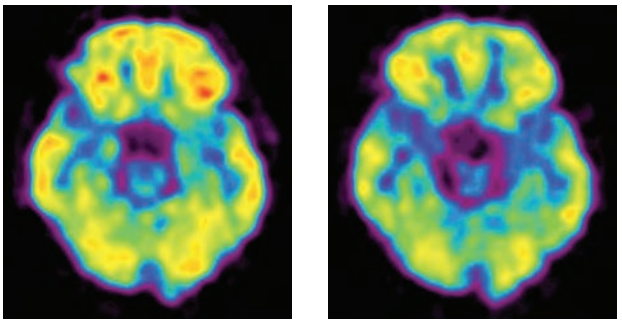


**FIGURE 42–22** Positron emission tomography (PET) system showing a ring of detectors to detect the two annihilation $\gamma$ rays $(e^+ + e^- \rightarrow 2\gamma)$ emitted at 180° to each other.

Both PET and SPECT systems can give images related to biochemistry, metabolism, and function. This is to be compared to X-ray CT scans, whose images reflect shape and structure—that is, the anatomy of the imaged region.

Figure 42–23 shows PET scans of the same person's brain (a) when using a cell phone near the ear and (b) with the cell phone off. The bright red spots in (a) indicate a higher rate of glucose metabolism, suggesting excitability of brain tissue (the glucose was tagged with a radioactive tracer). Emfs from the cell phone antenna thus seem to affect metabolism and may be harmful to us!

The colors shown here are faked (only visible light has colors). The original images are various shades of gray, representing intensity (or counts).

(a) (b)

**FIGURE 42–23** False-color PET scans of a horizontal section through a brain showing glucose metabolism rates (red is high) by a person (a) using a cell phone near the ear, and (b) with the cell phone off.

## *42–10 Nuclear Magnetic Resonance (NMR); Magnetic Resonance Imaging (MRI)

*Nuclear magnetic resonance* (NMR) is a phenomenon which soon after its discovery in 1946 became a powerful research tool in a variety of fields from physics to chemistry and biochemistry. It is also an important medical imaging technique. We first briefly discuss the phenomenon, and then look at its applications.

## *Nuclear Magnetic Resonance (NMR)

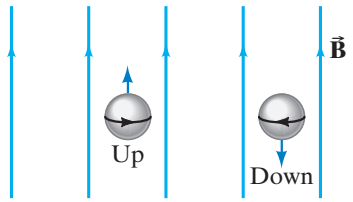
We saw in Chapter 39 (Section 39–2) that when atoms are placed in a magnetic field $B$, atomic energy levels are split into several closely spaced levels (the Zeeman effect) according to the angular momentum or spin of the state. The splitting is proportional to $B$ and to the magnetic moment, $\mu$. Nuclei too have magnetic moments (Section 41–1), and we examine mainly the simplest nucleus, hydrogen $\left({}^{1}_{1}\mathrm{H}\right)$ because it is the one most used, even for medical imaging. The ${}^{1}_{1}\mathrm{H}$ nucleus consists of a single proton. Its spin angular momentum (and its magnetic moment), like that of the electron, can take on only two values when placed in a magnetic field: we call these "spin up" (parallel to the field) and "spin down" (antiparallel to the field) as suggested in Fig. 42–24. When a magnetic field is present, an energy state of a nucleus splits into two levels as shown in Fig. 42–25, with the spin-up state (parallel to field) having the lower energy. The spin-down state acquires an additional energy $\mu_p B_T$ and the spin-up state has its energy changed by $-\mu_p B_T$ (see Eq. 27–12, Example 27–12, and Section 39–7), where $B_T$ is the total magnetic field *at the nucleus*. The difference in energy between the two states (Fig. 42–25) is thus

$$\Delta E = 2\mu_p B_T,$$

where $\mu_p$ is the magnetic moment of the proton. For materials other than hydrogen, the splitting is still proportional to $B_T$:

$$\Delta E = kB_T$$

where $k$ is a constant that is different for different nuclides.



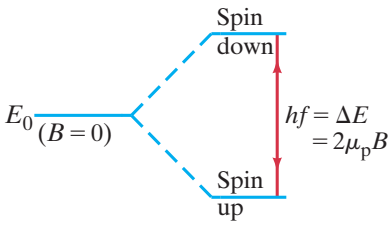


**FIGURE 42–24** Schematic picture of a proton in a magnetic field $\vec{\mathbf{B}}$ (pointing upward) with the two possible states of proton spin, up and down.

**FIGURE 42–25** Energy $E_0$ in the absence of a magnetic field splits into two levels in the presence of a magnetic field. The vertical red line with arrowheads represents transitions between the two states.

In a standard **nuclear magnetic resonance** (NMR) setup, the sample to be examined is placed in a static magnetic field. A radiofrequency (RF) pulse of electromagnetic radiation (that is, photons) is applied to the sample. If the frequency, $f$, of this pulse corresponds precisely to the energy difference between the two energy levels (Fig. 42–25), so that

$$hf = \Delta E = 2\mu_p B_T, \qquad \textbf{(42–12)}$$

then the photons of the RF beam will be absorbed, exciting many of the nuclei from the lower state to the upper state. This is a resonance phenomenon because there is significant absorption only if $f$ is very near $f = 2\mu_p B_T/h$. Hence the name "nuclear magnetic resonance." For free ${}^{1}_{1}\mathrm{H}$ nuclei, the frequency is 42.58 MHz for a field $B_T = 1.0\,\mathrm{T}$ (Example 42–15). If the H atoms are bound in a molecule, the total magnetic field $B_T$ at the H nuclei will be the sum of the external applied field $(B_{ext})$ plus the local magnetic field $(B_{local})$ due to electrons and nuclei of neighboring atoms. Since $f$ is proportional to $B_T$, the value of $f$ for a given external field will be slightly different for bound H atoms than for free atoms:

$$hf = 2\mu_p(B_{ext} + B_{local}).$$

This small change in frequency can be measured, and is called the "chemical shift." A great deal has been learned about the structure of molecules and bonds using this NMR technique.

**EXAMPLE 42–15** **NMR for free protons.** Calculate the resonant frequency for free protons in a 1.000-T magnetic field.

**APPROACH** We use Eq. 42–12, where the magnetic moment of the proton (Section 41–1) is

$$\mu_p = 2.7928\mu_N = 2.7928\left(\frac{e\hbar}{2m_p}\right) = 2.7928\left(\frac{eh}{4\pi m_p}\right).$$

**SOLUTION** We solve for $f$ in Eq. 42–12 and find

$$f = \frac{\Delta E}{h} = \frac{2\mu_p B}{h}$$

$$= (2.7928)\left(\frac{eB}{2\pi m_p}\right) = 2.7928\left[\frac{(1.6022\times10^{-19}\,\mathrm{C})(1.000\,\mathrm{T})}{2\pi(1.6726\times10^{-27}\,\mathrm{kg})}\right]$$

$$= 42.58\,\mathrm{MHz}.$$

## *Magnetic Resonance Imaging (MRI)

PHYSICS APPLIED
*NMR imaging (MRI)*

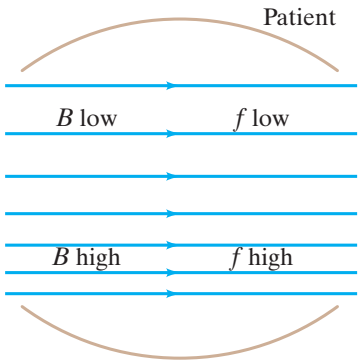
For producing medically useful NMR images—now commonly called MRI, or **magnetic resonance imaging**—the element most used is hydrogen since it is the commonest element in the human body and gives the strongest NMR signals. The experimental apparatus is shown in Fig. 42–26. The large coils set up the static magnetic field, and the RF coils produce the RF pulse of electromagnetic waves (photons) that cause the nuclei to jump from the lower state to the upper one (Fig. 42–24). These same coils (or another coil) can detect the absorption of energy or the emitted radiation (also of frequency $f = \Delta E/h$) when the nuclei jump back down to the lower state.

**FIGURE 42–26** Typical MRI imaging setup: (a) diagram; (b) photograph; (c) xxxx.

The formation of a two-dimensional or three-dimensional image can be done using techniques similar to those for computed tomography (Section 35–11). The simplest thing to measure for creating an image is the intensity of absorbed and/or reemitted radiation from many different points of the body, and this would be a measure of the density of H atoms at each point. But how do we determine from what part of the body a given photon comes? One technique is to give the static magnetic field a gradient; that is, instead of applying a uniform magnetic field, $B_T$, the field is made to vary with position across the width of the sample (or patient), Fig. 42–27. Because the frequency absorbed by the H nuclei is proportional to $B_T$ (Eq. 42–12), only one plane within the body will have the proper value of $B_T$ to absorb photons of a particular frequency $f$. By varying $f$, absorption by different planes can be measured. Alternately, if the field gradient is applied *after* the RF pulse, the frequency of the emitted photons will be a measure of where they were emitted. If a magnetic field gradient in one direction is applied during excitation (absorption of photons) and photons of a single frequency are transmitted, only H nuclei in one thin slice will be excited. By applying a gradient during reemission in a direction perpendicular to the first, the frequency $f$ of the reemitted radiation will represent depth in that slice. Other ways of varying the magnetic field throughout the volume of the body can be used in order to correlate NMR frequency with position.

A reconstructed image based on the density of H atoms (that is, the intensity of absorbed or emitted radiation) is not very interesting. More useful are images based on the rate at which the nuclei decay back to the ground state, and such images can produce resolution of 1 mm or better. This NMR technique (sometimes called **spin-echo**) produces images of great diagnostic value, both in the delineation of structure (anatomy) and in the study of metabolic processes. An NMR image is shown in Fig. 42–28, color enhanced—no medical imaging uses visible light, so the colors shown are added. The original images, those looked at by your doctor, are various shades of gray, representing intensity (or counts).

**FIGURE 42–27** A static field that is stronger at the bottom than at the top. The frequency of absorbed or emitted radiation is proportional to $B$ in NMR.



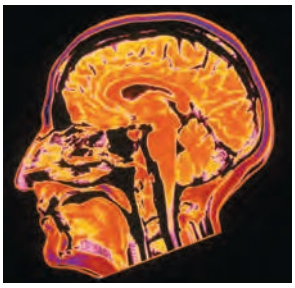


**FIGURE 42–28** False-color NMR image (MRI) through the head showing structures in the brain.

NMR imaging is considered to be noninvasive. We can calculate the energy of the photons involved: as shown in Example 42–15, in a 1.0-T magnetic field, $f = 42.58\,\text{MHz}$ for $^1_1\text{H}$. This corresponds to an energy of $hf = (6.6 \times 10^{-34}\,\text{J}\cdot\text{s})(43 \times 10^6\,\text{Hz}) \approx 3 \times 10^{-26}\,\text{J}$ or about $10^{-7}\,\text{eV}$. Since molecular bonds are on the order of 1 eV, the RF photons can cause little cellular disruption. This should be compared to X- or $\gamma$ rays, whose energies are $10^4$ to $10^6\,\text{eV}$ and thus can cause significant damage. The static magnetic fields, though often large (typically about 2.0 T), are believed to be harmless (except for people who wear heart pacemakers).

Table 42–2 lists the major techniques we have discussed for imaging the interior of the human body, along with the optimum resolution attainable today. Resolution is only one factor that must be considered, because the different imaging techniques provide different types of information that are useful for different types of diagnosis.

**TABLE 42–2 Medical Imaging Techniques**

| Technique | Where Discussed in This Book | Optimal Resolution |
|---|---|---|
| Conventional X-ray | Section 35–11 | $\frac{1}{2}$ mm |
| CT scan, X-ray | Section 35–11 | 0.2 mm |
| Nuclear medicine (tracers) | Section 42–8 | 1 cm |
| SPECT (single photon emission) | Section 42–9 | 1 cm |
| PET (positron emission) | Section 42–9 | 2–5 mm |
| MRI (NMR) | Section 42–10 | $\frac{1}{2}$–1 mm |
| Ultrasound | Section 16–9 | 0.3–2 mm |

# Summary

A **nuclear reaction** occurs when two nuclei collide and two or more other nuclei (or particles) are produced. In this process, as in radioactivity, **transmutation** (change) of elements occurs.

The **reaction energy** or ***Q*-value** of a reaction $a + X \rightarrow Y + b$ is

$$Q = (M_a + M_X - M_b - M_Y)c^2 \qquad \textbf{(42–2a)}$$

$$= K_b + K_Y - K_a - K_X. \qquad \textbf{(42–2b)}$$

The effective **cross section** $\sigma$ for a reaction is a measure of the reaction probability per target nucleus.

In **fission**, a heavy nucleus such as uranium splits into two intermediate-sized nuclei after being struck by a neutron. $^{235}_{92}\text{U}$ is fissionable by slow neutrons, whereas some fissionable nuclei require fast neutrons. Much energy is released in fission ($\approx 200\,\text{MeV}$ per fission) because the binding energy per nucleon is lower for heavy nuclei than it is for intermediate-sized nuclei, so the mass of a heavy nucleus is greater than the total mass of its fission products. The fission process releases neutrons, so that a **chain reaction** is possible. The **critical mass** is the minimum mass of fuel needed so that enough emitted neutrons go on to produce more fissions and sustain a chain reaction. In a **nuclear reactor** or nuclear weapon, a **moderator** is used to slow down the released neutrons.

The **fusion** process, in which small nuclei combine to form larger ones, also releases energy. The energy from our Sun originates in the fusion reactions known as the **proton–proton chain** in which four protons fuse to form a $^4_2\text{He}$ nucleus producing 25 MeV of energy. A useful fusion reactor for power generation has not yet proved possible because of the difficulty in containing the fuel (e.g., deuterium) long enough at the extremely high temperature required ($\approx 10^8\,\text{K}$). Nonetheless, progress has been made in confining the collection of charged ions known as a **plasma**. The two main methods are **magnetic confinement**, using a magnetic field in a device such as the donut-shaped **tokamak**, and **inertial confinement** in which intense laser beams compress a fuel pellet of deuterium and tritium.

Radiation can cause damage to materials, including biological tissue. Quantifying amounts of radiation is the subject of **dosimetry**. The **curie** (Ci) and the **becquerel** (Bq) are units that measure the **source activity** or rate of decay of a sample: $1\,\text{Ci} = 3.70 \times 10^{10}$ decays per second, whereas 1 Bq = 1 decay/s. The **absorbed dose**, often specified in **rads**, measures the amount of energy deposited per unit mass of absorbing material: 1 rad is the amount of radiation that deposits energy at the rate of $10^{-2}\,\text{J/kg}$ of material. The SI unit of absorbed dose is the **gray**: 1 Gy = 1 J/kg = 100 rad. The **effective dose** is often specified by the **rem** = rad × RBE, where RBE is the "relative biological effectiveness" of a given type of radiation; 1 rem of any type of radiation does approximately the same amount of biological damage. The average dose received per person per year in the United States is about 360 mrem. The SI unit for effective dose is the **sievert**: 1 Sv = 100 rem.

[*Nuclear radiation is used in medicine for cancer therapy, and for imaging of biological structure and processes. Tomographic imaging of the human body, which can provide 3-dimensional detail, includes several types: PET, SPET (= SPECT), MRI, and CT scans (discussed in Chapter 35). MRI makes use of **nuclear magnetic resonance** (NMR).]

PSE5_CH42_v1.6_23Jun-20

# Questions

**1.** Fill in the missing particles or nuclei:
($a$) $n + {}^{232}_{90}Th \rightarrow ? + \gamma$;
($b$) $n + {}^{137}_{56}Ba \rightarrow {}^{137}_{55}Cs + ?$;
($c$) $d + {}^{2}_{1}H \rightarrow {}^{4}_{2}He + ?$;
($d$) $d + {}^{2}_{1}H \rightarrow {}^{4}_{2}He + ?$;
where d stands for deuterium.

**2.** When ${}^{22}_{11}Na$ is bombarded by deuterons $\left({}^{2}_{1}H\right)$, an $\alpha$ particle is emitted. What is the resulting nuclide? Write down the reaction equation.

**3.** The isotope ${}^{32}_{15}P$ is produced by the reaction: $n + ? \rightarrow {}^{32}_{15}P + p$. What must be the target nucleus?

**4.** What is the $Q$-value for radioactive decay reactions?
($a$) $Q < 0$. ($b$) $Q > 0$. ($c$) $Q = 0$.
($d$) The sign of $Q$ depends on the nucleus.

**5.** Why are neutrons such good projectiles for producing nuclear reactions?

**6.** The energy from nuclear fission appears in the form of thermal energy—but the thermal energy of what?

**7.** ($a$) If ${}^{235}_{92}U$ released only 1.5 neutrons per fission on average (instead of 2.5), would a chain reaction be possible? ($b$) If so, how would the chain reaction be different than if 3 neutrons were released per fission?

**8.** Why can't uranium be enriched by chemical means?

**9.** How can a neutron, with practically no kinetic energy, excite a nucleus to the extent shown in Fig. 42–4?

**10.** A reactor that uses highly enriched uranium can use ordinary water (instead of heavy water) as a moderator and still have a self-sustaining chain reaction. Explain.

**11.** Why would a porous block of uranium be more likely to explode if kept under water rather than in air?

**12.** Why are neutrons released in a fission reaction?

**13.** What is the reason for the "secondary system" in a nuclear reactor, Fig. 42–9? That is, why is the water heated by the fuel in a nuclear reactor not used directly to drive the turbines?

**14.** Why must the fission process release neutrons if it is to be useful?

**15.** ${}^{238}_{92}U$ releases an average of 2.5 neutrons per fission compared to 2.9 for ${}^{239}_{94}Pu$. Which of these two nuclei do you think would have the smaller critical mass? Explain.

**16.** What is the basic difference between fission and fusion?

**17.** Why do gamma particles penetrate matter more easily than beta particles do?

**18.** Light energy emitted by the Sun and stars comes from the fusion process. What conditions in the interior of stars make this possible?

**19.** A higher temperature is required for deuterium–deuterium ignition than for deuterium–tritium. Explain.

**20.** How do stars, and our Sun, maintain confinement of the plasma for fusion?

**21.** People who work around metals that emit alpha particles are trained that there is little danger from proximity or touching the material, but they must take extreme precautions against ingesting it. Why? (Eating and drinking while working are forbidden.)

***22.** How might radioactive tracers be used to find a leak in a pipe?

**23.** Radiation is sometimes used to sterilize medical supplies and even food. Explain how it works.

**24.** What is the difference between absorbed dose and effective dose? What are the SI units for each?

**25.** What keeps the Sun and stars together, allowing them to sustain fusion?

**26.** State three problems that must be overcome to make a functioning fission nuclear reactor.

**27.** Why can small nuclei combine to form larger ones, releasing energy in the process?

**28.** ($a$) State three environmental problems or dangers that do or could result from the operation of a nuclear fission reactor; ($b$) describe an additional problem or danger associated with a breeder reactor.

**29.** Why does the first reaction in the proton–proton chain limit the rate at which the Sun produces energy?

**30.** What are the heaviest elements for which energy is released if the elements are created by fusion of lighter elements?

***31.** Explain how each of the following can cause damage to materials: beta particles, alpha particles, energetic neutrons, and gamma rays.

# MisConceptual Questions

**1.** In a nuclear reaction, which of the following is *not* conserved?
($a$) Energy.
($b$) Momentum.
($c$) Electric charge.
($d$) Nucleon number.
($e$) None of the above.

**2.** Fission fragments are typically
($a$) $\beta^+$ emitters.
($b$) $\beta^-$ emitters.
($c$) Both.
($d$) Neither.

**3.** Which of the following properties would decrease the critical mass needed to sustain a nuclear chain reaction?
($a$) Low boiling point.
($b$) High melting point.
($c$) More neutrons released per fission.
($d$) Low nuclear density.
($e$) Filled valence shell.
($f$) All of the above.

**4.** Rather than having a maximum at about $A \approx 60$, as shown in Fig. 42–13, suppose the average binding energy per nucleon continually increased with increasing mass number. Then,
($a$) fission would still be possible, but not fusion.
($b$) fusion would still be possible, but not fission.
($c$) both fission and fusion would still be possible.
($d$) neither fission nor fusion would be possible.

**5.** Why is a moderator needed in a normal uranium fission reactor?
($a$) To increase the rate of neutron capture by uranium-235.
($b$) To increase the rate of neutron capture by uranium-238.
($c$) To increase the rate of production of plutonium-239.
($d$) To increase the critical mass of the fission fuel.
($e$) To provide more neutrons for the reaction.
($f$) All of the above.

6. For neutrons to induce nuclear fusion
(*a*) neutrons must be moving fast to provide energy to the reaction.
(*b*) neutrons must be moving slow to be captured by the nucleus.
(*c*) the speed of neutrons is irrelevant.

7. A primary difficulty in energy production by fusion is
(*a*) the scarcity of necessary fuel.
(*b*) the disposal of radioactive by-products produced.
(*c*) the high temperatures necessary to overcome the electrical repulsion of protons.
(*d*) the fact that it is possible in volcanic regions only.

8. If two hydrogen nuclei, ${}^{2}_{1}\text{H}$, each of mass $m_{\text{H}}$, fuse together and form a helium nucleus of mass $m_{\text{He}}$,
(*a*) $m_{\text{He}} < 2m_{\text{H}}$.
(*b*) $m_{\text{He}} = 2m_{\text{H}}$.
(*c*) $m_{\text{He}} > 2m_{\text{H}}$.
(*d*) All of the above are possible.

9. Which radiation induces the most biological damage for a given amount of energy deposited in tissue?
(*a*) Alpha particles.
(*b*) Gamma radiation.
(*c*) Beta radiation.
(*d*) All do the same damage for the same deposited energy.

10. Which would produce the most energy in a single reaction?
(*a*) The fission reaction associated with uranium-235.
(*b*) The fusion reaction of the Sun (two hydrogen nuclei fused to one helium nucleus).
(*c*) Both (*a*) and (*b*) are about the same.
(*d*) Need more information.

11. The fuel necessary for fusion-produced energy could be derived from
(*a*) water.
(*b*) superconductors.
(*c*) uranium.
(*d*) helium.
(*e*) sunlight.

12. Which of the following is true?
(*a*) Any amount of radiation is harmful to living tissue.
(*b*) Radiation is a natural part of the environment.
(*c*) Radiation can be used for imaging.
(*d*) All of the above are true.

13. Which of the following would reduce the cell damage due to radiation for a lab technician who works with radioactive isotopes in a hospital or lab?
(*a*) Increase the worker's distance from the radiation source.
(*b*) Decrease the time the worker is exposed to the radiation.
(*c*) Use shielding to reduce the amount of radiation that strikes the worker.
(*d*) Have the worker wear a radiation badge when working with the radioactive isotopes.
(*e*) All of the above except (*d*).
(*f*) All of the above.

14. If the same dose in rads of each type of radiation was provided over the same amount of time, which type would be most harmful?
(*a*) X-rays.
(*b*) $\gamma$ rays.
(*c*) $\beta$ rays.
(*d*) $\alpha$ particles.

15. ${}^{235}_{92}\text{U}$ releases an average of 2.5 neutrons per fission compared to 2.9 for ${}^{239}_{94}\text{Pu}$. Which has the smaller critical mass?
(*a*) ${}^{235}_{92}\text{U}$.
(*b*) ${}^{239}_{94}\text{Pu}$.
(*c*) Both the same.

# Problems

(NOTE: Masses are found in Appendix G.)

## 42–1 Nuclear Reactions, Transmutation

1. (I) Natural aluminum is all ${}^{27}_{13}\text{Al}$. If it absorbs a neutron, what does it become? Does it decay by $\beta^+$ or $\beta^-$? What will be the product nucleus?

2. (I) Determine whether the reaction ${}^{2}_{1}\text{H} + {}^{2}_{1}\text{H} \rightarrow {}^{3}_{2}\text{He} + \text{n}$ requires a threshold energy, and why.

3. (I) Is the reaction $\text{n} + {}^{238}_{92}\text{U} \rightarrow {}^{239}_{92}\text{U} + \gamma$ possible with slow neutrons? Explain.

4. (II) (*a*) Complete the following nuclear reaction, $\text{p} + ? \rightarrow {}^{32}_{16}\text{S} + \gamma$. (*b*) What is the *Q*-value?

5. (II) The reaction $\text{p} + {}^{18}_{8}\text{O} \rightarrow {}^{18}_{9}\text{F} + \text{n}$ requires an input of energy equal to 2.438 MeV. What is the mass of ${}^{18}_{9}\text{F}$?

6. (II) (*a*) Can the reaction $\text{n} + {}^{24}_{12}\text{Mg} \rightarrow {}^{23}_{11}\text{Na} + \text{d}$ occur if the bombarding particles have 19.00 MeV of kinetic energy? (d stands for deuterium, ${}^{2}_{1}\text{H}$.) (*b*) If so, how much energy is released? If not, what kinetic energy is needed?

7. (II) (*a*) Can the reaction $\text{p} + {}^{7}_{3}\text{Li} \rightarrow {}^{4}_{2}\text{He} + \alpha$ occur if the incident proton has kinetic energy = 2800 keV? (*b*) If so, what is the total kinetic energy of the products? If not, what kinetic energy is needed?

8. (II) In the reaction $\alpha + {}^{14}_{7}\text{N} \rightarrow {}^{17}_{8}\text{O} + \text{p}$, the incident $\alpha$ particles have 8.95 MeV of kinetic energy. The mass of ${}^{17}_{8}\text{O}$ is 16.999132 u. (*a*) Can this reaction occur? (*b*) If so, what is the total kinetic energy of the products? If not, what kinetic energy is needed?

9. (II) Calculate the *Q*-value for the "capture" reaction $\alpha + {}^{16}_{8}\text{O} \rightarrow {}^{20}_{10}\text{Ne} + \gamma$.

10. (II) Calculate the total kinetic energy of the products of the reaction $\text{d} + {}^{13}_{6}\text{C} \rightarrow {}^{14}_{7}\text{N} + \text{n}$ if the incoming deuteron has kinetic energy $K = 45.3$ MeV.

11. (II) Radioactive ${}^{14}_{6}\text{C}$ is produced in the atmosphere when a neutron is absorbed by ${}^{14}_{7}\text{N}$. Write the reaction and find its *Q*-value.

12. (II) An example of a **stripping** nuclear reaction is $\text{d} + {}^{6}_{3}\text{Li} \rightarrow \text{X} + \text{p}$. (*a*) What is X, the resulting nucleus? (*b*) Why is it called a "stripping" reaction? (*c*) What is the *Q*-value of this reaction? Is the reaction endothermic or exothermic?

13. (II) An example of a **pick-up** nuclear reaction is ${}^{3}_{2}\text{He} + {}^{12}_{6}\text{C} \rightarrow \text{X} + \alpha$. (*a*) Why is it called a "pick-up" reaction? (*b*) What is the resulting nucleus? (*c*) What is the *Q*-value of this reaction? Is the reaction endothermic or exothermic?

**14.** (II) Calculate the energy released (or energy input required) for the reaction $\alpha + {}^{9}_{4}\text{Be} \rightarrow {}^{12}_{6}\text{C} + \text{n}$.

**15.** (III) Use conservation of energy and momentum to show that a bombarding proton must have an energy of 3.23 MeV in order to make the reaction ${}^{13}_{6}\text{C}(\text{p}, \text{n}){}^{13}_{7}\text{N}$ occur. (See Example 42–3.)

**16.** (III) How much kinetic energy (if any) would the proton require for the reaction ${}^{14}_{6}\text{C}(\text{p}, \text{n}){}^{14}_{7}\text{N}$ to proceed?

## 42–2 Cross Section

**17.** (I) The cross section for the reaction $\text{n} + {}^{10}_{5}\text{B} \rightarrow {}^{7}_{3}\text{Li} + {}^{4}_{2}\text{He}$ is about 40 bn for an incident neutron of low energy (kinetic energy $\approx 0$). The boron is contained in a gas with $n = 1.3 \times 10^{21}$ nuclei/m$^3$ and the target has thickness $\ell = 12.0$ cm. What fraction of incident neutrons will be scattered?

**18.** (I) What is the effective cross section for the collision of two hard spheres of radius $R_1$ and $R_2$?

**19.** (II) When the target is thick, the rate at which projectile particles collide with nuclei in the rear of the target is less than in the front of the target, since some scattering (i.e., collisions) takes place in the front layers. Let $R_0$ be the rate at which incident particles strike the front of the target, and $R_x$ be the rate at a distance $x$ into the target ($R_x = R_0$ at $x = 0$). Then show that the rate at which particles are scattered (and therefore lost from the incident beam) in a thickness $dx$ is $-dR_x = R_x n\sigma\, dx$, where the minus sign means that $R_x$ is decreasing and $n$ is the number of nuclei per unit volume. Then show that $R_x = R_0 e^{-n\sigma x}$, where $\sigma$ is the total cross section. If the thickness of the target is $\ell$, what does $R_x = R_0 e^{-n\sigma\ell}$ represent?

**20.** (II) A 1.3-cm-thick lead target reduces a beam of gamma rays to 25% of its original intensity. What thickness of lead will allow only one $\gamma$ in $10^6$ to penetrate (see Problem 19)?

**21.** (II) Use Fig. 42–3 to estimate what thickness of ${}^{114}_{48}\text{Cd}$ ($\rho = 8650$ kg/m$^3$) will cause a 3.0% reaction rate ($R/R_0 = 0.030$) for (*a*) 0.10-eV neutrons (*b*) 5.0-eV neutrons.

## 42–3 Nuclear Fission

**22.** (I) What is the energy released in the fission reaction of Eq. 42–5? (The masses of ${}^{141}_{56}\text{Ba}$ and ${}^{92}_{36}\text{Kr}$ are 140.914411 u and 91.926156 u, respectively.)

**23.** (I) Calculate the energy released in the fission reaction $\text{n} + {}^{235}_{92}\text{U} \rightarrow {}^{88}_{38}\text{Sr} + {}^{136}_{54}\text{Xe} + 12\text{n}$. Use Appendix G, and assume the initial kinetic energy of the neutron is very small.

**24.** (I) How many fissions take place per second in a 1000-MW reactor? Assume 200 MeV is released per fission.

**25.** (I) The energy produced by a fission reactor is about 200 MeV per fission. What fraction of the mass of a ${}^{235}_{92}\text{U}$ nucleus is this?

**26.** (II) Suppose that the average electric power consumption, day and night, in a typical house is 1200 W. What initial mass of ${}^{235}_{92}\text{U}$ would have to undergo fission to supply the electrical needs of such a house for a year? (Assume 200 MeV is released per fission, as well as 100% efficiency.)

**27.** (II) Consider the fission reaction

$$ {}^{235}_{92}\text{U} + \text{n} \rightarrow {}^{133}_{51}\text{Sb} + {}^{98}_{41}\text{Nb} + ?\text{n}. $$

(*a*) How many neutrons are produced in this reaction? (*b*) Calculate the energy release. The atomic masses for Sb and Nb isotopes are 132.915250 u and 97.910328 u, respectively.

**28.** (II) How much mass of ${}^{235}_{92}\text{U}$ is required to produce the same amount of energy as burning 1.0 kg of coal (about $3 \times 10^7$ J)?

**29.** (II) What initial mass of ${}^{235}_{92}\text{U}$ is required to operate an 880-MW reactor for 1 yr? Assume 32% efficiency.

**30.** (II) If a 1.0-MeV neutron emitted in a fission reaction loses one-half of its kinetic energy in each collision with moderator nuclei, how many collisions must it make to reach thermal energy ($\frac{3}{2}kT = 0.040$ eV)?

**31.** (II) Assuming a fission of ${}^{236}_{92}\text{U}$ into two roughly equal fragments, estimate the electric potential energy just as the fragments separate from each other. Assume that the fragments are spherical (see Eq. 41–1) and compare your calculation to the nuclear fission energy released, about 200 MeV.

**32.** (II) Estimate the ratio of the height of the Coulomb barrier for $\alpha$ decay to that for fission of ${}^{236}_{92}\text{U}$. (Both are described by a potential energy diagram of the shape shown in Fig. 41–7.)

**33.** (III) Suppose that the neutron multiplication factor is 1.0004. If the average time between successive fissions in a chain of reactions is 1.0 ms, by what factor will the reaction rate increase in 1.0 s?

## 42–4 Nuclear Fusion

**34.** (I) What is the average kinetic energy of protons at the center of a star where the temperature is $2 \times 10^7$ K? [*Hint*: See Eq. 18–4.]

**35.** (II) Show that the energy released in the fusion reaction ${}^{2}_{1}\text{H} + {}^{3}_{1}\text{H} \rightarrow {}^{4}_{2}\text{He} + \text{n}$ is 17.57 MeV.

**36.** (II) Show that the energy released when two deuterium nuclei fuse to form ${}^{3}_{2}\text{He}$ with the release of a neutron is 3.23 MeV.

**37.** (II) Verify the $Q$-value stated for each of the reactions of Eqs. 42–7. [*Hint*: Be careful with electrons (included in mass values for p, d, t in Appendix G).]

**38.** (II) (*a*) Calculate the energy release per gram of fuel for the reactions of Eqs. 42–9a, b, and c. (*b*) Calculate the energy release per gram of uranium ${}^{235}_{92}\text{U}$ in fission, and give its ratio to each reaction in (*a*).

**39.** (II) How much energy is released when ${}^{238}_{92}\text{U}$ absorbs a slow neutron (kinetic energy $\approx 0$) and becomes ${}^{239}_{92}\text{U}$?

**40.** (II) If a typical house requires 1200 W of electric power on average, what minimum amount of deuterium fuel would have to be used in a year to supply these electrical needs? Assume the reaction of Eq. 42–9b.

**41.** (II) If ${}^{6}_{3}\text{Li}$ is struck by a slow neutron, it can form ${}^{4}_{2}\text{He}$ and another isotope. (*a*) What is the second isotope? (This is a method of generating this isotope.) (*b*) How much energy is released in the process?

**42.** (II) Suppose a fusion reactor ran on "d–d" reactions, Eqs. 42–9a and b in equal amounts. Estimate how much natural water, for fuel, would be needed per hour to run a 1150-MW reactor, assuming 33% efficiency.

**43.** (II) How much energy (J) is contained in 1.00 kg of water if its natural deuterium is used in the fusion reaction of Eq. 42–9a? Compare to the energy obtained from the burning of 1.0 kg of gasoline, about $5 \times 10^7$ J.

**44.** (II) Determine the energy output for each of the 6 reactions and decays of the carbon cycle.

**45.** (III) Show that the energies carried off by the $^4_2$He nucleus and the neutron for the reaction of Eq. 42–9c are about 3.5 MeV and 14 MeV, respectively. Are these fixed values, independent of the plasma temperature?

**46.** (III) (*a*) Give the ratio of the energy needed for the first reaction of the *carbon cycle* to the energy needed for a deuterium–tritium reaction (Example 42–10). (*b*) If a deuterium–tritium reaction actually requires a temperature $T \approx 3 \times 10^8$ K, estimate the temperature needed for the first carbon-cycle reaction.

**47.** (III) The energy output of massive stars is believed to be due to the *carbon cycle* (see text). (*a*) Show that no carbon is consumed in this cycle and that the net effect is the same as for the proton–proton cycle. (*b*) What is the total energy release? (*c*) Why might the carbon cycle require a higher temperature $(\approx 2 \times 10^7\,\text{K})$ than the proton–proton chain $(\approx 1.5 \times 10^7\,\text{K})$?

## 42–6 Dosimetry

**48.** (I) 210 rads of $\alpha$-particle radiation is equivalent to how many rads of X-rays in terms of biological damage?

**49.** (I) A dose of 4.0 Sv of $\gamma$ rays in a short period would be lethal to about half the people subjected to it. How many grays is this?

**50.** (I) How much energy is deposited in the body of a 65-kg adult exposed to a 2.5-Gy dose?

**51.** (I) How many rads of slow neutrons will do as much biological damage as 75 rads of fast neutrons?

**52.** (II) A cancer patient is undergoing radiation therapy in which protons with an energy of 1.2 MeV are incident on a 0.20-kg tumor. (*a*) If the patient receives an effective dose of 1.0 rem, what is the absorbed dose? (*b*) How many protons are absorbed by the tumor? Assume RBE $\approx 1$.

**53.** (II) A 0.042-$\mu$Ci sample of $^{32}_{15}$P is injected into an animal for tracer studies. If a Geiger counter intercepts 25% of the emitted $\beta$ particles, what will be the counting rate, assumed 85% efficient?

**54.** (II) About 35 eV is required to produce one ion pair in air. Show that this is consistent with the two definitions of the roentgen given in the text.

**55.** (II) A 1.4-mCi source of $^{32}_{15}$P (in $NaHPO_4$), a $\beta$ emitter, is implanted in a tumor where it is to administer 36 Gy. The half-life of $^{32}_{15}$P is 14.3 days, and 1.0 mCi delivers about 10 mGy/min. Approximately how long should the source remain implanted?

**56.** (II) What is the mass of a 3.00-$\mu$Ci $^{14}_6$C source?

**57.** (II) $^{57}_{27}$Co emits 122-keV $\gamma$ rays. If a 63-kg person swallowed 1.55 $\mu$Ci of $^{57}_{27}$Co, what would be the dose rate (Gy/day) averaged over the whole body? Assume that 50% of the $\gamma$-ray energy is deposited in the body. [*Hint*: Determine the rate of energy deposited in the body and use the definition of the gray.]

**58.** (II) Ionizing radiation can be used on meat products to reduce the levels of microbial pathogens. Refrigerated meat is limited to 4.5 kGy. If 1.2-MeV electrons irradiate 4 kg of beef, how many electrons would it take to reach the allowable limit?

**59.** (III) Huge amounts of radioactive $^{131}_{53}$I were released in the accident at Chernobyl in 1986. Chemically, iodine goes to the human thyroid. (It can be used for diagnosis and treatment of thyroid problems.) In a normal thyroid, $^{131}_{53}$I absorption can cause damage to the thyroid. (*a*) Write down the reaction for the decay of $^{131}_{53}$I. (*b*) Its half-life is 8.0 d; how long would it take for ingested $^{131}_{53}$I to become 5.0% of the initial value? (*c*) Absorbing 1 mCi of $^{131}_{53}$I can be harmful; what mass of iodine is this?

**60.** (III) Assume a liter of milk typically has an activity of 2000 pCi due to $^{40}_{19}$K. If a person drinks two glasses (0.5 L) per day, estimate the total effective dose (in Sv and in rem) received in a year. As a crude model, assume the milk stays in the stomach 12 hr and is then released. Assume also that very roughly 10% of the 1.5 MeV released per decay is absorbed by the body. Compare your result to the normal allowed dose of 100 mrem per year. Make your estimate for (*a*) a 60-kg adult, and (*b*) a 6-kg baby.

**61.** (II) Radon gas, $^{222}_{86}$Rn, is considered a serious health hazard (see discussion in text). It decays by $\alpha$-emission. (*a*) What is the daughter nucleus? (*b*) Is the daughter nucleus stable or radioactive? If the latter, how does it decay, and what is its half-life? (See Fig. 41–12.) (*c*) Is the daughter nucleus also a noble gas, or is it chemically reactive? (*d*) Suppose 1.4 ng of $^{222}_{86}$Rn seeps into a basement. What will be its activity? If the basement is then sealed, what will be the activity 1 month later?

## *42–9 NMR

***62.** (II) Calculate the wavelength of photons needed to produce NMR transitions in free protons in a 1.500-T field. In what region of the spectrum is this wavelength?

***63.** (II) Carbon-13 has a magnetic moment $\mu = 0.7023\mu_N$ (see Eq. 41–2). What magnetic field would be necessary if $^{13}_6$C were to be detected in a proton NMR spectrometer operating at 42.58 MHz? (This large field necessitates that a $^{13}_6$C spectrometer operate at a lower frequency.)

# General Problems

**64.** J. Chadwick discovered the neutron by bombarding $^{9}_{4}\text{Be}$ with the popular projectile of the day, alpha particles. (*a*) If one of the reaction products was the then unknown neutron, what was the other product? (*b*) What is the *Q*-value of this reaction?

**65.** Fusion temperatures are often given in keV. Determine the conversion factor from kelvins to keV using, as is common in this field, $\overline{K} = kT$ without the factor $\frac{3}{2}$.

**66.** One means of enriching uranium is by diffusion of the gas $UF_6$. Calculate the ratio of the speeds of molecules of this gas containing $^{235}_{92}\text{U}$ and $^{238}_{92}\text{U}$, on which this process depends.

**67.** (*a*) What mass of $^{235}_{92}\text{U}$ was actually fissioned in the first atomic bomb, whose energy was the equivalent of about 20 kilotons of TNT (1 kiloton of TNT releases $5 \times 10^{12}$ J)? (*b*) What was the actual mass transformed to energy?

**68.** The average yearly background radiation in a certain town consists of 26 mrad of X-rays and $\gamma$ rays plus 3.6 mrad of particles having a RBE of 10. How many rem will a person receive per year on the average?

**69.** Deuterium makes up 0.0115% of natural hydrogen on average. Make a rough estimate of the total deuterium in the Earth's oceans and estimate the total energy released if all of it were used in fusion reactors.

**70.** A shielded $\gamma$-ray source yields a dose rate of 0.058 rad/h at a distance of 1.0 m for an average-sized person. If workers are allowed a maximum dose of 5.0 rem in 1 year, how close to the source may they operate, assuming a 35-h work week? Assume that the intensity of radiation falls off as the square of the distance. (It actually falls off more rapidly than $1/r^2$ because of absorption in the air, so your answer will give a better-than-permissible value.)

**71.** Radon gas, $^{222}_{86}\text{Rn}$, is formed by $\alpha$ decay. (*a*) Write the decay equation. (*b*) Ignoring the kinetic energy of the daughter nucleus (it's so massive), estimate the kinetic energy of the $\alpha$ particle produced. (*c*) Estimate the momentum of the alpha and of the daughter nucleus. (*d*) Estimate the kinetic energy of the daughter, and show that your approximation in (*b*) was valid.

**72.** Consider a system of nuclear power plants that produce 2200 MW. (*a*) What total mass of $^{235}_{92}\text{U}$ fuel would be required to operate these plants for 1 yr, assuming that 200 MeV is released per fission? (*b*) Typically 6% of the $^{235}_{92}\text{U}$ nuclei that fission produce $^{90}_{38}\text{Sr}$, a $\beta^-$ emitter with a half-life of 29 yr. What is the total radioactivity of the $^{90}_{38}\text{Sr}$, in curies, produced in 1 yr? (Neglect the fact that some of it decays during the 1-yr period.)

**73.** In the net reaction, Eq. 42–8, for the proton–proton chain in the Sun, the neutrinos escape from the Sun with energy of about 0.5 MeV. The remaining energy, 26.2 MeV, is available to heat the Sun. Use this value to calculate the "heat of combustion" per kilogram of hydrogen fuel and compare it to the heat of combustion of coal, about $3 \times 10^7$ J/kg.

**74.** Estimate how much total energy would be released via fission if 1.0 kg of uranium were enriched to 5% of the isotope $^{235}_{92}\text{U}$.

**75.** Some stars, in a later stage of evolution, may begin to fuse two $^{12}_{6}\text{C}$ nuclei into one $^{24}_{12}\text{Mg}$ nucleus. (*a*) How much energy would be released in such a reaction? (*b*) What kinetic energy must two carbon nuclei each have when far apart, if they can then approach each other to within 6.0 fm, center-to-center? (*c*) Approximately what temperature would this require?

**76.** Energy reaches Earth from the Sun at a rate of about 1300 W/m$^2$. Calculate (*a*) the total power output of the Sun, and (*b*) the number of protons consumed per second in the reaction of Eq. 42–8, assuming that this is the source of all the Sun's energy. (*c*) Assuming that the Sun's mass of $2.0 \times 10^{30}$ kg was originally all protons and that all could be involved in nuclear reactions in the Sun's core, how long would you expect the Sun to "glow" at its present rate? See Problem 73. [*Hint*: Use $1/r^2$ law in (*a*).]

**77.** Estimate how many solar neutrinos pass through a 180-m$^2$ ceiling of a room, at latitude 45°, for an hour around midnight on midsummer night. [*Hint*: See Problems 73 and 76.]

**78.** An average adult body contains about 0.10 $\mu$Ci of $^{40}_{19}\text{K}$, which comes from food. (*a*) How many decays occur per second? (*b*) The potassium decay produces beta particles with energies of around 1.4 MeV. Estimate the dose per year in sieverts for a 62-kg adult. Is this a significant fraction of the 3.6-mSv/yr background rate?

**79.** When the nuclear reactor accident occurred at Chernobyl in 1986, $2.0 \times 10^7$ Ci were released into the atmosphere. Assuming that this radiation was distributed uniformly over the surface of the Earth, what was the activity per square meter? (The actual activity was not uniform; even within Europe wet areas received more radioactivity from rainfall.)

**80.** A star with a large helium abundance can burn helium in the reaction $^{4}_{2}\text{He} + {}^{4}_{2}\text{He} + {}^{4}_{2}\text{He} \rightarrow {}^{12}_{6}\text{C}$. What is the *Q*-value for this reaction?

**81.** A 1.2-$\mu$Ci $^{137}_{55}\text{Cs}$ source is used for 1.6 hours by a 58-kg worker. Radioactive $^{137}_{55}\text{Cs}$ decays by $\beta^-$ decay with a half-life of 30 yr. The average energy of the emitted betas is about 190 keV per decay. The $\beta$ decay is quickly followed by a $\gamma$ with an energy of 660 keV. Assuming the person absorbs *all* emitted energy, what effective dose (in rem) is received?

**82.** A large amount of $^{90}_{38}\text{Sr}$ was released during the Chernobyl nuclear reactor accident in 1986. The $^{90}_{38}\text{Sr}$ enters the body through the food chain. How long will it take for 95% of the $^{90}_{38}\text{Sr}$ released during the accident to decay? See Appendix G.

**83.** Three radioactive sources have the same activity, 35 mCi. Source A emits 1.0-MeV $\gamma$ rays, source B emits 2.0-MeV $\gamma$ rays, and source C emits 2.0-MeV alphas. What is the relative danger of these sources?

**84.** A 57-kg patient is to be given a medical test involving the ingestion of $^{99m}_{43}\text{Tc}$ (Section 42–8) which decays by emitting a 140-keV gamma. The half-life for this decay is 6 hours. Assuming that about half the gamma photons exit the body without interacting with anything, what must be the initial activity of the Tc sample if the whole-body dose cannot exceed 50 mrem? Make the rough approximation that biological elimination of Tc can be ignored.

**85.** The early scattering experiments performed around 1910 in Ernest Rutherford's laboratory in England produced the first evidence that an atom consists of a heavy nucleus surrounded by electrons. In one of these experiments, $\alpha$ particles struck a gold-foil target $4.0 \times 10^{-5}$ cm thick in which there were $5.9 \times 10^{28}$ gold atoms per cubic meter. Although most $\alpha$ particles either passed straight through the foil or were scattered at small angles, approximately $1.6 \times 10^{-3}$ percent were scattered at angles greater than 90°—that is, in the backward direction. (*a*) Calculate the cross section, in barns, for backward scattering. (*b*) Rutherford concluded that such backward scattering could occur only if an atom consisted of a very tiny, massive, and positively charged nucleus with electrons orbiting some distance away. Assuming that backward scattering occurs for nearly direct collisions (i.e., $\sigma \approx$ area of nucleus), estimate the diameter of a gold nucleus.

**86.** Suppose a future fusion reactor would be able to put out 1000 MW of electrical power continuously. Assume the reactor will produce energy solely through the reaction given in Eq. 42–9a and will convert this energy to electrical energy with an efficiency of 33%. Estimate the minimum amount of deuterium needed to run this facility per year.

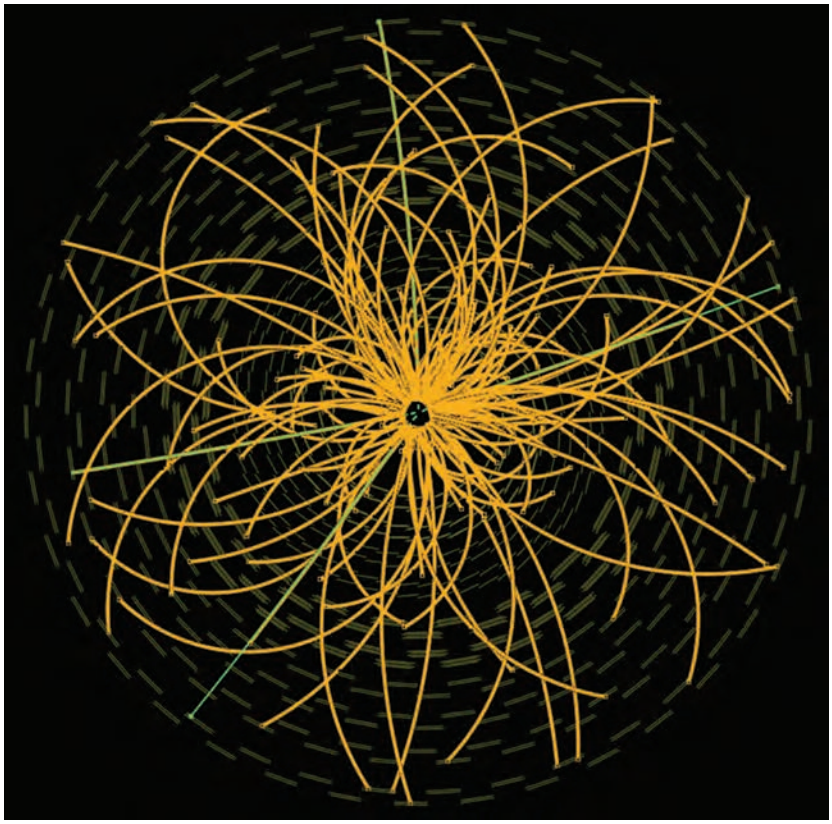
**87.** Centuries ago, paint generally contained a different amount of cobalt $\left({}^{59}_{27}\text{Co}\right)$ than paint today. A certain "old" painting is suspected of being a new forgery, and an examiner has decided to use **neutron activation analysis** to test this hypothesis. After placing the painting in a neutron flux of $5.0 \times 10^{12}$ neutrons/cm$^2$/s for 5.0 minutes, an activity of 62 decays/s of ${}^{60}_{27}\text{Co}$ $\left(T_{\frac{1}{2}} = 5.27\,\text{yr}\right)$ is observed. Assuming ${}^{59}_{27}\text{Co}$ has a cross section of 19 bn, how much cobalt (in grams) does the paint contain?

**88.** If a 72-kg power plant worker has been exposed to the maximum slow-neutron radiation for a given year, how much total energy (in J) has that worker absorbed? What if he were exposed to fast protons?

**89.** Consider the fission reaction

$$\text{n} + {}^{235}_{92}\text{U} \rightarrow {}^{92}_{38}\text{Sr} + \text{X} + 3\text{n}.$$

(*a*) What is X? (*b*) If this were part of a chain reaction in a fission power reactor running at "barely critical," what would happen on average to the three produced neutrons? (*c*) (optional) What is the $Q$-value of this reaction? [*Hint*: Mass values can be found at www.nist.gov/pml/data/comp.cfm.]



**90.** Consider the effort by humans to harness nuclear fusion as a viable energy source. (*a*) What are some advantages of using nuclear fusion rather than nuclear fission? (*b*) What is the major technological problem with using controlled nuclear fusion as a source of energy? (*c*) Discuss two different approaches to solving this problem. (*d*) What fuel is necessary in a nuclear fusion reaction? (*e*) Write a nuclear reaction using two nuclei of the fuel in part (*d*) to create a third nucleus. (*f*) Calculate the $Q$-value of the reaction in part (*e*).

**91.** Show, using the laws of conservation of energy and momentum, that for a nuclear reaction requiring energy, the minimum kinetic energy of the bombarding particle (the **threshold energy**) is equal to $\left[-Qm_{\text{pr}}/\left(m_{\text{pr}} - m_{\text{b}}\right)\right]$, where $-Q$ is the energy required (difference in total mass between products and reactants), $m_{\text{b}}$ is the mass of the bombarding particle, and $m_{\text{pr}}$ is the total mass of the products. Assume the target nucleus is at rest before an interaction takes place, and that all speeds are nonrelativistic.

## ANSWERS TO EXERCISES

**A:** ${}^{138}_{56}\text{Ba}$.
**B:** 3 neutrons.
**C:** $2 \times 10^{17}$.
**D:** (*e*).
**E:** (*b*).
**F:** (*a*).

This photo is a computer reconstruction of particles produced due to a 7 TeV proton–proton collision at the Large Hadron Collider (LHC). It is a candidate for having produced the long-sought Higgs boson (plus other particles).

The Higgs in this case could have decayed (very quickly $\sim 10^{-22}$ s) into two Z bosons (which are carriers of the weak force):

$$H^0 \rightarrow Z^0 + Z^0.$$

We don't see the tracks of the $Z^0$ particles because (1) they are neutral and (2) they decay too quickly $(\sim 10^{-24}\,\text{s})$, in this case:

$$Z^0 \rightarrow e^- + e^+.$$

The tracks of the 2 electrons and 2 positrons are shown as green lines. The Higgs is thought to play a fundamental role in the Standard Model of particle physics, importantly providing mass to fundamental particles.

The CMS detector of this photo uses a combination of the detector types discussed in Section 41–11. A magnetic field causes particles to move in curved paths so the momentum of each can be measured (Section 27–4). Tracks of particles with very large momentum, such as our electrons here, are barely curved.

We will study elementary particle physics from its beginnings until today, including antiparticles, neutrinos, quarks, the Standard Model, and theories that go beyond. We start with the great machines that accelerate particles so they can collide at high energies.

CHAPTER 43

# Elementary Particles

**CHAPTER-OPENING QUESTIONS—Guess now!**

**1.** Physicists reserve the term "fundamental particle" for particles with a special property. What do you think that special property is?

**(a)** Particles that are massless.
**(b)** Particles that possess the minimum allowable electric charge.
**(c)** Particles that have no known internal structure.
**(d)** Particles that produce no force on other objects.

**2.** The fundamental particles as we see them today, besides the long-sought-for Higgs boson, are

**(a)** atoms and electrons.
**(b)** protons, neutrons, and electrons.
**(c)** protons, neutrons, electrons, and photons.
**(d)** quarks, leptons, and gauge bosons (carriers of force).
**(e)** hadrons, leptons, and gauge bosons.

In the final two Chapters of this book we discuss two of the most exciting areas of contemporary physics: elementary particles in this Chapter, and cosmology and astrophysics in Chapter 44. These are subjects at the forefront of knowledge—elementary particles treats the smallest objects in the universe; cosmology treats the largest (and oldest) aspects of the universe. The reader who wants an understanding of the great beauties of present-day science (and its limits) will want to read these Chapters. So will those who want to be good citizens, even if there is not time to cover them in a physics course.

## CONTENTS

43 – 1 High-Energy Particles and Accelerators
43 – 2 Beginnings of Elementary Particle Physics—Particle Exchange
43 – 3 Particles and Antiparticles
43 – 4 Particle Interactions and Conservation Laws
43 – 5 Neutrinos
43 – 6 Particle Classification
43 – 7 Particle Stability and Resonances
43 – 8 Strangeness? Charm? Towards a New Model
43 – 9 Quarks
43–10 The Standard Model: QCD and Electroweak Theory
43–11 Grand Unified Theories
43–12 Strings and Supersymmetry

In this penultimate Chapter we discuss *elementary particle* physics, which represents the human endeavor to understand the basic building blocks of all matter, and the fundamental forces that govern their interactions.

Almost a century ago, by the 1930s, it was accepted that all atoms can be considered to be made up of neutrons, protons, and electrons. The basic constituents of the universe were no longer considered to be atoms (as they had been for 2000 years) but rather the proton, neutron, and electron. Besides these three "elementary particles," there were several others: the positron (a positive electron), the neutrino, and the $\gamma$ particle (or photon), for a total of six elementary particles.

By the 1950s and 1960s many new types of particles similar to the neutron and proton were discovered, as well as many "midsized" particles called *mesons* whose masses were mostly less than nucleon masses but more than the electron mass. (Other mesons, found later, have masses greater than nucleons.) Physicists felt that these particles could not all be fundamental, and must be made up of even smaller constituents (later confirmed by experiment), which were given the name *quarks*.

By the term **fundamental particle**, we mean a particle that is so simple, so basic, that it has no internal structure[†] (is not made up of smaller subunits)—see Chapter-Opening Question 1.

Today, the fundamental constituents of matter are considered to be **quarks** (they make up protons and neutrons as well as mesons) and **leptons** (a class that includes electrons, positrons, and neutrinos). There are also the "carriers of force" known as **gauge bosons**, including the photon, gluons, and W and Z bosons. In addition there is the **Higgs** boson, predicted in the 1960s but whose first suggestions of experimental detection were finally announced in 2012. The theory that describes our present view is called the **Standard Model**. How we came to our present understanding of elementary particles and the Standard Model is the subject of this Chapter.

One of the exciting developments of the last few years is an emerging synthesis between the study of elementary particles and astrophysics (Chapter 44). In fact, detailed observations in astrophysics have led to the conclusion that the greater part of the mass–energy content of the universe is not ordinary matter but two mysterious and invisible forms known as "dark matter" and "dark energy" which cannot be explained by the Standard Model in its present form.

Indeed, we are now aware that the Standard Model is not sufficient. There are problems and important questions still unanswered, and we will mention some of them in this Chapter and how we hope to answer them.

## 43–1 High-Energy Particles and Accelerators

In the late 1940s, after World War II, it was found that if the incoming particle in a nuclear reaction (Section 42–1) has sufficient energy, new types of particles can be produced. The earliest experiments used **cosmic rays**—particles that impinge on the Earth from space. In the laboratory, various types of particle accelerators have been constructed to accelerate protons or electrons to high energies so they can collide with other particles—often protons (the hydrogen nucleus). Heavy ions, up to uranium (U), have also been accelerated. These **high-energy accelerators** have been used to probe more deeply into matter, to produce and study new particles, and to give us information about the basic forces and constituents of nature. The particles produced in high-energy collisions can be detected by a variety of special detectors, discussed in Section 41–11, including scintillation counters, multiwire chambers, and semiconductors. The rate of production of any group of particles is quantified using the concept of *cross section*, Section 42–2. Because the projectile particles are at high energy, this field is sometimes called **high-energy physics**.

[†]Recall from Section 17–1 that the word "atom" comes from the Greek meaning "indivisible." Atoms have a substructure (protons, neutrons) so are not fundamental. Yet an atom is still the smallest "piece" of an element that has the characteristics of that material.

PSE5_CH43_v1.6_23Jun-20

## Wavelength and Resolution

Particles accelerated to high energy can probe the interior of nuclei and nucleons or other particles they strike. An important factor is that faster-moving projectiles can reveal finer detail. The wavelength of projectile particles is given by de Broglie's wavelength formula (Eq. 37–7),

$$\lambda = \frac{h}{p}, \tag{43–1}$$

showing that the greater the momentum $p$ of the bombarding particle, the shorter its wavelength. As discussed in Chapter 35 on diffraction, resolution of details in images is limited by the wavelength: the shorter the wavelength, the finer the detail that can be obtained. This is one reason why particle accelerators of higher and higher energy have been built in recent years: to probe ever deeper into the structure of matter, to smaller and smaller scales.

**EXAMPLE 43–1** **High resolution with electrons.** What is the wavelength, and hence the expected resolution, for 1.3-GeV electrons?

**APPROACH** Because 1.3 GeV is much larger than the electron mass, we must be dealing with relativistic speeds. The momentum of the electrons is found from Eq. 36–14, and the wavelength is $\lambda = h/p$.

**SOLUTION** Each electron has kinetic energy $K = 1.3\,\text{GeV} = 1300\,\text{MeV}$, which is about 2500 times the rest energy of the electron $(mc^2 = 0.51\,\text{MeV})$. Thus we can ignore the term $(mc^2)^2$ in Eq. 36–14, $E^2 = p^2c^2 + m^2c^4$, and we solve for $p$:

$$p = \sqrt{\frac{E^2 - m^2c^4}{c^2}} \approx \sqrt{\frac{E^2}{c^2}} = \frac{E}{c}.$$

Therefore the de Broglie wavelength is

$$\lambda = \frac{h}{p} = \frac{hc}{E},$$

where $E = 1.3\,\text{GeV}$. Hence

$$\lambda = \frac{(6.63 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^{8}\,\text{m/s})}{(1.3 \times 10^{9}\,\text{eV})(1.6 \times 10^{-19}\,\text{J/eV})} = 0.96 \times 10^{-15}\,\text{m},$$

or 0.96 fm. This resolution of about 1 fm is on the order of the size of nuclei (see Eq. 41–1).

**NOTE** The maximum possible resolution of this beam of electrons is far greater than for a light beam in a light microscope $(\lambda \approx 500\,\text{nm})$.

**EXERCISE A** What is the wavelength of a proton with $K = 1.00\,\text{TeV}$?

Another major reason today for building high-energy accelerators is that new particles of greater mass can be produced at higher collision energies, transforming the kinetic energy of the colliding particles into massive particles by $E = mc^2$, as we will discuss shortly. Now we look at particle accelerators.

## Cyclotron

The cyclotron was developed in 1930 by E. O. Lawrence (1901–1958; Fig. 43–1) at the University of California, Berkeley. It uses a magnetic field to maintain charged ions—usually protons—in nearly circular paths. Although particle physicists no longer use simple cyclotrons, they are used in medicine for treating cancer, and their operating principles are useful for understanding modern accelerators.

**FIGURE 43–1** Ernest O. Lawrence, left, with Donald Cooksey and the "dees" of an early cyclotron.

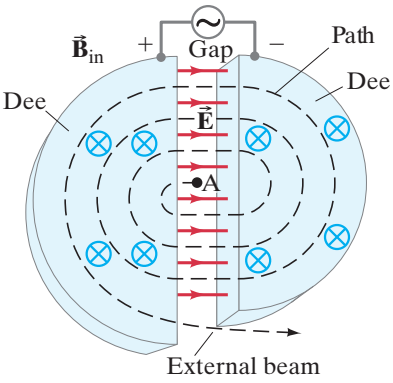


**FIGURE 43–2** Diagram of a cyclotron. The magnetic field, applied by a large electromagnet, points into the page. The protons start at A, the ion source. The red electric field lines shown are for the alternating electric field in the gap at a certain moment.

The protons move in a vacuum inside two D-shaped cavities, as shown in Fig. 43–2. Each time they pass into the gap between the "dees," a voltage accelerates them (the electric force), increasing their speed and increasing the radius of curvature of their path in the magnetic field. After many revolutions, the protons acquire high kinetic energy and reach the outer edge of the cyclotron where they strike a target. The protons speed up only when they are in the gap *between* the dees, and the voltage must be alternating. When protons are moving to the right across the gap in Fig. 43–2, the right dee must be electrically negative and the left one positive. A half-cycle later, the protons are moving to the left, so the left dee must be negative in order to accelerate them.

The frequency, $f$, of the applied voltage must be equal to the frequency of the circulating protons. When ions of charge $q$ are circulating *within* the hollow dees, the net force $F$ on each is due to the magnetic field $B$, so $F = qvB$, where $v$ is the speed of the ion at a given moment (Eq. 27–5). The magnetic force is perpendicular to both $\vec{\mathbf{v}}$ and $\vec{\mathbf{B}}$, and does not speed up the ions but causes them to move in circles; the acceleration within the dees is centripetal and equals $v^2/r$, where $r$ is the radius of the ion's path at a given moment. We use Newton's second law, $F = ma$, and find that

$$F = ma$$
$$qvB = \frac{mv^2}{r}$$

when the protons are within the dees (not the gap), so their (constant) speed at radius $r$ is

$$v = \frac{qBr}{m}.$$

The time required for a complete revolution is the period $T$ and is equal to

$$T = \frac{\text{distance}}{\text{speed}} = \frac{2\pi r}{qBr/m} = \frac{2\pi m}{qB}.$$

Hence the frequency of revolution $f$ is

$$f = \frac{1}{T} = \frac{qB}{2\pi m}. \qquad \textbf{(43–2)}$$

This is known as the **cyclotron frequency**.

**EXAMPLE 43–2** **Cyclotron.** A small cyclotron of maximum radius $R = 0.25$ m accelerates protons in a 1.7 T magnetic field. Calculate (*a*) the frequency needed for the applied alternating voltage, and (*b*) the kinetic energy of protons when they leave the cyclotron.

**APPROACH** The frequency of the protons revolving within the dees (Eq. 43–2) must equal the frequency of the voltage applied across the gap if the protons are going to increase in speed.

**SOLUTION** (*a*) From Eq. 43–2,

$$f = \frac{qB}{2\pi m} = \frac{(1.6\times10^{-19}\,\text{C})(1.7\,\text{T})}{(6.28)(1.67\times10^{-27}\,\text{kg})} = 2.6\times10^{7}\,\text{Hz} = 26\,\text{MHz},$$

which is in the radio-wave region of the EM spectrum (Fig. 31–12).

(*b*) The protons leave the cyclotron at $r = R = 0.25$ m. From $qvB = mv^2/r$ (see above), we have $v = qBr/m$, so their kinetic energy is

$$K = \frac{1}{2}mv^2 = \frac{1}{2}m\frac{q^2B^2R^2}{m^2} = \frac{q^2B^2R^2}{2m}$$
$$= \frac{(1.6\times10^{-19}\,\text{C})^2(1.7\,\text{T})^2(0.25\,\text{m})^2}{(2)(1.67\times10^{-27}\,\text{kg})} = 1.4\times10^{-12}\,\text{J} = 8.7\,\text{MeV}.$$

**NOTE** The kinetic energy is much less than the rest energy of the proton (938 MeV), so relativity is not needed.

**NOTE** The magnitude of the voltage applied to the dees does not appear in the formula for $K$, and so does not affect the final energy. But the higher this voltage, the fewer the revolutions required to bring the protons to full energy.

An important aspect of the cyclotron is that the frequency of the applied voltage, as given by Eq. 43–2, does not depend on the radius $r$ of the particle's path. Thus the frequency does not have to be changed as the protons or ions start from the source and are accelerated to paths of larger and larger radii. But this is only true at nonrelativistic energies. At higher speeds, the momentum (Eq. 36–8) is $p = \gamma mv = mv/\sqrt{1 - v^2/c^2}$, so $m$ in Eq. 43–2 has to be replaced by $\gamma m$ and the cyclotron frequency $f$ (Eq. 43–2) depends on speed $v$ because $\gamma$ does. To keep the particles in sync, machines called **synchrocyclotrons** reduce the frequency in time to correspond to the increase of $\gamma m$ (in Eq. 43–2) as a packet of charged particles increases in speed more slowly at larger orbits.

## Synchrotron

Another way to accelerate relativistic particles is to increase the magnetic field $B$ in time so as to keep $f$ (Eq. 43–2) constant as the particles speed up. Such devices are called **synchrotrons**; the particles move in a circle of fixed radius, which can be very large. The larger the radius, the greater the kinetic energy the particles can have for a given magnetic field strength (see argument on previous page). The biggest synchrotron of all is at the European Center for Nuclear Research (CERN) in Geneva, Switzerland, the Large Hadron Collider (LHC). It is 4.3 km in radius, and 27 km in circumference, and accelerates protons to 6.5 TeV.

The *Tevatron* accelerator at Fermilab (Fermi National Accelerator Laboratory, near Chicago, Illinois), has a radius of 1.0 km.[†] The Tevatron accelerated protons to about $1000\,\text{GeV} = 1\,\text{TeV}$ (hence its name, $1\,\text{TeV} = 10^{12}\,\text{eV}$). It was shut down in 2011, but Fermilab continues as a research facility, especially for studying properties of neutrinos.

These large synchrotrons use a narrow ring of magnets (see Fig. 43–3) with each magnet placed at the same radius from the center of the circle. The magnets are interrupted by gaps where high voltage accelerates the particles to higher speeds. Another way to describe the acceleration is to say the particles "surf" on a traveling electromagnetic wave within radiofrequency (RF) cavities. (The particles are first given considerable energy in smaller accelerators, "injectors," before being injected into the large ring of the large synchrotron.)

One problem of any accelerator is that accelerating electric charges radiate electromagnetic energy (see Chapter 31). Since ions or electrons are accelerated in an accelerator, we can expect considerable energy to be lost by radiation. The effect increases with energy and is especially important in circular machines where centripetal acceleration is present, such as synchrotrons, and hence is called **synchrotron radiation**. Synchrotron radiation can be useful, however. Intense beams of photons ($\gamma$ rays) are sometimes needed, and they are often obtained from an electron synchrotron. Strong sources of such photons are referred to as **light sources** and are used all over the world as $\gamma$-ray sources.

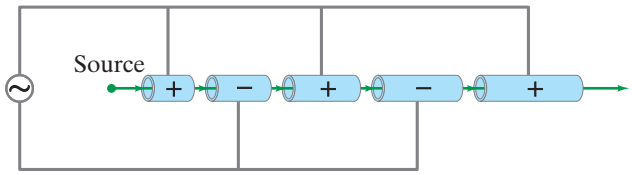
**FIGURE 43–3** The interior of the tunnel of the main accelerator at Fermilab, showing (red) the ring of superconducting magnets used to keep particles moving in a circular path at the 1-TeV Tevatron.

[†]Robert Wilson, who helped design the Tevatron, and founded the field of proton therapy (Section 42–7), expressed his views on accelerators and national security in this exchange with Senator John Pastore during testimony before a Congressional Committee in 1969:

> Pastore: "Is there anything connected with the hopes of this accelerator [the Tevatron] that in any way involves the security of the country?"
>
> Robert Wilson: "No sir, I don't believe so."
>
> Pastore: "Nothing at all?"
>
> Wilson: "Nothing at all. …"
>
> Pastore: "It has no value in that respect?"
>
> Wilson: "It has only to do with the respect with which we regard one another, the dignity of men, our love of culture. … It has to do with are we good painters, good sculptors, great poets? I mean all the things we really venerate in our country and are patriotic about … it has nothing to do directly with defending our country except to make it worth defending."

## Linear Accelerators

In a **linear accelerator** (linac), electrons or ions are accelerated along a straight-line path, Fig. 43–4, passing through a series of tubular conductors. Voltage applied to the tubes is alternating so that when electrons (say) reach a gap, the tube in front of them is positive and the one they just left is negative. At low speeds, the particles cover less distance in the same amount of time, so the tubes are shorter at first. Electrons, with their small mass, get close to the speed of light quickly, $v \approx c$, and the tubes are nearly equal in length. Linear accelerators are particularly important for accelerating electrons to avoid loss of energy due to synchrotron radiation. The largest electron linear accelerator has been at Stanford University (Stanford Linear Accelerator Center, or SLAC), about 3 km (2 mi) long, able to accelerate electrons to 50 GeV. Linacs accelerating protons are used as injectors into circular machines to provide initial kinetic energy. Many hospitals have 10- or 20-MeV electron linacs that strike a metal foil to produce $\gamma$-ray photons to irradiate tumors.



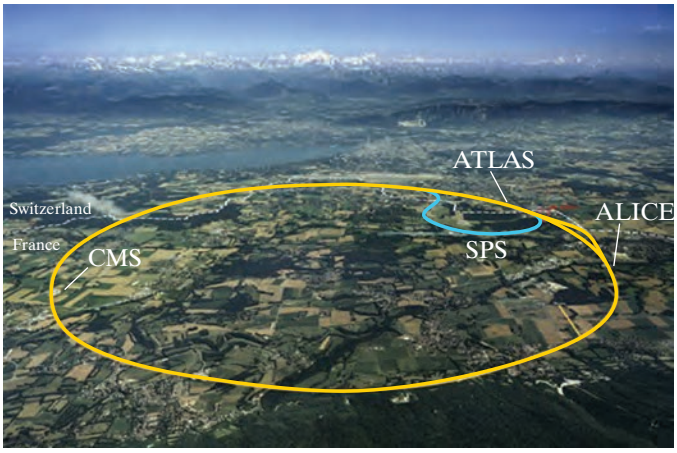


**FIGURE 43–4** Diagram of a simple linear accelerator.

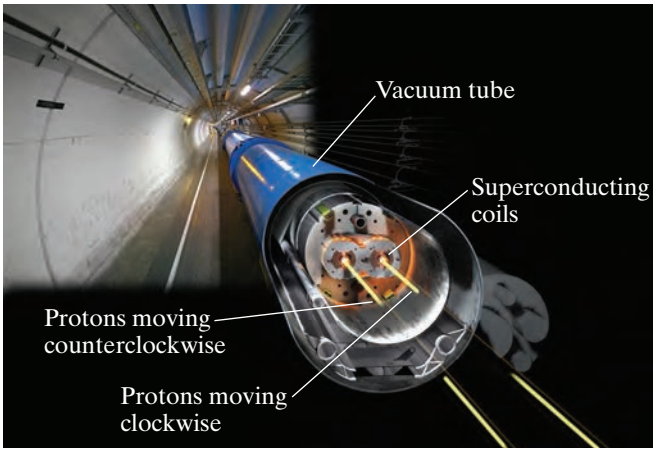

## Colliding Beams

High-energy physics experiments were once done by aiming a beam of particles from an accelerator at a stationary target. But to obtain the maximum possible collision energy from a given accelerator, two beams of particles are now accelerated to very high energy and are steered so that they collide head-on. One way to accomplish such **colliding beams** with a single accelerator is through the use of **storage rings**, in which oppositely circulating beams can be repeatedly brought into collision with one another at particular points. For example, in the experiments that provided strong evidence for the top quark (Section 43–9 and Fig. 43–15), the Fermilab Tevatron accelerated protons and antiprotons each to 900 GeV, so that the combined energy of head-on collisions was 1.8 TeV.

The largest collider is the Large Hadron Collider (LHC) at CERN, with a circumference of 27 km (Fig. 43–5). The two colliding beams are designed to each carry protons at up to 6.5 or 7 TeV for a total interaction energy of 13 TeV. For the experiments in 2011 and 2012 the total interaction energy was 7 TeV and 8 TeV. The protons for each of the beams, moving in opposite directions, are accelerated in several stages. The penultimate is SPS (Super Proton Synchrotron), seen in Fig. 43–5a which accelerates protons from 28 GeV to the 450 GeV, and then they are injected into the LHC itself.

(a)

(b)

**FIGURE 43–5** (a) The large circle represents the position of the tunnel, about 100 m below the ground at CERN (near Geneva) on the French-Swiss border, which houses the LHC. The smaller circle shows the position of the Super Proton Synchrotron used for accelerating protons prior to injection into the LHC. (b) Circulating proton beams, in opposite directions, inside the vacuum tube within the LHC tunnel.

Figure 43–6 shows part of one of the detectors (ATLAS) as it was being constructed at the LHC. The detectors within ATLAS include silicon semiconductor detectors with huge numbers of pixels used to track particle paths and find their point of interaction, and to measure their radius of curvature in a magnetic field and thus determine their momentum (Section 27–4). Their energy is determined in "calorimeters" utilizing plastic, liquid, or dense metal compound crystal scintillators (Section 41–11).

In the planning stage is the International Linear Collider (ILC) which would have colliding beams of electrons and positrons $(e^-$ and $e^+)$ at around 0.3 to 1 TeV. It would utilize semiconductor detectors using CMOS (Section 33–5) with embedded transistors to allow fast readout.

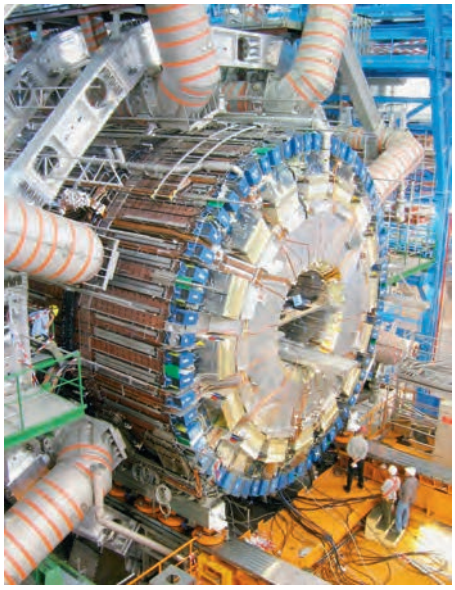

**FIGURE 43–6** ATLAS, one of the large complex detectors at the LHC, is shown here as it was being built. In 2012 it was used to provide evidence for the Higgs boson. Note the people near the bottom. From the outside, the CMS detector at the LHC looks similar.

**EXAMPLE 43–3** **Protons at relativistic speeds.** Determine the energy required to accelerate a proton in a high-energy accelerator (*a*) from rest to $v = 0.900c$, and (*b*) from $v = 0.900c$ to $v = 0.999c$. (*c*) What is the kinetic energy achieved by the proton in each case?

**APPROACH** We use the work-energy principle, which is still valid relativistically as mentioned in Section 36–11: $W = \Delta K$.

**SOLUTION** The kinetic energy of a proton of mass $m$ is given by Eq. 36–10,

$$K = (\gamma - 1)mc^2,$$

where the relativistic factor $\gamma$ is

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}}.$$

The work-energy theorem becomes

$$W = \Delta K = (\gamma_2 - 1)mc^2 - (\gamma_1 - 1)mc^2 = (\gamma_2 - \gamma_1)mc^2$$

where $\gamma_1$ and $\gamma_2$ are for the initial and final speeds.

(*a*) For $v = v_1 = 0$, $\gamma_1 = 1$; and for $v_2 = 0.900c$

$$\gamma_2 = \frac{1}{\sqrt{1 - (0.900)^2}} = 2.29.$$

For a proton, $mc^2 = 938\,\text{MeV}$, so the work (or energy) needed to accelerate it from rest to $v_2 = 0.900c$ is

$$W = \Delta K = (\gamma_2 - \gamma_1)mc^2$$
$$= (2.29 - 1.00)(938\,\text{MeV}) = 1.21\,\text{GeV}.$$

(*b*) To go from $v_2 = 0.900c$ to $v_3 = 0.999c$, we need

$$\gamma_3 = \frac{1}{\sqrt{1 - (0.999)^2}} = 22.4.$$

So the work needed to accelerate a proton from $0.900c$ to $0.999c$ is

$$W = \Delta K = (\gamma_3 - \gamma_2)mc^2$$
$$= (22.4 - 2.29)(938\,\text{MeV}) = 18.9\,\text{GeV},$$

which is 15 times as much.

(*c*) The kinetic energy reached by the proton in (*a*) is just equal to the work done on it, $K = 1.21\,\text{GeV}$. The final kinetic energy of the proton in (*b*), moving at $v_3 = 0.999c$, is

$$K = (\gamma_3 - 1)mc^2 = (21.4)(938\,\text{MeV}) = 20.1\,\text{GeV}.$$

**NOTE** This result makes sense because, starting from rest, we did work

$$W = 1.21\,\text{GeV} + 18.9\,\text{GeV} = 20.1\,\text{GeV}$$

on it.

**EXAMPLE 43–4** **Speed of a 6.5-TeV proton.** What is the speed of a 6.5-TeV proton produced at the LHC?

**APPROACH** The kinetic energy $K = 6.5\,\text{TeV} = 6.5 \times 10^{12}\,\text{eV}$ is much greater than the mass of the proton, $0.938 \times 10^{9}\,\text{eV}$, so relativistic calculations must be used. In particular, we use Eq. 36–10:

$$K = (\gamma - 1)mc^2 = \frac{mc^2}{\sqrt{1 - v^2/c^2}} - mc^2.$$

**SOLUTION** Compared to $K = 6.5 \times 10^{12}\,\text{eV}$, the rest energy $(\approx 10^{-3}\,\text{TeV})$ can be neglected, so we write

$$K = \frac{mc^2}{\sqrt{1 - v^2/c^2}}.$$

Then

$$1 - \frac{v^2}{c^2} = \left(\frac{mc^2}{K}\right)^2$$

or

$$\frac{v}{c} = \sqrt{1 - \left(\frac{mc^2}{K}\right)^2} = \sqrt{1 - \left(\frac{938 \times 10^6\,\text{eV}}{6.5 \times 10^{12}\,\text{eV}}\right)^2} = \sqrt{1 - 2.08 \times 10^{-8}}.$$

Using the binomial theorem

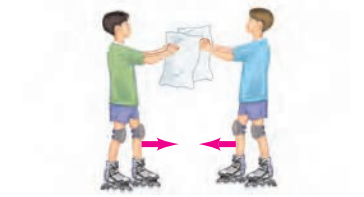
$$v = \left(1 - \tfrac{1}{2}(2.08 \times 10^{-8})\right)c = 0.999\,999\,9896c.$$

The proton is traveling at a speed extremely close to $c$, the speed of light.

# 43–2 Beginnings of Elementary Particle Physics—Particle Exchange

The accepted model for elementary particles today views *quarks* and *leptons* as the fundamental constituents of ordinary matter. To understand our present-day view of elementary particles, it is necessary to understand the ideas leading up to its formulation.

Elementary particle physics might be said to have begun in 1935 when the Japanese physicist Hideki Yukawa (1907–1981) predicted the existence of a new particle that would in some way mediate the strong nuclear force. To understand Yukawa's idea, we first consider the electromagnetic force. When we first discussed electricity, we saw that the electric force acts over a distance, without contact. To better perceive how a force can act over a distance, we used the idea of a **field**. The force that one charged particle exerts on a second can be said to be due to the electric field set up by the first. Similarly, the magnetic field can be said to carry the magnetic force. Later (Chapter 31), we saw that electromagnetic (EM) fields can travel through space as waves. Finally, in Chapter 37, we saw that electromagnetic radiation (light) can be considered as either a wave or as a collection of particles called *photons*. Because of this wave–particle duality, it is possible to imagine that the electromagnetic force between charged particles is due to



(1) the EM field set up by one charged particle and felt by the other, or

(2) an exchange of photons ($\gamma$ particles) between them.

It is (2) that we want to concentrate on here, and a crude analogy for how an exchange of particles could give rise to a force is suggested in Fig. 43–7. In part (a), two children start throwing heavy pillows at each other; each throw and each catch results in the child being pushed backward by the impulse. This is the equivalent of a repulsive force. On the other hand, if the two children exchange pillows by grabbing them out of the other person's hand, they will be pulled toward each other, as when an attractive force acts.

(a) Repulsive force (children throwing pillows)

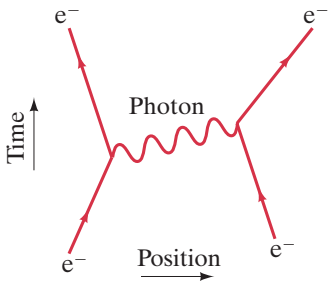
(b) Attractive force (children grabbing pillows from each other's hands)

**FIGURE 43–7** Forces equivalent to particle exchange. (a) Repulsive force (children on roller skates throwing pillows at each other). (b) Attractive force (children grabbing pillows from each other's hands).

PSE5_CH43_v1.6_23Jun-20

For the electromagnetic force, it is photons that are exchanged between two charged particles that give rise to the force between them. A simple diagram describing this photon exchange is shown in Fig. 43–8. Such a diagram, called a **Feynman diagram** after its inventor, the American physicist Richard Feynman (1918–1988), is based on the theory of **quantum electrodynamics** (QED).

Figure 43–8 represents the simplest case in QED, in which a single photon is exchanged. One of the charged particles emits the photon and recoils somewhat as a result; and the second particle absorbs the photon. In any collision or *interaction*, energy and momentum are transferred from one charged particle to the other, carried by the photon. The photon is absorbed by the second particle after it is emitted by the first particle and is not observable. Hence the photon is referred to as a **virtual** photon, in contrast to one that is free and can be detected by instruments. The photon is said to **mediate**, or **carry**, the electromagnetic force.



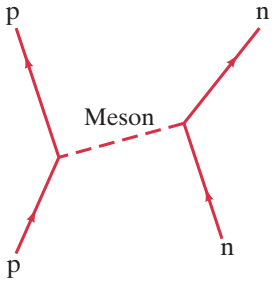


**FIGURE 43–8** Feynman diagram showing a photon acting as the carrier of the electromagnetic force between two electrons. This is sort of an $x$ vs. $t$ graph, with $t$ increasing upward. Starting at the bottom, two electrons approach each other (the distance between them decreases in time). As they get close, momentum and energy get transferred from one to the other, carried by a photon (or, perhaps, by more than one), and the two electrons bounce apart.

By analogy with photon exchange that mediates the electromagnetic force, Yukawa argued that there ought to be a particle that mediates the strong nuclear force—the force that holds nucleons together in the nucleus. Yukawa called this predicted particle a **meson** (meaning "medium mass"). Figure 43–9 is a Feynman diagram showing the original model of meson exchange: a meson carrying the strong force between a neutron and a proton.

**FIGURE 43–9** Early model showing meson exchange when a proton and neutron interact via the strong nuclear force. (Today, as we shall see shortly, we view the strong force as carried by gluons between quarks.)

A rough estimate of the mass of the meson can be made as follows. Suppose the proton on the left in Fig. 43–9 is at rest. For it to emit a meson would require energy (to make the meson's mass) which, coming from nowhere, would violate conservation of energy. But the uncertainty principle allows nonconservation of energy by an amount $\Delta E$ if it occurs only for a time $\Delta t$ given by $(\Delta E)(\Delta t) \approx h/2\pi$. We set $\Delta E$ equal to the energy needed to create the mass $m$ of the meson: $\Delta E = mc^2$. Conservation of energy is violated only as long as the meson exists, which is the time $\Delta t$ required for the meson to pass from one nucleon to the other, where it is absorbed and disappears. If we assume the meson travels at relativistic speed, close to the speed of light $c$, then $\Delta t$ need be at most about $\Delta t = d/c$, where $d$ is the maximum distance that can separate the interacting nucleons. Thus we can write

$$\Delta E\,\Delta t \approx \frac{h}{2\pi}$$

$$mc^2\left(\frac{d}{c}\right) \approx \frac{h}{2\pi}$$

or

$$mc^2 \approx \frac{hc}{2\pi d}. \qquad \textbf{(43–3)}$$

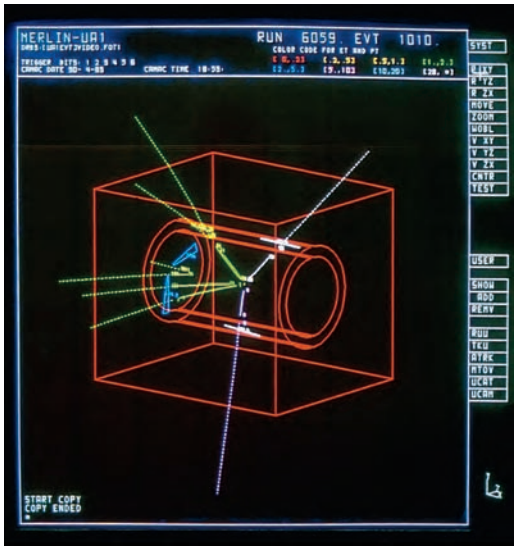
The range of the strong nuclear force (the maximum distance away it can be felt) is small—not much more than the size of a nucleon or small nucleus (see Eq. 41–1)—so let us take $d \approx 1.5 \times 10^{-15}\,\text{m}$. Then from Eq. 43–3,

$$mc^2 \approx \frac{hc}{2\pi d} = \frac{(6.6 \times 10^{-34}\,\text{J}\cdot\text{s})(3.0 \times 10^{8}\,\text{m/s})}{(6.28)(1.5 \times 10^{-15}\,\text{m})} \approx 2.1 \times 10^{-11}\,\text{J} = 130\,\text{MeV}.$$

The mass of the predicted meson, roughly $130\,\text{MeV}/c^2$, is about 250 times the electron mass of $0.51\,\text{MeV}/c^2$.

**EXERCISE B** What effect does an increase in the mass of the virtual exchange particle have on the range of the force it mediates? (*a*) Decreases it; (*b*) increases it; (*c*) has no appreciable effect; (*d*) decreases the range for charged particles and increases the range for neutral particles.

Note that since the electromagnetic force has infinite range, Eq. 43–3 with $d = \infty$ tells us that the exchanged particle for the electromagnetic force, the photon, will have zero mass, which it does.



The particle predicted by Yukawa was discovered in cosmic rays by C. F. Powell and G. Occhialini in 1947, and is called the "$\pi$" or pi meson, or simply the **pion**. It comes in three charge states: $+e$, $-e$, or 0, where $e = 1.6 \times 10^{-19}$ C. The $\pi^+$ and $\pi^-$ have mass of 139.6 MeV/$c^2$ and the $\pi^0$ a mass of 135.0 MeV/$c^2$, all close to Yukawa's prediction. All three interact strongly with matter. Reactions observed in the laboratory, using a particle accelerator, include

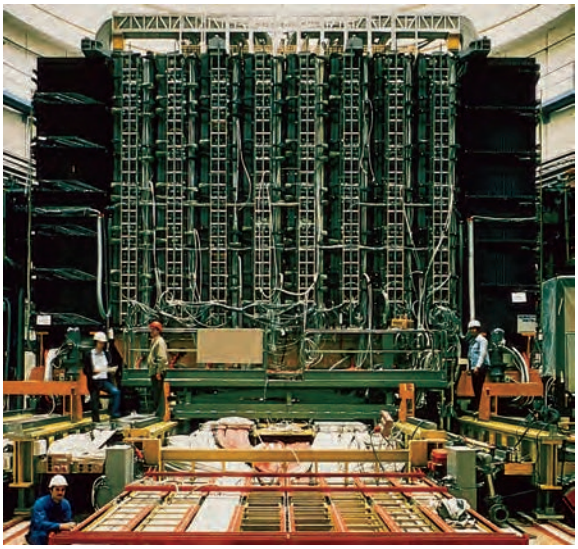
$$\begin{aligned} \mathrm{p} + \mathrm{p} &\rightarrow \mathrm{p} + \mathrm{p} + \pi^0, \\ \mathrm{p} + \mathrm{p} &\rightarrow \mathrm{p} + \mathrm{n} + \pi^+. \end{aligned} \qquad \textbf{(43–4)}$$

The incident proton from the accelerator must have sufficient energy to produce the additional mass of the free pion.

Yukawa's theory of pion exchange as carrier of the strong force has been superseded by *quantum chromodynamics* in which protons, neutrons, and other strongly interacting particles are made up of basic entities called *quarks*, and the basic carriers of the strong force are *gluons*, as we shall discuss shortly. But the basic idea of the earlier theory, that forces can be understood as the exchange of particles, remains valid.

There are four known types of force—or interactions—in nature. The electromagnetic force is carried by the photon, the strong force by gluons. What about the other two: the weak force and gravity? These too are believed to be mediated by particles. The particles that transmit the weak force are referred to as the $W^+$, $W^-$, and $Z^0$, and were detected in 1983 (Fig. 43–10). The quantum (or carrier) of the gravitational force has been named the **graviton**, but its existence has not been detected and it may not be detectable.

(a) 



(b) 

**FIGURE 43–10** (a) Computer reconstruction of a Z-particle decay into an electron and a positron $(Z^0 \rightarrow e^+ + e^-)$ whose tracks are shown in white, which took place in the UA1 detector at CERN. (b) Photo of the UA1 detector at CERN as it was being built in the 1980s.

A comparison of the four forces is given in Table 43–1, where they are listed according to their (approximate) relative strengths. Although gravity may be the most obvious force in daily life (because of the huge mass of the Earth), on a nuclear scale gravity is by far the weakest of the four forces, and its effect at the particle level can nearly always be ignored.

**TABLE 43–1 The Four Forces in Nature**

| Type | Relative Strength (approx., for 2 protons in nucleus) | Field Particle |
|---|---|---|
| Strong | 1 | Gluons (= g) |
| Electromagnetic | $10^{-2}$ | Photon ($= \gamma$) |
| Weak | $10^{-6}$ | $W^{\pm}$ and $Z^0$ |
| Gravitational | $10^{-38}$ | Graviton (?) |

PSE5_CH43_v1.6_23Jun-20

# 43–3 Particles and Antiparticles

The positron, as we discussed in Sections 37–5 (pair production) and 41–5 ($\beta^+$ decay), is basically a positive electron. That is, many of its properties are the same as for the electron, such as mass, but it has the opposite electric charge ($+e$). Other quantum numbers that we will discuss shortly are also reversed. The positron is said to be the **antiparticle** to the electron.

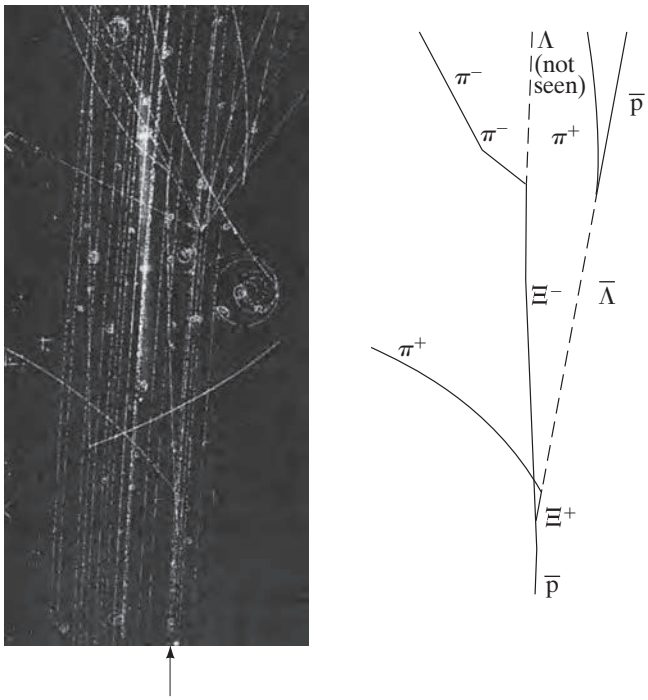


**FIGURE 43–11** Liquid-hydrogen bubble-chamber photograph of an antiproton ($\bar{p}$) colliding with a proton at rest, producing a Xi—anti-Xi pair ($\bar{p} + p \rightarrow \Xi^- + \Xi^+$) that subsequently decay into other particles. The drawing indicates the assignment of particles to each track, which is based on how or if that particle decays, and on mass values estimated from measurement of momentum (curvature of track in magnetic field) and energy (thickness of track, for example). Neutral particle paths are shown by dashed lines since neutral particles rarely ionize atoms, around which bubbles form, and hence leave no tracks. 1950s.

The positron was first detected as a curved path in a cloud chamber in a magnetic field by Carl Anderson in 1932. It was predicted that other particles also would have antiparticles. It was decades before another type was found. Finally, in 1955 the antiparticle to the proton, the **antiproton** ($\bar{p}$), which carries a negative charge (Fig. 43–11), was discovered at the University of California, Berkeley, by Emilio Segrè (1905–1989, Fig. 43–12) and Owen Chamberlain (1920–2006). A bar, such as over the p, is used to indicate the antiparticle ($\bar{p}$). Soon after, the antineutron ($\bar{n}$) was found. All particles have antiparticles. But a few, like the photon, the $\pi^0$, and the Higgs, do not have distinct antiparticles—we say that they are their own antiparticles.

Antiparticles are produced in nuclear reactions when there is sufficient energy available to produce the required mass, and they do not live very long in the presence of matter, because matter and antimatter annihilate each other. For example, a positron is stable when by itself but rarely survives for long; as soon as it encounters an electron, the two annihilate each other. The energy of their vanished mass, plus any kinetic energy they possessed, is usually converted into the energy of two $\gamma$ rays. Annihilation also occurs for all other particle–antiparticle pairs.

**Antimatter** is a term referring to material that would be made up of "antiatoms" in which antiprotons and antineutrons would form the nucleus around which positrons (antielectrons) would move. The term is also used for antiparticles in general. If there were pockets of antimatter in the universe, a huge explosion would occur when it encountered normal matter. It is believed that antimatter was prevalent in the very early universe (Section 44–7), but the vast majority annihilated with more prevalent ordinary matter.

**FIGURE 43–12** Emilio Segrè: he worked with Fermi in the 1930s, later discovered the first "man-made" element, technetium, and other elements, and then the antiproton. The inscription below the photo is from a book by Segrè given to this book's author.

### Negative Sea of Electrons; Vacuum State

The original idea for antiparticles came from a relativistic wave equation developed in 1928 by the Englishman P. A. M. Dirac (1902–1984). Recall that the non-relativistic Schrödinger equation took conservation of energy as a starting point. The Dirac equation too was based in part on energy conservation. We saw in Chapter 36 that the total energy $E$ of a particle with mass $m$ and momentum $p$ and zero potential energy is given by Eq. 36–14, $E^2 = p^2c^2 + m^2c^4$. Thus

$$E = \pm\sqrt{p^2c^2 + m^2c^4}.$$

Dirac applied his new equation and found that it included solutions with both + and − signs. He could not ignore the solution with the negative sign, which we might have thought unphysical. If those negative energy states are real, then we would expect normal free electrons to drop down into those states, emitting photons—never experimentally seen. To deal with this difficulty, Dirac postulated that all those negative energy states are *normally occupied*. That is, what we thought was the **vacuum** is instead a vast "**sea**" **of electrons** in negative energy states (Fig. 43–13a). These electrons are not normally observable. But if a photon strikes one of these negative energy electrons, that electron can be knocked up to a normal $(E > mc^2)$ energy state as shown in Fig. 43–13b. Note in Fig. 43–13 that there are no energy states between $E = -mc^2$ and $E = +mc^2$ (because $p^2$ cannot be negative in the equation $E = \pm\sqrt{p^2c^2 + m^2c^4}$). The photon that knocks an $e^-$ from the negative sea up to a normal state (Fig. 43–13b) must have an energy greater than $2mc^2$. What is left behind is a hole (as in semiconductors, Sections 40–7 and 40–8) with positive charge. We call that "hole" a **positron**, and it can move around as a free particle with positive energy. Thus Fig. 43–13b represents (Section 37–5) **pair production**: $\gamma \rightarrow e^-e^+$.

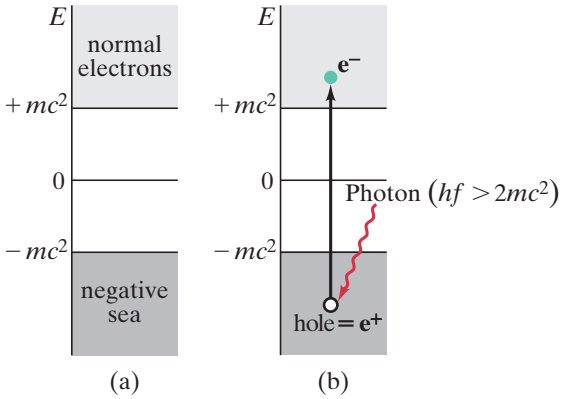

**FIGURE 43–13** (a) Possible energy states for an electron. Note the vast sea of fully occupied electron states at $E < -mc^2$. (b) An electron in the negative sea is hit by a photon $(E > 2mc^2)$ and knocks it up to a normal positive energy state. The positive "hole" left behind acts like a positive electron—it is a positron.

The vast sea of electrons with negative energy in Fig. 43–13 is the vacuum (or **vacuum state**). According to quantum mechanics, the vacuum is not empty, but contains electrons and other particles as well. The uncertainty principle allows a particle to jump briefly up to a normal energy, thus creating a **particle–antiparticle** pair. It is possible that they could be the source of the recently discovered *dark energy* that fills the universe (Chapter 44). We still have a lot to learn.

## 43–4 Particle Interactions and Conservation Laws

One of the important uses of high-energy accelerators and colliders is to study the interactions of elementary particles with each other. As a means of ordering this subnuclear world, the conservation laws are indispensable. The laws of conservation of energy, of momentum, of angular momentum, and of electric charge are found to hold precisely in all particle interactions.

PSE5_CH43_v1.6_23Jun-20

A study of particle interactions has revealed a number of new conservation laws which (just like the old ones) are ordering principles: they help to explain why some reactions occur and others do not. For example, the following reaction has never been observed:

$$\mathrm{p} + \mathrm{n} \not\rightarrow \mathrm{p} + \mathrm{p} + \bar{\mathrm{p}}$$

even though charge, energy, and so on, are conserved ($\not\rightarrow$ means the reaction does not occur). To understand why such a reaction does not occur, physicists hypothesized a new conservation law, the conservation of **baryon number**. (Baryon number is a generalization of nucleon number, which we saw earlier is conserved in nuclear reactions and decays.) All nucleons are defined to have baryon number $B = +1$, and all antinucleons (antiprotons, antineutrons) have $B = -1$. All other types of particles, such as photons, mesons, and electrons and other leptons, have $B = 0$. The reaction shown at the start of this paragraph does not conserve baryon number since the left side has $B = (+1) + (+1) = +2$, and the right has $B = (+1) + (+1) + (-1) = +1$. On the other hand, the following reaction does conserve $B$ and *does* occur if the incoming proton has sufficient energy:

$$\begin{aligned} \mathrm{p} + \mathrm{p} &\rightarrow \mathrm{p} + \mathrm{p} + \bar{\mathrm{p}} + \mathrm{p}, \\ B = +1 + 1 &= +1 + 1 - 1 + 1. \end{aligned}$$

As indicated, $B = +2$ on both sides of this equation. From these and other reactions, the **conservation of baryon number** has been established as a basic principle of physics.

Also useful are conservation laws for the three **lepton numbers**, associated with weak interactions including decays. In ordinary $\beta$ decay, an electron or positron is emitted along with a neutrino or antineutrino. In another type of decay, a particle known as a "$\mu$" or **muon** can be emitted instead of an electron. The muon (discovered in 1937) seems to be much like an electron, except its mass is 207 times larger $(106\,\mathrm{MeV}/c^2)$. The neutrino $(\nu_\mathrm{e})$ that accompanies an emitted electron is found to be different from the neutrino $(\nu_\mu)$ that accompanies an emitted muon. Each of these neutrinos has an antiparticle: $\bar{\nu}_\mathrm{e}$ and $\bar{\nu}_\mu$. In ordinary $\beta$ decay we have, for example,

**CAUTION**
*The different types of neutrinos are not identical*

$$\mathrm{n} \rightarrow \mathrm{p} + \mathrm{e}^- + \bar{\nu}_\mathrm{e}$$

but not $\mathrm{n} \not\rightarrow \mathrm{p} + \mathrm{e}^- + \bar{\nu}_\mu$. To explain why these do not occur, the concept of **electron lepton number**, $L_\mathrm{e}$, was invented. If the electron $(\mathrm{e}^-)$ and the electron neutrino $(\nu_\mathrm{e})$ are assigned $L_\mathrm{e} = +1$, and $\mathrm{e}^+$ and $\bar{\nu}_\mathrm{e}$ are assigned $L_\mathrm{e} = -1$, whereas all other particles have $L_\mathrm{e} = 0$, then all observed decays conserve $L_\mathrm{e}$. For example, in $\mathrm{n} \rightarrow \mathrm{p} + \mathrm{e}^- + \bar{\nu}_\mathrm{e}$, initially $L_\mathrm{e} = 0$, and afterward $L_\mathrm{e} = 0 + (+1) + (-1) = 0$. Decays that do not conserve $L_\mathrm{e}$, even though they would obey the other conservation laws, are not observed to occur.

In a decay involving muons, such as

$$\pi^+ \rightarrow \mu^+ + \nu_\mu,$$

a second quantum number, **muon lepton number** $(L_\mu)$, is conserved. The $\mu^-$ and $\nu_\mu$ are assigned $L_\mu = +1$, and their antiparticles $\mu^+$ and $\bar{\nu}_\mu$ have $L_\mu = -1$, whereas all other particles have $L_\mu = 0$. $L_\mu$ too is conserved in interactions and decays. Similar assignments can be made for the **tau lepton number**, $L_\tau$, associated with the $\tau$ lepton (discovered in 1976 with mass more than 3000 times the electron mass) and its neutrino, $\nu_\tau$.

Antiparticles have not only opposite electric charge from their particles, but also opposite $B$, $L_\mathrm{e}$, $L_\mu$, and $L_\tau$. For example, a neutron has $B = +1$, an antineutron has $B = -1$ (and all the $L$'s are zero).

**CONCEPTUAL EXAMPLE 43–5** **Lepton number in muon decay.** Which of the following decay schemes is possible for muon decay: (*a*) $\mu^- \rightarrow e^- + \bar{\nu}_e$; (*b*) $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$; (*c*) $\mu^- \rightarrow e^- + \nu_e$? All of these particles have $L_\tau = 0$.

**RESPONSE** A $\mu^-$ has $L_\mu = +1$ and $L_e = 0$. This is the initial state for all decays given, and the final state must also have $L_\mu = +1$, $L_e = 0$. In (*a*), the final state has $L_\mu = 0 + 0 = 0$, and $L_e = +1 - 1 = 0$; $L_\mu$ would not be conserved and indeed this decay is not observed to occur. The final state of (*b*) has $L_\mu = 0 + 0 + 1 = +1$ and $L_e = +1 - 1 + 0 = 0$, so both $L_\mu$ and $L_e$ are conserved. This is in fact the most common decay mode of the $\mu^-$. Lastly, (*c*) does not occur because $L_e$ (= +2 in the final state) is not conserved, nor is $L_\mu$.

**EXAMPLE 43–6** **Energy and momentum are conserved.** In addition to the "number" conservation laws which help explain the decay schemes of particles, we can also apply the laws of conservation of energy and momentum. The decay of a $\Sigma^+$ particle at rest with mass 1189 MeV/$c^2$ (Table 43–2 in Section 43–6) can yield a proton $(m_p = 938\ \text{MeV}/c^2)$ and a neutral pion, $\pi^0$ $(m_{\pi^0} = 135\ \text{MeV}/c^2)$:

$$\Sigma^+ \rightarrow p + \pi^0.$$

Determine the kinetic energies of the proton and $\pi^0$.

**APPROACH** We find the energy release from the change in mass $(E = mc^2)$ as we did for nuclear processes (Eq. 41–3 or 42–2a). Then we apply conservation of energy and momentum, using relativistic formulas as the energies are large.

**SOLUTION** The energy released, $Q = K_p + K_{\pi^0}$ (the sum of the kinetic energies of p and $\pi^0$) equals the change in mass $\times\, c^2$:

$$Q = [m_{\Sigma^+} - (m_p + m_{\pi^0})]c^2 = [1189 - (938 + 135)]\ \text{MeV} = 116\ \text{MeV}.$$

Next we apply conservation of momentum: the initial particle $\Sigma^+$ is at rest, so the $\pi^0$ and p have opposite momentum but are equal in magnitude: $p_{\pi^0} = p_p$. We square this equation, $p_{\pi^0}^2 = p_p^2$, which becomes, using Eq. 36–14 $(p^2c^2 = E^2 - m^2c^4)$,

$$E_{\pi^0}^2 - m_{\pi^0}^2c^4 = E_p^2 - m_p^2c^4.$$

Solving for $E_{\pi^0}^2$:

$$E_{\pi^0}^2 = E_p^2 - m_p^2c^4 + m_{\pi^0}^2c^4.$$

We substitute Eq. 36–11a, $E = K + mc^2$, for both the $\pi^0$ and the p:

$$(K_{\pi^0} + m_{\pi^0}c^2)^2 = (K_p + m_pc^2)^2 - m_p^2c^4 + m_{\pi^0}^2c^4$$

$$K_{\pi^0}^2 + 2K_{\pi^0}m_{\pi^0}c^2 + \cancel{m_{\pi^0}^2c^4} = K_p^2 + 2K_pm_pc^2 + \cancel{m_p^2c^4} - \cancel{m_p^2c^4} + \cancel{m_{\pi^0}^2c^4}.$$

Next (after cancelling as shown) we substitute $K_p = Q - K_{\pi^0}$:

$$\cancel{K_{\pi^0}^2} + 2K_{\pi^0}m_{\pi^0}c^2 = Q^2 - 2QK_{\pi^0} - \cancel{K_{\pi^0}^2} + 2Qm_pc^2 - 2K_{\pi^0}m_pc^2.$$

After cancelling as shown, we solve for $K_{\pi^0}$:

$$K_{\pi^0} = \frac{Q^2 + 2Qm_pc^2}{2m_{\pi^0}c^2 + 2Q + 2m_pc^2} = \frac{(116\ \text{MeV})^2 + 2(116\ \text{MeV})(938\ \text{MeV})}{2(135\ \text{MeV}) + 2(116\ \text{MeV}) + 2(938\ \text{MeV})}$$

which gives $K_{\pi^0} = 97$ MeV. Then $K_p = 116\ \text{MeV} - 97\ \text{MeV} = 19\ \text{MeV}$.

# 43–5 Neutrinos

We first met neutrinos with regard to $\beta$ decay in Section 41–5. The study of neutrinos is a "hot" subject today. Experiments are being carried out in deep underground laboratories, sometimes in deep mine shafts. The thick layer of earth above is meant to filter out all other "background" particles, leaving mainly the very weakly interacting neutrinos to arrive at the detectors.

Some very important results have come to the fore in recent years. First there was the **solar neutrino problem**. The energy output of the Sun is believed to be due to the nuclear fusion reactions discussed in Chapter 42, Eqs. 42–7 and 42–8.

PSE5_CH43_v1.6_23Jun-20

The neutrinos emitted in these reactions are all $\nu_e$ (accompanied by $e^+$). But the rate at which $\nu_e$ arrive at Earth was measured starting in the late 1960s to be much less than expected based on the power output of the Sun. It was then proposed that, on the long trip between Sun and Earth, $\nu_e$ might turn into $\nu_\mu$ or $\nu_\tau$. Subsequent experiments, definitive only in 2001, confirmed this hypothesis. Thus the three neutrinos, $\nu_e$, $\nu_\mu$, $\nu_\tau$, can change into one another in certain circumstances, a phenomenon called **neutrino flavor oscillation**.[†] (Each of the three neutrino types is called, whimsically, a different "flavor.") This result suggests that the lepton numbers $L_e$, $L_\mu$, and $L_\tau$ are not perfectly conserved. But the sum, $L_e + L_\mu + L_\tau$, is believed to be always conserved.

The second exceptional result has long been speculated on: are neutrinos massless as originally thought, or do they have a nonzero mass? Rough upper limits on the masses have been made. The latest astrophysical experiments show that the sum of all three neutrino masses combined is less than about $0.23\ \text{eV}/c^2$. But can all the masses be zero? Not if there are the flavor oscillations discussed above. It seems that at most, one type could have zero mass, and it is likely that at least one neutrino type has a mass of at least $0.04\ \text{eV}/c^2$.

As a result of neutrino oscillations, the three types of neutrino may not be exactly what we thought they were $(e, \mu, \tau)$. Instead, it seems the three basic neutrinos, called 1, 2, and 3, are combinations of $\nu_e$, $\nu_\mu$, and $\nu_\tau$.

Another outstanding question is whether or not neutrinos are in the category called **Majorana particles**,[‡] meaning they would be their own antiparticles, like $\gamma$, $\pi^0$, and Higgs. If so, a lot of other questions (and answers) would appear.

## *Neutrino Mass Estimate from a Supernova

The explosion of a supernova in the outer parts of our Galaxy observed in 1987 (Section 44–2) released vast numbers of neutrinos and offered an opportunity to estimate electron neutrino mass. If neutrinos do have mass, then their speed would be less than $c$, and neutrinos of different energy would take different times to travel the 170,000 light-years from the supernova to Earth. To get an idea of how such a measurement could be done, suppose two neutrinos from "SN1987A" were emitted at the same time and were actually detected on Earth $\left(\text{via the reaction } \bar{\nu}_e + p \rightarrow n + e^+\right)$ 10 seconds apart, with measured kinetic energies of about 20 MeV and 10 MeV. From other laboratory measurements we expect the neutrino mass to be less than 100 eV; and since our neutrinos have kinetic energy of 20 MeV and 10 MeV, we can make the approximation $m_\nu c^2 \ll E$, so that $E$ (the total energy) is essentially equal to the kinetic energy. We use Eq. 36–11b, which tells us

$$E = \frac{m_\nu c^2}{\sqrt{1 - v^2/c^2}}.$$

We solve this for $v$, the velocity of a neutrino with energy $E$:

$$v = c\left(1 - \frac{m_\nu^2 c^4}{E^2}\right)^{\frac{1}{2}} = c\left(1 - \frac{m_\nu^2 c^4}{2E^2} + \cdots\right),$$

where we have used the binomial expansion $(1-x)^{\frac{1}{2}} = 1 - \frac{1}{2}x + \cdots$, and we ignore higher-order terms since $m_\nu^2 c^4 \ll E^2$. The time $t$ for a neutrino to travel a distance $d$ $(= 170{,}000\ \text{ly})$ is

$$t = \frac{d}{v} = \frac{d}{c\left(1 - \frac{m_\nu^2 c^4}{2E^2}\right)} \approx \frac{d}{c}\left(1 + \frac{m_\nu^2 c^4}{2E^2}\right),$$

where again we used the binomial expansion $\left[(1-x)^{-1} = 1 + x + \cdots\right]$.

[†]Neutrino oscillations had first been proposed in 1957 by Bruno Pontecorvo. He also proposed that the electron and muon neutrinos are different species; and he also suggested a way to confirm the existence of neutrinos by detecting $\bar{\nu}_e$ emitted in huge numbers by a nuclear reactor, an experiment carried out by Frederick Reines and Clyde Cowan in the 1950s. The experimentalists who confirmed these two predictions were awarded the Nobel Prize, but not the theorist who proposed them.

[‡]The brilliant young physicist Ettore Majorana (1906–1938) disappeared from a ship under mysterious circumstances in 1938 at the age of 31.

The difference in arrival times for our two neutrinos of energies $E_1 = 20\,\text{MeV}$ and $E_2 = 10\,\text{MeV}$ is

$$t_2 - t_1 = \frac{d}{c}\frac{m_\nu^2 c^4}{2}\left(\frac{1}{E_2^2} - \frac{1}{E_1^2}\right).$$

We solve this for $m_\nu c^2$ and set $t_2 - t_1 = 10\,\text{s}$:

$$\begin{aligned} m_\nu c^2 &= \left[\frac{2c(t_2 - t_1)}{d}\frac{E_1^2 E_2^2}{E_1^2 - E_2^2}\right]^{\frac{1}{2}} \\ &= \left[\frac{2(3.0\times10^8\,\text{m/s})(10\,\text{s})}{(1.7\times10^5\,\text{ly})(1.0\times10^{16}\,\text{m/ly})}\frac{(400\,\text{MeV}^2)(100\,\text{MeV}^2)}{(400\,\text{MeV}^2 - 100\,\text{MeV}^2)}\right]^{\frac{1}{2}} \\ &= 22\times10^{-6}\,\text{MeV} = 22\,\text{eV}. \end{aligned}$$

This calculation, with its optimistic assumptions, estimates the mass of the neutrino to be $22\,\text{eV}/c^2$. But there would be experimental uncertainties, and even worse there is the unwarranted assumption that the two neutrinos were emitted at the same time.

Theoretical models of supernova explosions suggest that the neutrinos are emitted in a burst that lasts from a second or two up to perhaps 10 s. If we assume the neutrinos are not emitted simultaneously but rather at any time over a 10-s interval, then that 10-s difference in arrival times could be due to a 10-s difference in their emission time. In this case the data would be consistent with zero neutrino mass, and it put an approximate *upper limit* of $22\,\text{eV}/c^2$.

The actual detection of these neutrinos was brilliant—it was a rare event that allowed us to detect something other than EM radiation from beyond the solar system, and was an exceptional confirmation of theory. In the experiments, the most sensitive detector consisted of several thousand tons of water in an underground chamber. It detected 11 events in 12 seconds, probably via the reaction $\bar{\nu}_e + p \rightarrow n + e^+$. There was not a clear correlation between energy and time of arrival. Nonetheless, a careful analysis of that experiment set a rough upper limit on the electron antineutrino mass of about $4\,\text{eV}/c^2$. More recent results (mentioned earlier in this Section) are much more definitive—they provide evidence that mass is much smaller, and that it is *not zero*—but precise neutrino masses still elude us.

## 43–6 Particle Classification

In the decades after the discovery of the $\pi$ meson in the late 1940s, hundreds of other subnuclear particles were discovered. One way to categorize the particles is according to their interactions, since not all particles interact via all four of the forces known in nature (though all interact via gravity). Table 43–2 (next page) lists some of the more common particles classified in this way along with many of their properties. At the top of Table 43–2 are the so-called "fundamental" particles which we believe have no internal structure. Below them are some of the "composite" particles made up of quarks according to the Standard Model.

The **fundamental particles** include quarks and the **gauge bosons** (so-named after the theory that describes them, *gauge theory*) that include the gluons, the photon, and the W and Z particles; these are the particles that mediate (or "carry") the strong, electromagnetic, and weak interactions, respectively.

Also fundamental are the **leptons**, which are particles that do not interact via the strong force but do interact via the weak nuclear force. Leptons that carry electric charge also interact via the electromagnetic force. The leptons include the electron, the muon, and the tau, and three types of neutrino: the electron neutrino $(\nu_e)$, the muon neutrino $(\nu_\mu)$, and the tau neutrino $(\nu_\tau)$. Each lepton has an antiparticle. Finally, the recently detected Higgs boson is also considered to be fundamental, with no internal structure.

The second category of particle in Table 43–2 is the **hadrons**, which are **composite** particles (made up of quarks as we will discuss shortly). Hadrons are

PSE5_CH43_v1.6_23Jun-20

[†]See also Table 43–4 for particles with charm and bottom. $S$ in this Table stands for "strangeness" (see Section 43–8). More detail online at: pdglive.lbl.gov.

[‡]Neutrinos partake only in the weak interaction. Experimental upper limits on neutrino masses are given in parentheses, as obtained mainly from the Planck survey (Chapter 44). Detection of neutrino oscillations suggests that at least one type of neutrino has a nonzero mass greater than $0.04\,eV/c^2$.

particles that interact via the strong nuclear force and are said to be **strongly interacting particles**. They also interact via the other forces, but the strong force predominates at short distances. The hadrons include the proton, neutron, pion, and many other particles. They are divided into two subgroups: **baryons**, which are particles that have baryon number +1 (or −1 in the case of their antiparticles) and, as we shall see, are each made up of three quarks; and **mesons**, which have baryon number = 0, and are made up of a quark and an antiquark.

Only a few of the hundreds of hadrons (a veritable "zoo") are included in Table 43–2. Notice that the baryons $\Lambda$, $\Sigma$, $\Xi$, and $\Omega$ all decay to lighter-mass baryons, and eventually to a proton or neutron. All these processes conserve baryon number. Since there is no particle lighter than the proton with $B = +1$, if baryon number is strictly conserved, the proton itself does not decay and is stable. (But see Section 43–11.) Note that Table 43–2 gives the **mean life** ($\tau$) of each particle (as is done in particle physics), not the half-life ($T_{\frac{1}{2}}$). Recall that they differ by a factor 0.693: $\tau = T_{\frac{1}{2}}/\ln 2 = T_{\frac{1}{2}}/0.693$, Eq. 41–9. The term **lifetime** in particle physics means the mean life $\tau$ (= mean lifetime).

The baryon and lepton numbers ($B$, $L_e$, $L_\mu$, $L_\tau$), as well as strangeness $S$ (Section 43–8), as given in Table 43–2 are for particles; their antiparticles have opposite sign for these numbers.

PSE5_CH43_v1.6_23Jun-20

**EXAMPLE 43–7** **Baryon decay.** Show that the decay modes of the $\Sigma^+$ baryon given in Table 43–2 do not violate the conservation laws we have studied up to now: energy, charge, baryon number, lepton numbers.

**APPROACH** Table 43–2 shows two possible decay modes, (*a*) $\Sigma^+ \rightarrow p + \pi^0$, (*b*) $\Sigma^+ \rightarrow n + \pi^+$. All the particles have lepton numbers equal to zero.

**SOLUTION** (*a*) Energy: for $\Sigma^+ \rightarrow p + \pi^0$ the change in mass-energy is

$$\begin{aligned}\Delta(Mc^2) &= m_\Sigma c^2 - m_p c^2 - m_{\pi^0} c^2 \\ &= 1189.4\,\text{MeV} - 938.3\,\text{MeV} - 135.0\,\text{MeV} = +116.1\,\text{MeV},\end{aligned}$$

so energy can be conserved with the resulting particles having kinetic energy.
Charge: $+e = +e + 0$, so charge is conserved.
Baryon number: $+1 = +1 + 0$, so baryon number is conserved.
(*b*) Energy: for $\Sigma^+ \rightarrow n + \pi^+$, the mass-energy change is

$$\begin{aligned}\Delta(Mc^2) &= m_\Sigma c^2 - m_n c^2 - m_{\pi^+} c^2 \\ &= 1189.4\,\text{MeV} - 939.6\,\text{MeV} - 139.6\,\text{MeV} = +110.2\,\text{MeV}.\end{aligned}$$

This reaction releases 110.2 MeV of energy as kinetic energy of the products.
Charge: $+e = 0 + e$, so charge is conserved.
Baryon number: $+1 = +1 + 0$, so baryon number is conserved.

## 43–7 Particle Stability and Resonances

Many particles listed in Table 43–2 are unstable. The lifetime of an unstable particle depends on which force is most active in causing the decay. When a stronger force influences a decay, that decay occurs more quickly. Decays caused by the weak force typically have lifetimes of $10^{-13}$ s or longer (W and Z decay more quickly). Decays via the electromagnetic force have much shorter lifetimes, typically about $10^{-16}$ to $10^{-19}$ s, and normally involve a $\gamma$ (photon). Most of the unstable particles included in Table 43–2 decay either via the weak or the electromagnetic interaction.

Many particles have been found that decay via the strong interaction, with very short lifetimes, typically about $10^{-23}$ s. Their lifetimes are so short they do not travel far enough to be detected before decaying. The existence of such short-lived particles is inferred from their decay products. Consider the first such particle discovered (by Fermi), using a beam of $\pi^+$ particles with varying amounts of energy directed through a hydrogen target (protons). The number of interactions ($\pi^+$ scattered) plotted versus the pion's kinetic energy is shown in Fig. 43–14. The large number of interactions around 200 MeV led Fermi to

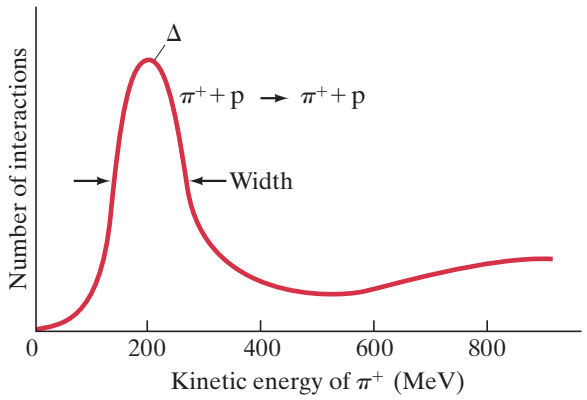

**FIGURE 43–14** Number of $\pi^+$ particles scattered elastically by a proton target as a function of the incident $\pi^+$ kinetic energy. The resonance shape represents the formation of a short-lived particle, the $\Delta$, which has a charge in this case of $+2e$ $(\Delta^{++})$.

conclude that the $\pi^+$ and proton combined momentarily to form a short-lived particle before coming apart again, or at least that they resonated together for a short time. Indeed, the large peak in Fig. 43–14 resembles a resonance curve (see Figs. 14–24, 14–27, and 30–22), and this new "particle"—now called the $\Delta$—is referred to as a **resonance**. Hundreds of other resonances have been found, and are regarded as excited states of lighter mass particles such as a nucleon.

The **width** of a resonance—in Fig. 43–14 the full width of the $\Delta$ peak at half the maximum is on the order of 100 MeV—is an interesting application of the uncertainty principle. If a particle lives only $10^{-23}$ s, then its mass (i.e., its rest energy) will be uncertain by an amount

$$\Delta E \approx \frac{h}{2\pi\,\Delta t} \approx \frac{(6.6\times10^{-34}\,\text{J}\cdot\text{s})}{(6)(10^{-23}\,\text{s})} \approx 10^{-11}\,\text{J} \approx 100\,\text{MeV},$$

which is what is observed. Actually, the lifetimes of $\approx 10^{-23}$ s for such resonances are inferred by the reverse process: from the measured width being $\approx 100$ MeV.

## 43–8 Strangeness? Charm? Towards a New Model

In the early 1950s, the newly found particles K, $\Lambda$, and $\Sigma$ were found to behave rather strangely in two ways. First, they were always produced in pairs. For example, the reaction

$$\pi^- + \text{p} \rightarrow \text{K}^0 + \Lambda^0$$

occurred with high probability, but the similar reaction $\pi^- + \text{p} \nrightarrow \text{K}^0 + \text{n}$ was never observed to occur even though it did not violate any known conservation law. The second feature of these **strange particles**, as they came to be called, was that they were produced via the strong interaction (that is, at a high interaction rate), but did not decay at a fast rate characteristic of the strong interaction (even though they decayed into strongly interacting particles).

To explain these observations, a new quantum number, **strangeness**, and a new conservation law, **conservation of strangeness**, were introduced. By assigning the strangeness numbers ($S$) indicated in Table 43–2, the production of strange particles in pairs was given an explanation. Antiparticles were assigned opposite strangeness from their particles. For example, in the reaction $\pi^- + \text{p} \rightarrow \text{K}^0 + \Lambda^0$, the initial state has strangeness $S = 0 + 0 = 0$, and the final state has $S = +1 - 1 = 0$, so strangeness is conserved. But for $\pi^- + \text{p} \nrightarrow \text{K}^0 + \text{n}$, the initial state has $S = 0$ and the final state has $S = +1 + 0 = +1$, so strangeness would not be conserved; and this reaction is not observed.

To explain the decay of strange particles, it is assumed that strangeness is conserved in the strong interaction but is *not conserved in the weak interaction*. Thus, strange particles were forbidden by strangeness conservation to decay to nonstrange particles of lower mass via the strong interaction, but could decay by means of the weak interaction at the observed longer lifetimes of $10^{-10}$ to $10^{-8}$ s.

**CAUTION**
*Partially conserved quantities*

The conservation of strangeness was the first example of a **partially conserved** quantity. In this case, the quantity strangeness is conserved by strong interactions but not by weak.

**CONCEPTUAL EXAMPLE 43–8** **Guess the missing particle.** Using the conservation laws for particle interactions, determine the possibilities for the missing particle in the reaction

$$\pi^- + \mathrm{p} \rightarrow \mathrm{K}^0 + ?$$

in addition to $\mathrm{K}^0 + \Lambda^0$ mentioned above.

**RESPONSE** We write equations for the conserved numbers in this reaction, with $B$, $L_e$, $S$, and $Q$ as unknowns whose determination will reveal what the possible particle might be:

| | |
|---|---|
| Baryon number: | $0 + 1 = 0 + B$ |
| Lepton number: | $0 + 0 = 0 + L_e$ |
| Charge: | $-1 + 1 = 0 + Q$ |
| Strangeness: | $0 + 0 = 1 + S.$ |

The unknown product particle would have to have these characteristics:

$$B = +1 \qquad L_e = 0 \qquad Q = 0 \qquad S = -1.$$

In addition to $\Lambda^0$, a neutral sigma particle, $\Sigma^0$, is also consistent with these numbers.

In the next Section we will discuss another partially conserved quantity which was given the name **charm**. The discovery in 1974 of a particle with charm helped solidify a new theory involving quarks, which we now discuss.

## 43–9 Quarks

One difference between leptons and hadrons is that the hadrons interact via the strong interaction, whereas the leptons do not. There is an even more fundamental difference. The six leptons $(e^-, \mu^-, \tau^-, \nu_e, \nu_\mu, \nu_\tau)$ are considered to be truly fundamental particles because they do not show any internal structure, and have no measurable size. (Attempts to determine the size of leptons have put an upper limit of about $10^{-18}$ m.) On the other hand, there are hundreds of hadrons, and experiments indicate they do have an internal structure. When an electron collides with another electron, it scatters off as per Coulomb's law. But electrons scattering off a proton reveal a more complex pattern, implying internal parts within the proton (= quarks).

In 1963, M. Gell-Mann and G. Zweig proposed that none of the hadrons, not even the proton and neutron, are truly fundamental, but instead are made up of combinations of three more fundamental pointlike entities called (somewhat whimsically) **quarks**.[†] Today, the quark theory is well-accepted, and quarks are considered truly fundamental particles, like leptons. The three quarks originally proposed were named **up**, **down**, and **strange**, with abbreviations u, d, s. The theory today has six quarks, just as there are six leptons—based on a presumed *symmetry* in nature. The other three quarks are called **charm**, **bottom**, and **top** (c, b, t). The names apply also to new properties of each quark (quantum numbers $c$, $b$, $t$) that distinguish these new quarks from the 3 original quarks (see Table 43–3).

[†]Gell-Mann chose the word from a phrase in James Joyce's *Finnegans Wake*.

**TABLE 43–3 Properties of Quarks** (Antiquarks have opposite sign *Q, B, S, c, b, t*)

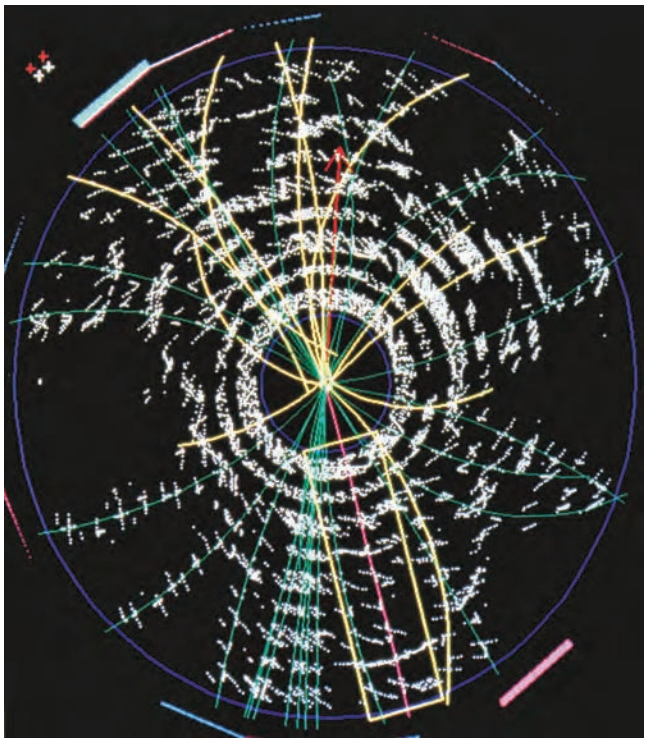
| Quarks | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| **Name** | **Symbol** | **Mass ($MeV/c^2$)** | **Charge *Q*** | **Baryon Number *B*** | **Strangeness *S*** | **Charm *c*** | **Bottom *b*** | **Top *t*** |
| Up | u | 2.3 | $+\frac{2}{3}e$ | $\frac{1}{3}$ | 0 | 0 | 0 | 0 |
| Down | d | 4.8 | $-\frac{1}{3}e$ | $\frac{1}{3}$ | 0 | 0 | 0 | 0 |
| Strange | s | 95 | $-\frac{1}{3}e$ | $\frac{1}{3}$ | −1 | 0 | 0 | 0 |
| Charm | c | 1275 | $+\frac{2}{3}e$ | $\frac{1}{3}$ | 0 | +1 | 0 | 0 |
| Bottom | b | 4180 | $-\frac{1}{3}e$ | $\frac{1}{3}$ | 0 | 0 | −1 | 0 |
| Top† | t | 173,500 | $+\frac{2}{3}e$ | $\frac{1}{3}$ | 0 | 0 | 0 | +1 |

†The top quark, with its extremely short lifetime of $5 \times 10^{-25}$ s, does not live long enough to form hadrons.

These properties (like strangeness) are conserved in strong, but not weak, interactions. Figure 43–15 shows one of the events that provided evidence for the top quark.

All quarks have spin $\frac{1}{2}$ and an electric charge of either $+\frac{2}{3}e$ or $-\frac{1}{3}e$ (that is, a fraction of the previously thought smallest charge, $e$, the charge on one electron). Antiquarks have opposite sign of electric charge $Q$, baryon number $B$, strangeness $S$, charm $c$, bottom $b$, and top $t$. Other properties of quarks are shown in Table 43–3.

All hadrons are considered to be made up of combinations of quarks (plus the gluons that hold them together), and their properties are described by looking at their quark content. Mesons consist of a quark–antiquark pair. For example, a $\pi^+$ meson is a $u\bar{d}$ combination: note that for the $u\bar{d}$ pair (Table 43–3), $Q = \frac{2}{3}e + \frac{1}{3}e = +1e$, $B = \frac{1}{3} - \frac{1}{3} = 0$, $S = 0 + 0 = 0$, as they must for a $\pi^+$; and a $K^+ = u\bar{s}$, with $Q = +1$, $B = 0$, $S = +1$. A $\pi^0$ can be made of $u\bar{u}$ or $d\bar{d}$, or a combination of the two.



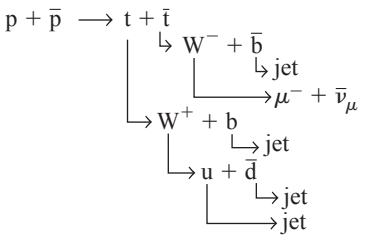


**FIGURE 43–15** This computer-generated reconstruction of a proton–antiproton collision at Fermilab occurred at an energy of nearly 2 TeV. It is one of the events that provided evidence for the top quark (1995). The multiwire chamber (Section 41–11) is in a magnetic field, and the radius of curvature of the charged particle tracks is a measure of each particle's momentum (Chapter 27). The white dots represent signals seen on the electric wires of the multiwire chamber. The colored lines are particle paths. The top quark (t) has too brief a lifetime ($\approx 10^{-23}$ s) to be detected itself, so we look for its possible decay products. Analysis indicates the following interaction and subsequent decays:

The tracks in the photo include jets (groups of particles moving in roughly the same direction), and a muon ($\mu^-$) whose track is the pink one enclosed by a yellow rectangle to make it stand out.

**TABLE 43–4 Partial List of Heavy Hadrons, with Charm and Bottom ($L_e = L_\mu = L_\tau = 0$)**

| Category | Particle | Anti-particle | Spin | Mass ($MeV/c^2$) | Baryon Number $B$ | Strangeness $S$ | Charm $c$ | Bottom $b$ | Mean life (s) | Principal Decay Modes |
|---|---|---|---|---|---|---|---|---|---|---|
| Mesons | $D^+$ | $D^-$ | 0 | 1869.6 | 0 | 0 | +1 | 0 | $10.4 \times 10^{-13}$ | K + others, e + others |
| | $D^0$ | $\overline{D}^0$ | 0 | 1864.8 | 0 | 0 | +1 | 0 | $4.1 \times 10^{-13}$ | K + others, $\mu$ or e + others |
| | $D_S^+$ | $D_S^-$ | 0 | 1968.3 | 0 | +1 | +1 | 0 | $5.0 \times 10^{-13}$ | K + others |
| | $J/\psi$ (3097) | Self | 1 | 3096.9 | 0 | 0 | 0 | 0 | $0.71 \times 10^{-20}$ | Hadrons, $e^+e^-$, $\mu^+\mu^-$ |
| | Y (9460) | Self | 1 | 9460.3 | 0 | 0 | 0 | 0 | $1.2 \times 10^{-20}$ | Hadrons, $\mu^+\mu^-$, $e^+e^-$, $\tau^+\tau^-$ |

| | $B^0$ | $\overline{B}^0$ | 0 | 5279.6 | 0 | 0 | 0 | −1 | $1.5 \times 10^{-12}$ | $D^0$ + others |
| Baryons | $\Lambda_c^+$ | $\Lambda_c^-$ | $\frac{1}{2}$ | 2286.5 | +1 | 0 | +1 | 0 | $2.0 \times 10^{-13}$ | Hadrons (e.g., $\Lambda$ + others) |
| | $\Sigma_c^{++}$ | $\Sigma_c^{--}$ | $\frac{1}{2}$ | 2454 | +1 | 0 | +1 | 0 | $2.9 \times 10^{-22}$ | $\Lambda_c^+\pi^+$ |
| | $\Sigma_c^+$ | $\Sigma_c^-$ | $\frac{1}{2}$ | 2453 | +1 | 0 | +1 | 0 | $>1.4 \times 10^{-22}$ | $\Lambda_c^+\pi^0$ |
| | $\Sigma_c^0$ | $\overline{\Sigma}_c^0$ | $\frac{1}{2}$ | 2454 | +1 | 0 | +1 | 0 | $3.0 \times 10^{-22}$ | $\Lambda_c^+\pi^-$ |
| | $\Lambda_b^0$ | $\overline{\Lambda}_b^0$ | $\frac{1}{2}$ | 5619.5 | +1 | 0 | 0 | −1 | $1.5 \times 10^{-12}$ | $J/\psi\Lambda^0$, $pD^0\pi^-$, $\Lambda_c^+\pi^+\pi^-\pi^-$ |

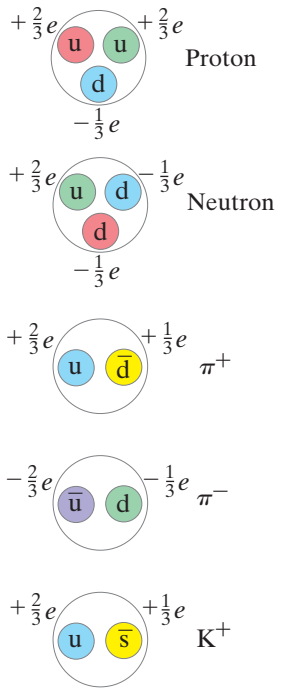

**FIGURE 43–16** Quark compositions for several particles.

Baryons, on the other hand, consist of three quarks. For example, a neutron is $n = ddu$, whereas an antiproton is $\bar{p} = \bar{u}\,\bar{u}\,\bar{d}$. See Fig. 43–16. Strange particles all contain an s or $\bar{s}$ quark, whereas charm particles contain a c or $\bar{c}$ quark. A few of these hadrons are listed in Table 43–4.

Current models suggest that quarks may be so tightly bound together that they may not ever exist singly in the free state. But quarks can be detected indirectly when they turn into narrow **jets** of other particles, as in Fig. 43–15. Also, observations of very high energy electrons scattered off protons suggest that protons are indeed made up of constituents.

Today, the truly **fundamental particles** are considered to be the six quarks, the six leptons, the gauge bosons that carry the fundamental forces, and the Higgs (page 1320). See Table 43–5, where the quarks and leptons are arranged in three "families" or "generations." Ordinary matter—atoms made of protons, neutrons, and electrons—is contained in the "first generation." The others are thought to have existed in the very early universe, but are seen by us today only at powerful colliders or in cosmic rays. All of the hundreds of hadrons can be accounted for by combinations of the six quarks and six antiquarks.

**EXERCISE C** Return to the Chapter-Opening Questions, page 1289, and answer them again now. Try to explain why you may have answered differently the first time.

**TABLE 43–5 The Fundamental Particles† of the Standard Model**

| | | | | |
|---|---|---|---|---|
| Gauge bosons | $\gamma$ | g | $Z^0$ | $W^\pm$ |
| Higgs boson | $H^0$ | | | |
| | Quarks | | and Leptons | |
| First generation | u | d | e | $\nu_e$ |
| Second generation | s | c | $\mu$ | $\nu_\mu$ |
| Third generation | b | t | $\tau$ | $\nu_\tau$ |

†The graviton ($G^0$) has been hypothesized but not detected and may not be detectable. It is not part of the Standard Model.

**CONCEPTUAL EXAMPLE 43–9** **Quark combinations.** Find the baryon number, charge, and strangeness for the following quark combinations, and identify the hadron particle that is made up of these quark combinations: (*a*) udd, (*b*) $u\bar{u}$, (*c*) uss, (*d*) sdd, and (*e*) $b\bar{u}$.

**RESPONSE** We use Table 43–3 to get the properties of the quarks, then Table 43–2 or 43–4 to find the particle that has these properties.

(*a*) udd has

$$Q = +\tfrac{2}{3}e - \tfrac{1}{3}e - \tfrac{1}{3}e = 0,$$

$$B = \tfrac{1}{3} + \tfrac{1}{3} + \tfrac{1}{3} = 1,$$

$$S = 0 + 0 + 0 = 0,$$

as well as $c = 0$, bottom $= 0$, top $= 0$. The only baryon $(B = +1)$ that has $Q = 0$, $S = 0$, etc., is the neutron (Table 43–2).

(*b*) $u\bar{u}$ has $Q = \frac{2}{3}e - \frac{2}{3}e = 0$, $B = \frac{1}{3} - \frac{1}{3} = 0$, and all other quantum numbers $= 0$. Sounds like a $\pi^0$ ($d\bar{d}$ also gives a $\pi^0$).

(*c*) uss has $Q = 0$, $B = +1$, $S = -2$, others $= 0$. This is a $\Xi^0$.

(*d*) sdd has $Q = -1$, $B = +1$, $S = -1$, so must be a $\Sigma^-$.

(*e*) $b\bar{u}$ has $Q = -1$, $B = 0$, $S = 0$, $c = 0$, bottom $= -1$, top $= 0$. This must be a $B^-$ meson (Table 43–4).

**EXERCISE D** What is the quark composition of a $K^-$ meson?

## 43–10 The Standard Model: QCD and Electroweak Theory

Not long after the quark theory was proposed, it was suggested that quarks have another property (or quality) called **color**, or "color charge" (analogous to electric charge). The distinction between the six types of quark (u, d, s, c, b, t) was referred to as **flavor**. According to theory, each flavor of quark can have one of three colors, usually designated red, green, and blue. (These are the three primary colors which, when added together in appropriate amounts, as on a TV screen, produce white.) Note that the names "color" and "flavor" have nothing to do with our senses, but are purely whimsical—as are other names, such as charm, in this new field. (We did, however, "color" the quarks in Fig. 43–16.) The antiquarks are colored antired, antigreen, and antiblue. Baryons are made up of three quarks, one of each color. Mesons consist of a quark–antiquark pair of a particular color and its anticolor. Both baryons and mesons are thus colorless or white.

Originally, the idea of quark color was proposed to preserve the Pauli exclusion principle (Section 39–4). Not all particles obey the exclusion principle. Those that do, such as electrons, protons, and neutrons, are called **fermions**. Those that don't are called **bosons**. These two categories are distinguished also in their spin:† bosons have integer spin (0, 1, 2, etc.) whereas fermions have half-integer spin, usually $\frac{1}{2}$ as for electrons and nucleons, but other fermions have spin $\frac{3}{2}$, $\frac{5}{2}$, etc. Matter is made up mainly of fermions, but the carriers of the forces ($\gamma$, W, Z, and gluons) are all bosons. Quarks are fermions (they have spin $\frac{1}{2}$) and therefore should obey the exclusion principle. Yet for three particular baryons (uuu, ddd, and sss), all three quarks would have the same quantum numbers, and at least two quarks have their spin in the same direction (since there are only two choices, spin up $[m_s = +\frac{1}{2}]$ or spin down $[m_s = -\frac{1}{2}]$).

†Spin is written in units of $\hbar$: $1\hbar$, $2\hbar$, etc; $\frac{1}{2}\hbar$, $\frac{3}{2}\hbar$.

This would seem to violate the exclusion principle; but if quarks have that additional quantum number *color*, which is different for each quark, it would serve to distinguish them and allow the exclusion principle to hold. Although quark color, and the resulting threefold increase in the number of quarks, was originally an *ad hoc* idea, it also served to bring the theory into better agreement with experiment, such as predicting the correct lifetime of the $\pi^0$ meson, and the measured rate of hadron production in observed $e^+e^-$ collisions at accelerators. The idea of color soon became a central feature of the theory as determining the force binding quarks together in a hadron.

Each quark is assumed to carry a *color charge*, analogous to electric charge, and the strong force between quarks is referred to as the **color force**. This theory of the strong force is called **quantum chromodynamics** (*chroma* = color in Greek), or **QCD**, to indicate that the force acts between color charges (and not between, say, electric charges). The strong force between two hadrons is considered to be a force between the quarks that make them up, as suggested in Fig. 43–17.

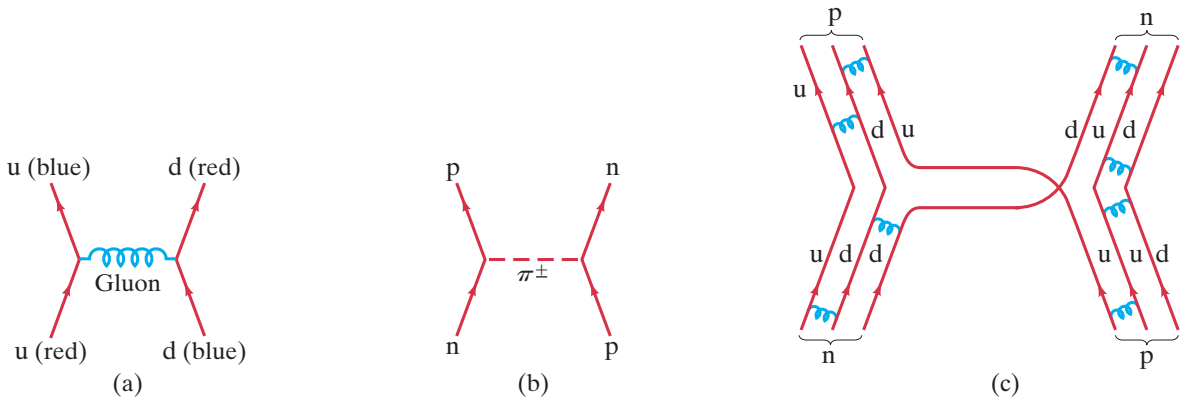

**FIGURE 43–17** (a) The force between two quarks holding them together as part of a proton, for example, is carried by a gluon, which in this case involves a change in color. (b) Strong interaction $n + p \rightarrow n + p$ with the exchange of a charged $\pi$ meson (+ or −, depending on whether it is considered moving to the left or to the right). (c) Quark representation of the same interaction $n + p \rightarrow n + p$. The blue coiled lines between quarks represent gluon exchanges holding the hadrons together. (The exchanged meson may be regarded as $\bar{u}d$ emitted by the n and absorbed by the p, or as $u\bar{d}$ emitted by p and absorbed by n, because a u (or d) quark going to the left in the diagram is equivalent to a $\bar{u}$ (or $\bar{d}$) going to the right.)

The particles that transmit the color force (analogous to photons for the EM force) are called **gluons** (a play on "glue"). They are included in Tables 43–2 and 43–5. There are eight gluons, according to the theory, all massless and all have color charge.[†]

You might ask what would happen if we try to see a single quark with color by reaching deep inside a hadron and extracting a single quark. Quarks are so tightly bound to other quarks that extracting one would require a tremendous amount of energy, so much that it would be sufficient to create more quarks $(E = mc^2)$. Indeed, such experiments are done at modern particle colliders and all we get is more hadrons (quark–antiquark pairs, or triplets, which we observe as mesons or baryons), never an isolated quark. This property of quarks, that they are always bound in groups that are colorless, is called **confinement**.

The color force has the interesting property that, as two quarks approach each other very closely (equivalently, have high energy), the force between them becomes small. This aspect is referred to as **asymptotic freedom**.

[†]Compare to the EM interaction, where the photon has no electric charge. Because gluons have color charge, they could attract each other and form composite particles (photons cannot). Such "glueballs" are being searched for.

PSE5_CH43_v1.6_23Jun-20

The weak force, as we have seen, is assumed to be mediated by the $W^+$, $W^-$, and $Z^0$ particles. It acts between the "weak charges" that each particle has. Each fundamental particle can thus have electric charge, weak charge, color charge, and gravitational mass, although one or more of these could be zero. For example, all leptons have color charge of zero, so they do not interact via the strong force.

**CONCEPTUAL EXAMPLE 43–10** **Beta decay.** Draw a Feynman diagram, showing what happens in beta decay using quarks.

**RESPONSE** Beta decay is a result of the weak interaction, and the mediator is either a $W^\pm$ or $Z^0$ particle. What happens, in part, is that a neutron (udd quarks) decays into a proton (uud). Apparently a d quark (charge $-\frac{1}{3}e$) has turned into a u quark (charge $+\frac{2}{3}e$). Charge conservation means that a negatively charged particle, namely a $W^-$, was emitted by the d quark. Since an electron and an antineutrino appear in the final state, they must have come from the decay of the virtual $W^-$, as shown in Fig. 43–18.

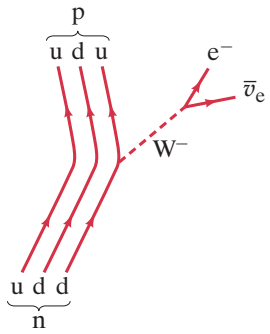

**FIGURE 43–18** Quark representation of the Feynman diagram for $\beta$ decay of a neutron into a proton. Example 43–10.

To summarize, the Standard Model says that the truly fundamental particles (Table 43–5) are the leptons, the quarks, the gauge bosons (photon, W and Z, and the gluons), and the Higgs boson. The photon, leptons, $W^+$, $W^-$, and $Z^0$ have all been observed in experiments. But only combinations of quarks (baryons and mesons) have been observed in the free state, and it seems likely that free quarks and gluons cannot be observed in isolation.

One important aspect of theoretical work is the attempt to find a **unified** basis for the different forces in nature. This was a long-held hope of Einstein, which he was never able to fulfill. A so-called **gauge theory** that unifies the weak and electromagnetic interactions was put forward in the 1960s by S. Weinberg, S. Glashow, and A. Salam. In this **electroweak theory**, the weak and electromagnetic forces are seen as two different manifestations of a single, more fundamental, *electroweak* interaction. The electroweak theory has had many successes, including the prediction of the $W^\pm$ particles as carriers of the weak force, with masses of $80.38 \pm 0.02\,\text{GeV}/c^2$ in excellent agreement with the measured values of $80.385 \pm 0.015\,\text{GeV}/c^2$ (and similar accuracy for the $Z^0$).

The combination of electroweak theory plus QCD for the strong interaction is referred to today as the **Standard Model** (**SM**) of fundamental particles.

**EXAMPLE 43–11** **ESTIMATE** **Range of weak force.** The weak nuclear force is of very short range, meaning it acts over only a very short distance. Estimate its range using the masses (Table 43–2) of the $W^\pm$ and Z: $m \approx 80$ or $90\,\text{GeV}/c^2 \approx 10^2\,\text{GeV}/c^2$.

**APPROACH** We assume the $W^\pm$ or $Z^0$ exchange particles can exist for a time $\Delta t$ given by the uncertainty principle (Section 38–3), $\Delta t \approx \hbar/\Delta E$, where $\Delta E \approx mc^2$ is the energy needed to create the virtual particle $(W^\pm, Z)$ that carries the weak force.

**SOLUTION** Let $\Delta x$ be the distance the virtual W or Z can move before it must be reabsorbed within the time $\Delta t \approx \hbar/\Delta E$. To find an upper limit on $\Delta x$, and hence the maximum range of the weak force, we let the W or Z travel close to the speed of light, so $\Delta x \lesssim c\,\Delta t$. Recalling that $1\,\text{GeV} = 1.6 \times 10^{-10}\,\text{J}$, then

$$\Delta x \lesssim c\,\Delta t \approx \frac{c\hbar}{\Delta E} \approx \frac{(3 \times 10^8\,\text{m/s})(10^{-34}\,\text{J}\cdot\text{s})}{(10^2\,\text{GeV})(1.6 \times 10^{-10}\,\text{J/GeV})} \approx 10^{-18}\,\text{m}.$$

This is indeed a very small range.

**NOTE** Compare this to the range of the electromagnetic force whose range is infinite ($1/r^2$ never becomes zero for any finite $r$), which makes sense because the mass of its virtual exchange particle, the photon, is zero (in the denominator of the above equation).

We did a similar calculation for the strong force in Section 43–2, estimating the mass of the $\pi$ meson as exchange particle. In our deeper view of the strong force, namely the color force between quarks within a nucleon, the gluons have zero mass, which implies infinite range (see formula in Example 43–11). We might have expected a range of about $10^{-15}$ m (nuclear size). But according to the Standard Model, the color force is weak at very close distances and increases greatly with distance (causing quark confinement). Thus its range could be very large.

Theoreticians have wondered why the W and Z have large masses rather than being massless like the photon. Peter Higgs and others in 1964 used electroweak theory to suggest an explanation by means of a **Higgs field** and its particle, the **Higgs boson**, which interact with the W and Z to "slow them down." In being forced to go slower than the speed of light, they would have to have mass ($m = 0$ only if $v = c$). Indeed, the Higgs field is thought to permeate the vacuum ("empty space") and to perhaps confer mass on particles that now have mass by slowing them down. In 2012 strong evidence was announced at CERN's Large Hadron Collider (Section 43–1) for a particle of mass 125 GeV/$c^2$ that is thought to be the long-sought Higgs boson of the Standard Model. Intense research continues, not only to better understand this particle, but to search for additional Higgs-like particles suggested by theories that go beyond the Standard Model such as *supersymmetry* (Section 43–12) and Majorana neutrinos.

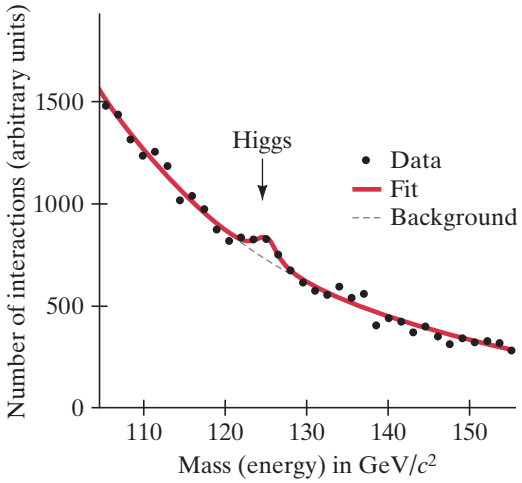

**FIGURE 43–19** Evidence for the Higgs boson.

**FIGURE 43–20** Fabiola Gianotti, leader of the ATLAS team (3000 physicists), at the LHC with theorist Peter Higgs, July 4, 2012, when the long hoped-for boson was announced.

Figure 43–19 shows the "resonance" bump (Section 43–7) that represents the Higgs boson as detected by the CMS team at the LHC. A second experiment, ATLAS, came up with the same mass. ATLAS is considered the largest scientific experiment ever (see Fig. 43–20).

There is no way to know if the Chapter-Opening Photo of a possible Higgs event, page 1289, is actually a Higgs or is a background event. As can be seen in Fig. 43–19, there are many more background events around 125 GeV than there are in the resonance bump representing the Higgs boson.

## 43–11 Grand Unified Theories

The Standard Model, for all its success, cannot explain some important issues—such as why the charge on the electron has *exactly* the same magnitude as the charge on the proton. This is crucial, because if the charge magnitudes were even a little different, atoms would not be neutral and the resulting large electric forces would surely have made life impossible. Indeed, the Standard Model is now considered to be a low-energy approximation to a more complete theory.

With the success of unified electroweak theory, theorists are trying to incorporate it and QCD for the strong (color) force into a so-called **grand unified theory** (**GUT**).

PSE5_CH43_v1.6_23Jun-20

One type of such a grand unified theory of the electromagnetic, weak, and strong forces has been proposed in which there is only one class of particle—leptons and quarks belong to the same family and are able to change freely from one type to the other—and the three forces are different aspects of a single underlying force. The unity is predicted to occur, however, only on a scale of less than about $10^{-31}$ m, corresponding to a typical particle energy of about $10^{16}$ GeV. If two elementary particles (leptons or quarks) approach each other to within this **unification scale**, the apparently fundamental distinction between them would not exist at this level, and a quark could readily change to a lepton, or vice versa. Baryon and lepton numbers would not be conserved. The weak, electromagnetic, and strong (color) force would blend to a force of a single strength.

What happens between the unification distance of $10^{-31}$ m and more normal (larger) distances is referred to as **symmetry breaking**. As an analogy, consider an atom in a crystal. Deep within the atom, there is much symmetry—in the innermost regions the electron cloud is spherically symmetric (Chapter 39). Farther out, this symmetry breaks down—the electron clouds are distributed preferentially along the lines (bonds) joining the atoms in the crystal. In a similar way, at $10^{-31}$ m the force between elementary particles is theorized to be a single force—it is symmetrical and does not single out one type of "charge" over another. But at larger distances, that symmetry is broken and we see three distinct forces. (In the "Standard Model" of electroweak interactions, Section 43–10, the symmetry breaking between the electromagnetic and the weak interactions occurs at about $10^{-18}$ m.)

**CONCEPTUAL EXAMPLE 43–12** **Symmetry.** The table in Fig. 43–21 has four identical place settings. Four people sit down to eat. Describe the symmetry of this table and what happens to it when someone starts the meal.

**RESPONSE** The table has several kinds of symmetry. It is symmetric to rotations of 90°: that is, the table will look the same if everyone moved one chair to the left or to the right. It is also north–south symmetric and east–west symmetric, so that swaps across the table don't affect the way the table looks. It also doesn't matter whether any person picks up the fork to the left of the plate or the fork to the right. But once that first person picks up either fork, the choice is set for all the rest at the table as well. The symmetry has been *broken*. The underlying symmetry is still there—the blue glasses could still be chosen either way—but some choice must get made and at that moment the symmetry of the diners is broken.

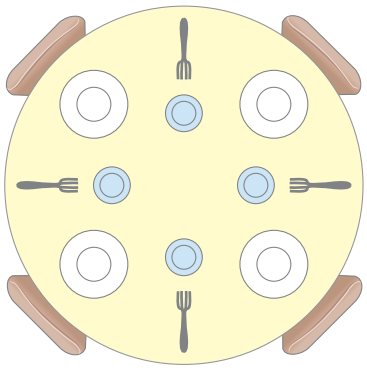

**FIGURE 43–21** Symmetry around a table. Example 43–12.

Another example of symmetry breaking is a pencil standing on its point before falling. Standing, it looks the same from any horizontal direction. From above, it is a tiny circle. But when it falls to the table, it points in one particular direction—the symmetry is broken.

## Proton Decay

Since unification is thought to occur at such tiny distances and huge energies, the theory is difficult to test experimentally. But it is not completely impossible. One testable prediction is the idea that the proton might decay (via, for example, $p \rightarrow \pi^0 + e^+$) and violate conservation of baryon number. This could happen if two quarks within a proton approached to within $10^{-31}$ m of each other. But it is very unlikely at normal temperature and energy, so the decay of a proton can only be an unlikely process. In the simplest form of GUT, the theoretical estimate of the proton mean life for the decay mode $p \rightarrow \pi^0 + e^+$ is about $10^{31}$ yr, and is within the realm of testability.[†] Proton decays have still not been seen, and experiments put the lower limit on the proton mean life for the above mode to be about $10^{33}$ yr, somewhat greater than this prediction. This may seem a disappointment, but on the other hand, it presents a challenge. Indeed more complex GUTs may resolve this conflict.

[†]This is much larger than the age of the universe ($\approx 14 \times 10^9$ yr). But we don't have to wait $10^{31}$ yr to see. Instead we can wait for one decay among $10^{31}$ protons over a year (see Eqs. 41–4 and 41–9a, $\Delta N = \lambda N\, \Delta t = N\, \Delta t/\tau$, and Example 43–13).

**EXAMPLE 43–13 ESTIMATE** **Proton decay.** An experiment uses 3300 tons of water waiting to see a proton decay of the type $p \rightarrow \pi^0 + e^+$. If the experiment is run for 4 years without detecting a decay, estimate the lower limit on the proton mean life.

**APPROACH** As with radioactive decay, the number of decays is proportional to the number of parent species ($N$), the time interval ($\Delta t$), and the decay constant ($\lambda$) which is related to the mean life $\tau$ by (see Eqs. 41–4 and 41–9a):

$$\Delta N = -\lambda N \, \Delta t = -\frac{N \, \Delta t}{\tau}.$$

**SOLUTION** Dealing only with magnitudes, we solve for $\tau$:

$$\tau = \frac{N \, \Delta t}{\Delta N}.$$

Thus for $\Delta N < 1$ (we don't see even one decay) over the four-year trial,

$$\tau > N\,(4\,\text{yr}),$$

where $N$ is the number of protons in 3300 tons of water. To determine $N$, we note that each molecule of $H_2O$ contains $2 + 8 = 10$ protons. So one mole of water (18 g, $6 \times 10^{23}$ molecules) contains $10 \times 6 \times 10^{23} = 6 \times 10^{24}$ protons in 18 g of water ($= 18\,\text{g}/1000\,\text{g} = 1/56$ of a kg), or about $3 \times 10^{26}$ protons per kilogram. One ton is $10^3$ kg, so the 3300 tons contains $(3.3 \times 10^6\,\text{kg})(3 \times 10^{26}\,\text{protons/kg}) \approx 1 \times 10^{33}$ protons. Then our very rough estimate for a lower limit on the proton mean life is $\tau > (10^{33})(4\,\text{yr}) \approx 4 \times 10^{33}\,\text{yr}$.

## *GUT and Cosmology

An interesting prediction of unified theories relates to cosmology (Chapter 44). It was thought by many theorists that during the first $10^{-35}$ s after the theorized Big Bang that created the universe, the temperature was so extremely high that particles had energies corresponding to the unification scale. Baryon number would not have been conserved then, perhaps allowing an imbalance that might account for the observed predominance of matter ($B > 0$) over antimatter ($B < 0$) in the universe. The fact that we are surrounded by matter, with no significant antimatter in sight, is considered a problem in search of an explanation (not given by the Standard Model). We call this the **matter–antimatter problem**. To understand it may require still undiscovered phenomena—perhaps related to quarks or neutrinos, or the Higgs boson or supersymmetry (next Section).

Many theorists no longer think the Big Bang was sufficiently hot to create unification. Nonetheless we see that there is a deep connection between investigations at either end of the size scale: theories about the tiniest objects (elementary particles) have a strong bearing on the understanding of the universe on a large scale. We look at this more in the next Chapter.

Figure 43–22 is a rough diagram indicating how the four fundamental forces in nature might have "condensed out" (a symmetry was broken) as time went on after the Big Bang (Chapter 44), and as the mean temperature of the universe and the typical particle energy decreased.

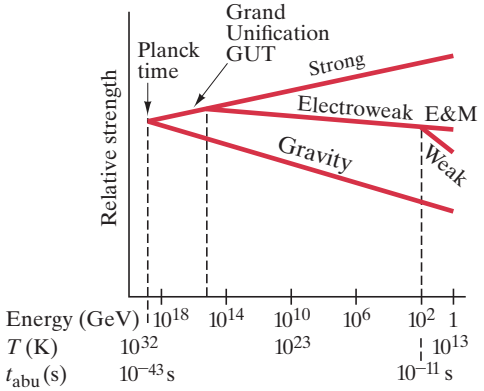

**FIGURE 43–22** Time and energy plot of the four fundamental forces, perhaps unified at the "Planck time" ($10^{-43}$ s after the birth of the universe), and how each condensed out, assuming a very hot Big Bang. The symbol $t_{abu}$ means time after the birth of the universe. Note that the typical particle energy (and average temperature of the universe) decreases to the right, as time increases.

## 43–12 Strings and Supersymmetry

We have seen that the Standard Model is unable to address important experimental issues, and that theoreticians are attacking the problem as experimenters search for new data, new particles, new concepts.

Even more ambitious than grand unified theories are attempts to also incorporate gravity, and thus unify all four forces in nature into a single theory. (Such theories are sometimes referred to misleadingly as **theories of everything**.) A major attempt to unify all four forces is called **string theory**, introduced by Gabriele Veneziano in 1968: Each fundamental particle (Table 43–5) is imagined not as a point but as a one-dimensional **string**, perhaps $10^{-35}$ m long, which vibrates in a particular standing wave pattern. (You might say each particle is a different note on a tiny stretched string.) More sophisticated theories propose the fundamental entities as being multidimensional **branes** (after 2-D membranes).

A related idea that also goes way beyond the Standard Model is **supersymmetry**, which applied to strings is known as **superstring theory**. Supersymmetry, developed by Bruno Zumino (1923–2014) and Julius Wess (1934–2007), predicts that interactions exist that would change fermions into bosons and vice versa, and that each known fermion would have a supersymmetric boson partner. Thus, for each quark (a fermion), there would be a **squark** (a boson) or "supersymmetric" quark. For every lepton there would be a **slepton**. Likewise, for every known boson (photons and gluons, for example), there would be a supersymmetric fermion (**photinos** and **gluinos**). Supersymmetry predicts also that a *graviton*, which transmits the gravity force, has a partner, the **gravitino**. Supersymmetry (often abbreviated SUSY) offers solutions to a number of important theoretical problems. Supersymmetric particles are a candidate for the "dark matter" of the universe (discussed in Chapter 44). But why hasn't this "missing part" of the universe ever been detected? The best guess is that supersymmetric particles might be heavier than their conventional counterparts, perhaps too heavy to have been produced in today's accelerators. A search for supersymmetric particles is already being done at CERN's new Large Hadron Collider.

Versions of these theories predict other interesting properties, such as that space has 11 dimensions, but 7 of them are "coiled up" so we normally only notice the 4-D of space–time. We would like to know if and how many extra dimensions there are, and how and why they are hidden. We hope to have some answers from the LHC (Section 43–1).

Some theorists think SUSY and other theories are approximations to a more fundamental, still undiscovered, **M-theory**. Edward Witten coined the term when proposing an 11 dimensional approximation, but never said what "M" stands for (could it be W upside-down?).

The world of elementary particles is opening new vistas. What happens in the future is bound to be exciting.

## Summary

**Particle accelerators** are used to accelerate charged particles, such as electrons and protons, so they can have very high energy collisions with other particles. High-energy particles have short wavelength and so can be used to probe the structure of matter in great detail (very small distances). High kinetic energy also allows the creation of new particles through collisions (via $E = mc^2$).

**Cyclotrons** and **synchrotrons** use a magnetic field to keep the particles in a circular path and accelerate them at intervals by high voltage. **Linear accelerators** accelerate particles along a line. **Colliding beams** allow higher interaction energy.

An **antiparticle** has the same mass as a particle but opposite charge. Certain other properties are also opposite: for example, the antiproton has **baryon number** (nucleon number) opposite ($B = -1$) to that for the proton ($B = +1$).

In all nuclear and particle reactions, the following conservation laws hold: momentum, angular momentum, mass–energy, electric charge, baryon number, and **lepton numbers**.

Certain particles have a property called **strangeness**, which is conserved by the strong force but not by the weak force. The properties **charm**, **bottom**, and **top** also are conserved by the strong force but not by the weak force.

Just as the electromagnetic force can be said to be due to an exchange of photons, the strong nuclear force is carried by massless **gluons**. The W and Z particles carry the weak force. These fundamental force carriers (photon, W and Z, gluons) are called **gauge bosons**.

Other particles can be classified as either *leptons* or *hadrons*. **Leptons** participate only in gravity, the weak, and the electromagnetic interactions. **Hadrons**, which today are considered **composite** particles, are made up of **quarks**, and participate in all four interactions, including the strong interaction. The hadrons can be classified as: **mesons**, each made up of 2 quarks and having baryon number zero; and **baryons**, each made up of 3 quarks and having nonzero baryon number.

Most particles, except for the photon, electron, neutrinos, and proton, decay with measurable mean lives varying from $10^{-25}$ s to $10^{3}$ s. The mean life depends on which force is predominant. Weak decays usually have mean lives greater than about $10^{-13}$ s. Electromagnetic decays typically have mean lives on the order of $10^{-16}$ to $10^{-19}$ s. The shortest lived particles, called **resonances**, decay via the strong interaction and live typically for only about $10^{-23}$ s.

Today's **Standard Model** of elementary particles considers **quarks** as the basic building blocks of the hadrons. The six quark "flavors" are called **up**, **down**, **strange**, **charm**, **bottom**, and **top**. It is expected that there are the same number of quarks as leptons (six of each), and that quarks and leptons are the truly fundamental particles along with the gauge bosons ($\gamma$, W, Z, gluons) and the Higgs boson.

Quarks are said to have **color**, and, according to **quantum chromodynamics** (QCD), the strong color force acts between their color charges and is transmitted by **gluons**. **Electroweak theory** views the weak and electromagnetic forces as two aspects of a single underlying interaction. QCD plus the electroweak theory are referred to as the **Standard Model** of the fundamental particles.

**Grand unified theories** of forces suggest that at very short distance $(10^{-31}\,\text{m})$ and very high energy, the weak, electromagnetic, and strong forces would appear as a single force, and the fundamental difference between quarks and leptons would disappear.

According to **string theory**, the fundamental particles may be tiny strings, $10^{-35}$ m long, distinguished by their standing wave pattern. **Supersymmetry** predicts that each fermion (or boson) has a corresponding boson (or fermion) partner.

# Questions

1. Give a reaction between two nucleons, similar to Eq. 43–4, that could produce a $\pi^-$.
2. If a proton is moving at very high speed, so that its kinetic energy is much greater than its rest energy $(mc^2)$, can it then decay via $\text{p} \rightarrow \text{n} + \pi^+$? Why or why not?
3. What would an "antiatom," made up of the antiparticles to the constituents of normal atoms, consist of? What might happen if *antimatter*, made of such antiatoms, came in contact with our normal world of matter?
4. What particle in a decay signals the electromagnetic interaction?
5. (*a*) Does the presence of a neutrino among the decay products of a particle necessarily mean that the decay occurs via the weak interaction? (*b*) Do all decays via the weak interaction produce a neutrino? Explain.
6. Why is it that a neutron decays via the weak interaction even though the neutron and one of its decay products (proton) are strongly interacting?
7. Which of the four interactions (strong, electromagnetic, weak, gravitational) does an electron take part in? A neutrino? A proton?
8. Verify that charge and baryon number are conserved in each of the decays shown in Table 43–2.
9. Which of the particle decays listed in Table 43–2 occur via the electromagnetic interaction?
10. Which of the particle decays listed in Table 43–2 occur by the weak interaction?
11. The $\Delta$ baryon has spin $\frac{3}{2}$, baryon number 1, and charge $Q = +2,\ +1,\ 0,$ or $-1$. Why is there no charge state $Q = -2$?
12. Which of the particle decays in Table 43–4 occur via the electromagnetic interaction?
13. Which of the particle decays in Table 43–4 occur by the weak interaction?
14. Quarks have spin $\frac{1}{2}$. How do you account for the fact that baryons have spin $\frac{1}{2}$ or $\frac{3}{2}$, and mesons have spin 0 or 1?
15. Suppose there were a kind of "neutrinolet" that was massless, had no color charge or electrical charge, and did not feel the weak force. Could you say that this particle even exists?
16. Is it possible for a particle to be both (*a*) a lepton and a baryon? (*b*) a baryon and a hadron? (*c*) a meson and a quark? (*d*) a hadron and a lepton? Explain.
17. Using the ideas of quantum chromodynamics, would it be possible to find particles made up of two quarks and no antiquarks? What about two quarks and two antiquarks?
18. Why can neutrons decay when they are free, but not when they are inside a stable nucleus?
19. Is the reaction $\text{e}^- + \text{p} \rightarrow \text{n} + \bar{\nu}_\text{e}$ possible? Explain.
20. Occasionally, the $\Lambda$ will decay by the following reaction: $\Lambda^0 \rightarrow \text{p}^+ + \text{e}^- + \bar{\nu}_\text{e}$. Which of the four forces in nature is responsible for this decay? How do you know?
21. (*a*) What are the two major classes of particles that make up the matter of the universe? (*b*) Name six types, or flavors, of each class of particles. (*c*) What are the four known fundamental forces in the universe? (*d*) Name the particles that carry the forces in part *c*. Which force is much weaker than the other three?
22. (*a*) What property characterizes all hadrons? (*b*) What property characterizes all baryons? (*c*) What property characterizes all mesons?

PSE5_CH43_v1.6_23Jun-20

# MisConceptual Questions

1. Quarks are considered to be fundamental particles because (choose all that apply)
   (*a*) they are components of many leptons.
   (*b*) they are components of all ordinary matter.
   (*c*) they have no known internal structure.
   (*d*) None of the above.
2. Which of the following forces is most important for understanding how atoms form molecules?
   (*a*) Electromagnetic. (*c*) Strong nuclear.
   (*b*) Gravitational. (*d*) Weak nuclear.
3. Which of the following are considered to be truly fundamental particles? Choose all that apply.
   (*a*) Electrons. (*c*) Neutrons. (*e*) Pions.
   (*b*) Protons. (*d*) Quarks. (*f*) Mesons.
4. There are six kinds (= flavors) of quarks: up, down, strange, charm, bottom, and top. Which flavors make up most of the known matter in the universe?
   (*a*) Up and down quarks.
   (*b*) Strange and charm quarks.
   (*c*) Bottom and top quarks.
   (*d*) All of the above.
5. Which of the following particles can not be composed of quarks?
   (*a*) Proton. (*d*) Neutron.
   (*d*) Electron. (*e*) Higgs boson.
   (*c*) $\pi$ meson.
6. If gravity is the weakest force, why is it the one we notice most?
   (*a*) Our bodies are not sensitive to the other forces.
   (*b*) The other forces act only within atoms and therefore have no effect on us.
   (*c*) Gravity may be "very weak" but always attractive, and the Earth has enormous mass. The strong and weak nuclear forces have very short range. The electromagnetic force has a long range, but most matter is electrically neutral.
   (*d*) At long distances, the gravitational force is actually stronger than the other forces.
   (*e*) The other forces act only on elementary particles, not on objects our size.
7. Is it possible for a tau lepton (whose mass is almost twice that of a proton) to decay into only hadrons?
   (*a*) Yes, because it is so massive it could decay into a proton and pions.
   (*b*) Yes, it could decay into pions and nothing else.
   (*c*) No, such a decay would violate lepton number; all of its decay products must be leptons.
   (*d*) No, its decay products must include a tau neutrino but could include hadrons such as pions.
   (*e*) No, the tau lepton is too massive to decay.
8. Which of the following are today considered fundamental particles (that is, not composed of smaller components)? Choose as many as apply.
   (*a*) Atoms. (*e*) Quarks.
   (*b*) Electrons. (*f*) Photon.
   (*c*) Protons. (*g*) Higgs boson.
   (*d*) Neutrons.
9. The electron's antiparticle is called the positron. Which of the following properties, if any, are the same for electrons and positrons?
   (*a*) Mass.
   (*b*) Charge.
   (*c*) Lepton number.
   (*d*) None of the above.
10. The strong nuclear force between a neutron and a proton is due to
    (*a*) the exchange of $\pi$ mesons between the neutron and the proton.
    (*b*) the conservation of baryon number.
    (*c*) the beta decay of the neutron into the proton.
    (*d*) the exchange of gluons between the quarks within the neutron and the proton.
    (*e*) Both (*a*) and (*d*) at different scales.
11. Electrons are still considered fundamental particles (in the group called leptons). But protons and neutrons are no longer considered fundamental; they have substructure and are made up of
    (*a*) pions. (*c*) quarks. (*e*) photons.
    (*b*) leptons. (*d*) bosons.
12. Which of the following will interact via the weak nuclear force *only*?
    (*a*) Quarks. (*e*) Electrons.
    (*b*) Gluons. (*f*) Muons.
    (*c*) Neutrons. (*g*) Higgs boson.
    (*d*) Neutrinos.
13. Which of the following conservation laws are not obeyed for some types of interaction?
    (*a*) Conservation of strangeness.
    (*b*) Conservation of energy.
    (*c*) Conservation of charge.
    (*d*) Conservation of momentum.
    (*e*) None of the above.
14. Which of the following are not leptons?
    (*a*) Neutrinos.
    (*b*) Electrons.
    (*c*) Mesons.
    (*d*) Positrons.

# Problems

## 43–1 Particles and Accelerators

1. (I) What is the total energy of a proton whose kinetic energy is 5.25 GeV?
2. (I) Calculate the wavelength of 24-GeV electrons.
3. (I) If $\alpha$ particles are accelerated by the cyclotron of Example 43–2, what must be the frequency of the voltage applied to the dees?
4. (I) What is the time for one complete revolution for a very high-energy proton in the 27-km LHC circumference?
5. (II) What strength of magnetic field is used in a cyclotron in which protons make $3.5 \times 10^7$ revolutions per second?

6. (II) (*a*) If the cyclotron of Example 43–2 accelerated $\alpha$ particles, what maximum energy could they attain? What would their speed be? (*b*) Repeat for deuterons $\left({}^{2}_{1}\mathrm{H}\right)$. (*c*) In each case, what frequency of voltage is required?

7. (II) Which is better for resolving details of the nucleus: 25-MeV alpha particles or 25-MeV protons? Compare each of their wavelengths with the size of a nucleon in a nucleus.

8. (II) What is the wavelength (= minimum resolvable size) of 6.5-TeV protons at the LHC?

9. (II) The 1.0-km radius Fermilab Tevatron took about 20 seconds to bring the energies of the stored protons from 150 GeV to 1.0 TeV. The acceleration was done once per turn. Estimate the energy given to the protons on each turn. (You can assume that the speed of the protons is essentially $c$ the whole time.)

10. (II) If $2 \times 10^{14}$ protons moving at $v \approx c$, with $K = 6.5\text{TeV}$, are stored in the 4.3-km-radius ring of the LHC, (*a*) how much current (amperes) is carried by this beam? (*b*) How fast would a 1600-kg car have to move to carry the same kinetic energy as this beam?

11. (II) Protons are injected into the 4.3-km-radius Large Hadron Collider with an energy of 450 GeV. If they are accelerated by 8.0 MV each revolution, how far do they travel and approximately how much time does it take for them to reach 6.5 TeV?

12. (II) What magnetic field is required for 6.5-TeV protons in the 4.25-km-radius Large Hadron Collider (LHC)? [Use relativity.]

13. (II) A cyclotron with a radius of 1.0 m is to accelerate deuterons $\left({}^{2}_{1}\mathrm{H}\right)$ to an energy of 14 MeV. (*a*) What is the required magnetic field? (*b*) What frequency is needed for the voltage between the dees? (*c*) If the potential difference between the dees averages 22 kV, how many revolutions will the particles make before exiting? (*d*) How much time does it take for one deuteron to go from start to exit? (*e*) Estimate how far it travels during this time.

14. (II) Show that the energy of a particle (charge $e$) in a synchrotron, in the relativistic limit $(v \approx c)$, is given by $E\ (\text{in eV}) = Brc$, where $B$ is the magnetic field and $r$ is the radius of the orbit (SI units).

## 43–2 to 43–6 Particle Interactions, Particle Exchange

15. (I) About how much energy is released when a $\Lambda^0$ decays to $\mathrm{n} + \pi^0$? (See Table 43–2.)

16. (I) How much energy is released in the decay

$$\pi^+ \rightarrow \mu^+ + \nu_\mu ?$$

See Table 43–2.

17. (I) Estimate the range of the strong force if the mediating particle were the kaon instead of a pion.

18. (I) How much energy is required to produce a neutron–antineutron pair?

19. (II) Determine the total energy released when $\Sigma^0$ decays to $\Lambda^0$ and then to a proton.

20. (II) Two protons collide while heading toward each other with equal speeds. What minimum kinetic energy must each have if a $\pi^0$ meson is to be created in the process? (See Table 43–2.)

21. (II) What minimum kinetic energy must a proton and an antiproton each have if they are traveling at the same speed toward each other, collide, and produce a $\mathrm{K^+K^-}$ pair in addition to themselves? (See Table 43–2.)

22. (II) What are the wavelengths of the two photons produced when a proton and an antiproton at rest annihilate?

23. (II) (*a*) How much energy is released when an electron and a positron annihilate each other? (*b*) How much energy is released when a proton and an antiproton annihilate each other? (All particles have $K \approx 0$.)

24. (II) What is the total energy of a proton whose kinetic energy is 12 GeV? What is its wavelength?

25. (II) The $\Lambda^0$ cannot decay by the following reactions. What conservation laws are violated in each of the reactions?
(*a*) $\Lambda^0 \not\rightarrow \mathrm{n} + \pi^-$ (*c*) $\Lambda^0 \not\rightarrow \pi^+ + \pi^-$
(*b*) $\Lambda^0 \not\rightarrow \mathrm{p} + \mathrm{K^-}$

26. (II) What would be the wavelengths of the two photons produced when an electron and a positron, each with 390 keV of kinetic energy, annihilate in a head-on collision?

27. (II) Which of the following reactions and decays are possible? For those forbidden, explain what laws are violated.
(a) $\pi^- + \mathrm{p} \rightarrow \mathrm{n} + \eta^0$ (d) $\mathrm{p} \rightarrow \mathrm{e^+} + \nu_\mathrm{e}$
(b) $\pi^+ + \mathrm{p} \rightarrow \mathrm{n} + \pi^0$ (e) $\mu^+ \rightarrow \mathrm{e^+} + \bar{\nu}_\mu$
(c) $\pi^+ + \mathrm{p} \rightarrow \mathrm{p} + \mathrm{e^+}$ (*f*) $\mathrm{p} \rightarrow \mathrm{n} + \mathrm{e^+} + \nu_\mathrm{e}$

28. (II) Antiprotons can be produced when a proton with sufficient energy hits a stationary proton. Even if there is enough energy, which of the following reactions will not happen?

$$\mathrm{p} + \mathrm{p} \rightarrow \mathrm{p} + \bar{\mathrm{p}}$$
$$\mathrm{p} + \mathrm{p} \rightarrow \mathrm{p} + \mathrm{p} + \bar{\mathrm{p}}$$
$$\mathrm{p} + \mathrm{p} \rightarrow \mathrm{p} + \mathrm{p} + \mathrm{p} + \bar{\mathrm{p}}$$
$$\mathrm{p} + \mathrm{p} \rightarrow \mathrm{p} + \mathrm{e^+} + \mathrm{e^+} + \bar{\mathrm{p}}$$

29. (II) Calculate the kinetic energy of each of the two products in the decay $\Xi^- \rightarrow \Lambda^0 + \pi^-$. Assume the $\Xi^-$ decays from rest.

30. (II) In the rare decay $\pi^+ \rightarrow \mathrm{e^+} + \nu_\mathrm{e}$, what is the kinetic energy of the positron? Assume the $\pi^+$ decays from rest and $m_\nu = 0$.

31. (III) For the decay $\Lambda^0 \rightarrow \mathrm{p} + \pi^-$, calculate (*a*) the $Q$-value (energy released), and (*b*) the kinetic energy of the p and $\pi^-$, assuming the $\Lambda^0$ decays from rest. (Use relativistic formulas.)

32. (III) Calculate the maximum kinetic energy of the electron when a muon decays from rest via $\mu^- \rightarrow \mathrm{e^-} + \bar{\nu}_\mathrm{e} + \nu_\mu$. [*Hint*: In what direction do the two neutrinos move relative to the electron in order to give the electron the maximum kinetic energy? Both energy and momentum are conserved; use relativistic formulas.]

33. (III) Could a $\pi^+$ meson be produced if a 130-MeV proton struck a proton at rest? What minimum kinetic energy must the incoming proton have?

## 43–7 to 43–11 Resonances, Standard Model, Quarks, QCD, GUT

34. (I) The mean life of the $\Sigma^0$ particle is $7 \times 10^{-20}$ s. What is the uncertainty in its rest energy? Express your answer in MeV.

35. (I) The measured width of the $\psi$ (3686) meson is about 300 keV. Estimate its mean life.

36. (I) The measured width of the $\mathrm{J}/\psi$ meson is 88 keV. Estimate its mean life.

37. (I) The $\mathrm{B^-}$ meson is a $\mathrm{b\bar{u}}$ quark combination. (*a*) Show that this is consistent for all quantum numbers. (*b*) What are the quark combinations for $\mathrm{B^+}$, $\mathrm{B^0}$, $\mathrm{\bar{B}^0}$?

38. (I) What is the energy width (or uncertainty) of (*a*) $\eta^0$, and (*b*) $\rho^+$? See Table 43–2.

39. (II) Which of the following decays are possible? For those that are forbidden, explain which laws are violated.
(*a*) $\Xi^0 \rightarrow \Sigma^+ + \pi^-$ (*c*) $\Sigma^0 \rightarrow \Lambda^0 + \gamma + \gamma$
(*b*) $\Omega^- \rightarrow \Sigma^0 + \pi^- + \nu$

**40.** (II) Calculate the $Q$-value for each of the reactions, Eq. 43–4, for producing a pion.

**41.** (II) In ordinary radioactive decay, a W particle may be created even though the decaying particle has less mass than the W particle. If you assume $\Delta E \approx$ mass of the virtual W, what is the expected lifetime of the W?

**42.** (II) What quark combinations produce (*a*) a $\Xi^0$ baryon and (*b*) a $\Xi^-$ baryon?

**43.** (II) What are the quark combinations that can form (*a*) a neutron, (*b*) an antineutron, (*c*) a $\Lambda^0$, (*d*) a $\overline{\Sigma}^0$?

**44.** (II) What particles do the following quark combinations produce: (*a*) uud, (*b*) $\bar{u}\,\bar{u}\,\bar{s}$, (*c*) $\bar{u}s$, (*d*) $d\bar{u}$, (*e*) $\bar{c}s$?

**45.** (II) What is the quark combination needed to produce a $D^0$ meson ($Q = B = S = 0, \quad c = +1$)?

**46.** (II) The $D_S^+$ meson has $S = c = +1, \quad B = 0$. What quark combination would produce it?

**47.** (II) Draw a possible Feynman diagram using quarks (as in Fig. 43–17c) for the reaction $\pi^- + p \rightarrow \pi^0 + n$.

**48.** (II) Draw a Feynman diagram for the reaction $n + \nu_\mu \rightarrow p + \mu^-$.

# General Problems

**49.** The mean lifetimes listed in Table 43–2 are in terms of *proper time*, measured in a reference frame where the particle is at rest. If a tau lepton is created with a kinetic energy of 920 MeV, how long would its track be as measured in the lab, on average, ignoring any collisions?

**50.** Which of the following reactions are possible, and by what interaction could they occur? For those forbidden, explain why.
(a) $\pi^- + p \rightarrow K^0 + p + \pi^0$
(b) $K^- + p \rightarrow \Lambda^0 + \pi^0$
(c) $K^+ + n \rightarrow \Sigma^+ + \pi^0 + \gamma$
(d) $K^+ \rightarrow \pi^0 + \pi^0 + \pi^+$
(e) $\pi^+ \rightarrow e^+ + \nu_e$

**51.** Which of the following reactions are possible, and by what interaction could they occur? For those forbidden, explain why.
(*a*) $\pi^- + p \rightarrow K^+ + \Sigma^-$
(*b*) $\pi^+ + p \rightarrow K^+ + \Sigma^+$
(*c*) $\pi^- + p \rightarrow \Lambda^0 + K^0 + \pi^0$
(*d*) $\pi^+ + p \rightarrow \Sigma^0 + \pi^0$
(*e*) $\pi^- + p \rightarrow p + e^- + \bar{\nu}_e$

**52.** One decay mode for a $\pi^+$ is $\pi^+ \rightarrow \mu^+ + \nu_\mu$. What would be the equivalent decay for a $\pi^-$? Check conservation laws.

**53.** Symmetry breaking occurs in the electroweak theory at about $10^{-18}$ m. Show that this corresponds to an energy that is on the order of the mass of the $W^\pm$.

**54.** How many fundamental fermions are there in a water molecule?

**55.** Use the quark model to describe the reaction

$$\bar{p} + n \rightarrow \pi^- + \pi^0.$$

**56.** Identify the missing particle in the following reactions.
(*a*) $p + p \rightarrow p + n + \pi^+ + ?$ (*b*) $p + ? \rightarrow n + \mu^+$

**57.** The mass of a $\pi^0$ can be measured by observing the reaction $\pi^- + p \rightarrow \pi^0 + n$ with initial kinetic energy near zero. The neutron is observed to be emitted with a kinetic energy of 0.60 MeV. Use conservation of energy and momentum to determine the $\pi^0$ mass.

**58.** (*a*) Show that the so-called unification distance of $10^{-31}$ m in grand unified theory is equivalent to an energy of about $10^{16}$ GeV. Use the uncertainty principle, and also de Broglie's wavelength formula, and explain how they apply. (*b*) Calculate the temperature corresponding to $10^{16}$ GeV.

**59.** Calculate the $Q$-value for the reaction $\pi^- + p \rightarrow \Lambda^0 + K^0$, when negative pions strike stationary protons. Estimate the minimum pion kinetic energy needed to produce this reaction. [*Hint*: Assume $\Lambda^0$ and $K^0$ move off with the same velocity.]

**60.** A proton and an antiproton annihilate each other at rest and produce two pions, $\pi^-$ and $\pi^+$. What is the kinetic energy of each pion?

**61.** For the reaction $p + p \rightarrow 3p + \bar{p}$, where one of the initial protons is at rest, use relativistic formulas to show that the threshold energy is $6m_p c^2$, equal to three times the magnitude of the $Q$-value of the reaction, where $m_p$ is the proton mass. [*Hint*: Assume all final particles have the same velocity.]

**62.** At about what kinetic energy (in eV) can the rest energy of a proton be ignored when calculating its wavelength, if the wavelength is to be within 2.0% of its true value? What are the corresponding wavelength and speed of the proton?

**63.** What fraction of the speed of light $c$ is the speed of a 6.0-TeV proton?

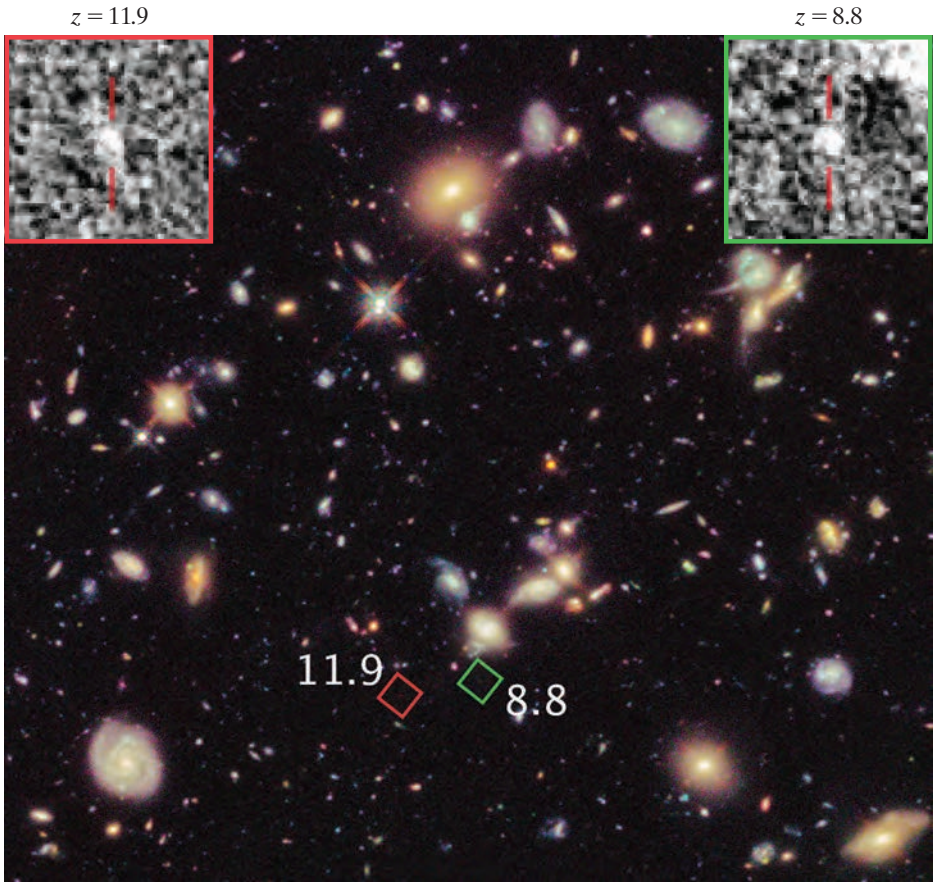
**64.** Using the information in Section 43–1, show that the Large Hadron Collider's two colliding proton beams can resolve details that are less than 1/10,000 the size of a nucleus.

**65.** Searches are underway for a process called **neutrinoless double beta decay**, in which a nucleus decays by emitting two electrons. (*a*) If the parent nucleus is $^{96}_{40}$Zr, what would the daughter nucleus be? (*b*) What conservation laws would be violated during this decay? (*c*) How could $^{96}_{40}$Zr decay to the same daughter nucleus without violating any conservation laws?

**66.** Estimate the lifetime of the Higgs boson from the width of the "bump" in Fig. 43–19, using the uncertainty principle. [Note: This is not a realistic estimate because the underlying processes are very complicated.]

**67.** Show that all conservation laws hold for all the decays described in Fig. 43–15 for the decays of the top quark.

**68.** The Higgs boson, Section 43–10, has very probably been detected at the CERN LHC. (*a*) If a Higgs boson at rest decays into two tau leptons, what is the kinetic energy of each tau? Follow the analysis of Example 43–6. See Table 43–2. (*b*) What are the signs of the electric charges of the two tau leptons? (*c*) Could a Higgs boson decay into two Z bosons (Table 43–2)?



**69.** (*a*) Show, by conserving momentum and energy, that it is impossible for an isolated electron to radiate only a single photon. (*b*) With this result in mind, how can you defend the photon exchange diagram in Fig. 43–8?

**70.** A particle at rest, with a rest energy of $mc^2$, decays into two fragments with rest energies of $m_1 c^2$ and $m_2 c^2$. Show that the kinetic energy of fragment 1 is

$$K_1 = \frac{1}{2mc^2}\left[(mc^2 - m_1 c^2)^2 - (m_2 c^2)^2\right].$$

## ANSWERS TO EXERCISES

**A:** $1.24 \times 10^{-18}$ m = 1.24 am.
**B:** (*a*).
**C:** (*c*); (*d*).
**D:** $s\bar{u}$.

This Hubble eXtreme Deep Field (XDF) photograph is of a very small part of the sky. It includes what may be the most distant galaxies observable by us (small red and green squares, and shown enlarged in the corners), with $z \approx 8.8$ and 11.9, that already existed when the universe was about 0.4 billion years old. We see these galaxies as they appeared then, 13.4 billion years ago, which is when they emitted this light. The most distant galaxies were young and small and grew to become large galaxies by colliding and merging with other small galaxies.

We examine the latest theories on how stars and galaxies form and evolve, including the role of nucleosynthesis, as well as Einstein's general theory of relativity which deals with gravity and curvature of space. We take a thorough look at the evidence for the expansion of the universe, and the Standard Model of the universe evolving from an initial Big Bang. We point out some unsolved problems, including the nature of dark matter and dark energy that make up most of our universe.

CHAPTER 44

# Astrophysics and Cosmology

## CONTENTS

44 – 1 Stars and Galaxies
44 – 2 Stellar Evolution: Birth and Death of Stars, Nucleosynthesis
44 – 3 Distance Measurements
44 – 4 General Relativity: Gravity and the Curvature of Space
44 – 5 The Expanding Universe: Redshift and Hubble's Law
44 – 6 The Big Bang and the Cosmic Microwave Background
44 – 7 The Standard Cosmological Model: Early History of the Universe
44 – 8 Inflation: Explaining Flatness, Uniformity, and Structure
44 – 9 Dark Matter and Dark Energy
44–10 Large-Scale Structure of the Universe
44–11 Gravitational Waves—LIGO
44–12 Finally …

## CHAPTER-OPENING QUESTIONS—Guess now!

**1.** Until recently, astronomers expected the expansion rate of the universe would be decreasing. Why?

**(a)** Friction.
**(b)** The second law of thermodynamics.
**(c)** Gravity.
**(d)** The electromagnetic force.

**2.** The universe began expanding right at the beginning. How long will it continue to expand?

**(a)** Until it runs out of room.
**(b)** Until friction slows it down and brings it to a stop.
**(c)** Until all galaxies are moving at the speed of light relative to the center.
**(d)** Possibly forever.

In the previous Chapter, we studied the tiniest objects in the universe—the elementary particles. Now we leap to the grandest objects in the universe—stars, galaxies, and clusters of galaxies—plus the history and structure of the universe itself. These two extreme realms, elementary particles and the cosmos, are among the most intriguing and exciting subjects in science. And, surprisingly, these two extreme realms are related in a fundamental way, as was already hinted in Chapter 43.

Use of the techniques and ideas of physics to study the night sky is often referred to as **astrophysics**. Central to our present theoretical understanding of the universe (or cosmos) is Einstein's *general theory of relativity* which represents our most complete understanding of gravitation. Many other aspects of physics are involved, from electromagnetism and thermodynamics to atomic and nuclear physics as well as elementary particles. General Relativity serves also as the foundation for modern **cosmology**, which is the study of the universe as a whole. Cosmology deals especially with the search for a theoretical framework to understand the observed universe, its origin, and its future. The questions posed by cosmology are profound and difficult; the possible answers stretch the imagination. They are questions like "Has the universe always existed, or did it have a beginning in time?" Either alternative is difficult to imagine: time going back indefinitely into the past, or an actual moment when the universe began (but, then, what was there before?). And what about the size of the universe? Is it infinite in size? It is hard to imagine infinity. Or is it finite in size? This is also hard to imagine, for if the universe is finite, it does not make sense to ask what is beyond it, because the universe is all there is.

During the last 20 years, so much progress has occurred in astrophysics and cosmology that many scientists are calling recent work a "Golden Age" for cosmology. Our survey will be qualitative, but we will nonetheless touch on the major ideas. We begin with a look at what can be seen beyond the Earth.

## 44–1 Stars and Galaxies

According to the ancients, the stars, except for the few that seemed to move relative to the others (the planets), were fixed on a sphere beyond the last planet. The universe was neatly self-contained, and we on Earth were at or near its center. But in the centuries following Galileo's first telescopic observations of the night sky in 1609, our view of the universe has changed dramatically. We no longer place ourselves at the center, and we view the universe as vastly larger. The distances involved are so great that we specify them in terms of the time it takes light to travel the given distance: for example,

$$1 \text{ light-second} = (3.0 \times 10^8 \text{ m/s})(1.0 \text{ s}) = 3.0 \times 10^8 \text{ m} = 300{,}000 \text{ km};$$

$$1 \text{ light-minute} = (3.0 \times 10^8 \text{ m/s})(60 \text{ s}) = 18 \times 10^6 \text{ km}.$$

The most common unit is the **light-year** (ly):

$$\begin{aligned} 1 \text{ ly} &= (2.998 \times 10^8 \text{ m/s})(3.156 \times 10^7 \text{ s/yr}) \\ &= 9.46 \times 10^{15} \text{ m} \approx 10^{16} \text{ m} \\ &\approx 10^{13} \text{ km}. \end{aligned}$$

For specifying distances to the Sun and Moon, we usually use meters or kilometers, but we could specify them in terms of light-seconds or -minutes. The Earth–Moon distance is 384,000 km, which is 1.28 light-seconds. The Earth–Sun distance is $1.50 \times 10^{11}$ m, or 150,000,000 km; this is equal to 8.3 light-minutes (it takes 8.3 min for light emitted by the Sun to reach us). Far out in our solar system, Pluto is about $6 \times 10^9$ km from the Sun, or $6 \times 10^{-4}$ ly.† The nearest star to us, other than the Sun, is Proxima Centauri, about 4.2 ly away.

On a clear moonless night, thousands of stars of varying degrees of brightness can be seen, as well as the long cloudy stripe known as the Milky Way (Fig. 44–1). Galileo first observed, with his telescope, that the Milky Way is comprised of countless individual stars. A century and a half later (about 1750), Thomas Wright suggested that the Milky Way was a flat disk of stars extending to great distances in a plane, which we call the **Galaxy** (Greek for "milky way").

†We can also say this is about 5 light-hours.

(a)

(b)

**FIGURE 44–1** Sections of the Milky Way. In (a), the thin line is the trail of an artificial Earth satellite in this long time exposure. The dark diagonal area is due to dust absorption of visible light, blocking the view. In (b) the view is toward the center of the Galaxy (taken in summer from Arizona).

Our Galaxy has a diameter of about 100,000 light-years and a thickness of roughly 2000 ly. It has a central bulge ($\approx$ 10,000 ly in diameter) very tightly packed with stars, and spiral arms (Fig. 44–2). Our Sun, which is a star like many others, is located about halfway from the galactic center to the edge, some 28,000 ly from the center. Our Galaxy contains roughly 200 to 400 billion $(4 \times 10^{11})$ stars. The Sun orbits the galactic center approximately once every 250 million years, so its speed is roughly 200 km/s relative to the center of the Galaxy. The total mass of all the stars in our Galaxy is estimated to be about $4 \times 10^{42}$ kg of ordinary matter. There is also strong evidence that our Galaxy is permeated and surrounded by a massive invisible "halo" of "dark matter" (Section 44–9) that extends almost $10^6$ ly from the center. At the center there seems to be a supermassive black hole whose mass is $4 \times 10^6$ times the mass of our Sun.

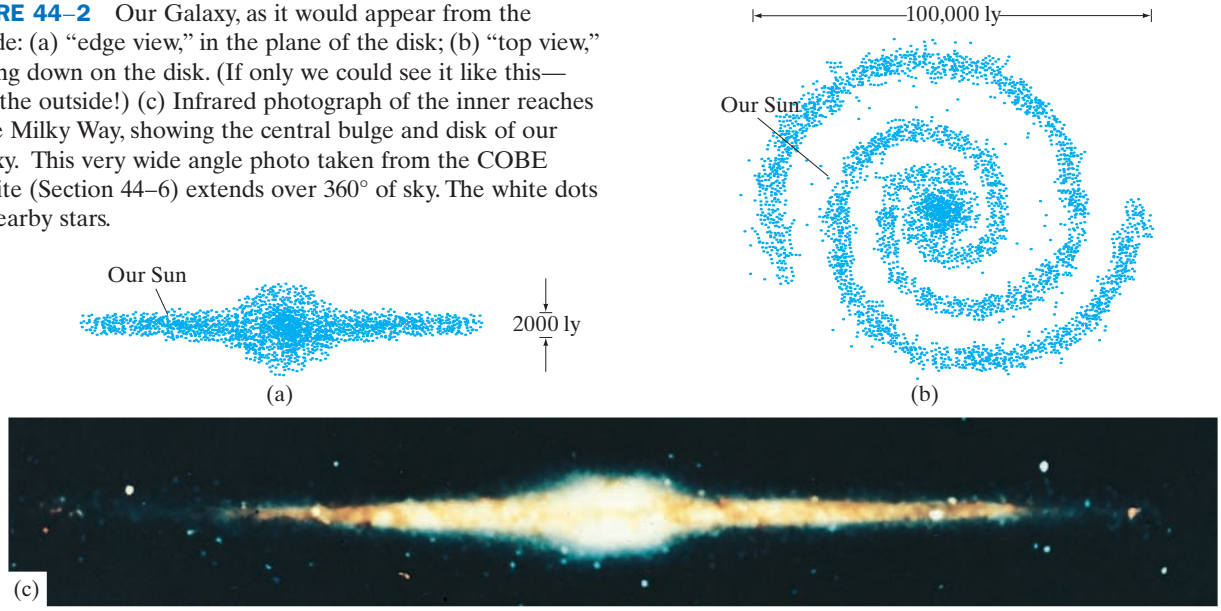


**FIGURE 44–2** Our Galaxy, as it would appear from the outside: (a) "edge view," in the plane of the disk; (b) "top view," looking down on the disk. (If only we could see it like this—from the outside!) (c) Infrared photograph of the inner reaches of the Milky Way, showing the central bulge and disk of our Galaxy. This very wide angle photo taken from the COBE satellite (Section 44–6) extends over 360° of sky. The white dots are nearby stars.

**EXAMPLE 44–1** **ESTIMATE** **Our Galaxy's mass.** Estimate the total mass of our Galaxy using the orbital data above for the Sun about the center of the Galaxy. Assume the mass of the Galaxy is concentrated in the central bulge.

**APPROACH** We assume that the Sun (including our solar system) has total mass $m$ and moves in a circular orbit about the center of the Galaxy (total mass $M$), and that the mass $M$ can be considered as being located at the center of the Galaxy. We then apply Newton's second law, $F = ma$, with $a$ being the centripetal acceleration, $a = v^2/r$, and for $F$ we use the universal law of gravitation (Chapter 6).

**SOLUTION** Our Sun and solar system orbit the center of the Galaxy, according to the best measurements as mentioned above, with a speed of about $v = 200$ km/s at a distance from the Galaxy center of about $r = 26{,}000$ ly. We use Newton's second law:

$$F = ma$$

$$G\frac{Mm}{r^2} = m\frac{v^2}{r}$$

where $M$ is the mass of the Galaxy and $m$ is the mass of our Sun and solar system. Solving this, we find

$$M = \frac{rv^2}{G} \approx \frac{(26{,}000\text{ ly})(10^{16}\text{ m/ly})(2 \times 10^5\text{ m/s})^2}{6.67 \times 10^{-11}\text{ N}\cdot\text{m}^2/\text{kg}^2} \approx 2 \times 10^{41}\text{ kg}.$$

**NOTE** In terms of *numbers* of stars, if they are like our Sun $(m = 2.0 \times 10^{30}\text{ kg})$, there would be about $(2 \times 10^{41}\text{ kg})/(2 \times 10^{30}\text{ kg}) \approx 10^{11}$ or very roughly on the order of 100 billion stars.

PSE5_CH44_v1.6_23Jun-20

In addition to stars both within and outside the Milky Way, we can see by telescope many faint cloudy patches in the sky which were all referred to once as "nebulae" (Latin for "clouds"). A few of these, such as those in the constellations Andromeda and Orion, can actually be discerned with the naked eye on a clear night. Some are **star clusters** (Fig. 44–3), groups of stars that are so numerous they appear to be a cloud. Others are glowing clouds of gas or dust (Fig. 44–4), and it is for these that we now mainly reserve the word **nebula**.

Most fascinating are those that belong to a third category: they often have fairly regular elliptical shapes. Immanuel Kant (about 1755) guessed they are faint because they are a great distance beyond our Galaxy. At first it was not universally accepted that these objects were **extragalactic**—that is, outside our Galaxy. But the very large telescopes constructed in the twentieth century revealed that individual stars could be resolved within these extragalactic objects and that many contain spiral arms. Edwin Hubble (1889–1953) did much of this observational work in the 1920s using the 2.5-m (100-inch) telescope[†] on Mt. Wilson near Los Angeles, California, then the world's largest. Hubble demonstrated that these objects were indeed extragalactic because of their great distances. The distance to our nearest large galaxy,[‡] Andromeda, is over 2 million light-years, a distance 20 times greater than the diameter of our Galaxy. It seemed logical that these nebulae must be **galaxies** similar to ours. (Note that it is usual to capitalize the word "galaxy" only when it refers to our own.) Today it is thought there are roughly $10^{11}$ galaxies in the observable universe—that is, roughly as many galaxies as there are stars in a galaxy. See Fig. 44–5.

Many galaxies tend to be grouped in **galaxy clusters** held together by their mutual gravitational attraction. There may be anywhere from a few dozen to many thousands of galaxies in each cluster. Furthermore, clusters themselves seem to be organized into even larger aggregates: clusters of clusters of galaxies, or **superclusters**.

**FIGURE 44–3** This globular star cluster is located in the constellation Hercules.

**FIGURE 44–4** This gaseous nebula, found in the constellation Carina, is about 9000 light-years from us.

(a) (b) (c)

**FIGURE 44–5** Photographs of galaxies. (a) Spiral galaxy in the constellation Hydra. (b) Two galaxies: the larger and more dramatic one is known as the Whirlpool galaxy. (c) An infrared image (given "false" colors) of the same galaxies as in (b), here showing the arms of the spiral as having more substance than in the visible light photo (b); the different colors correspond to different light intensities. Visible light is scattered and absorbed by interstellar dust much more than infrared is, so infrared gives us a clearer image.

[†]2.5 m (= 100 inches) refers to the diameter of the curved objective mirror. The bigger the mirror, the more light it collects (greater brightness) and the less diffraction there is (better resolution), so more and fainter stars can be seen. See Chapters 33 and 35. Until recently, photographic films or plates were used to take long time exposures. Now large solid-state CCD or CMOS sensors (Section 33–5) are available containing hundreds of millions of pixels (compared to 10 million pixels in a good-quality digital camera).

[‡]The *Magellanic clouds* are much closer than Andromeda, but are small and are usually considered small satellite galaxies of our own Galaxy.

**TABLE 44–1 Astronomical Distances**

| Object | Approx. Distance from Earth (ly) |
|---|---|
| Moon | $4 \times 10^{-8}$ |
| Sun | $1.6 \times 10^{-5}$ |
| Size of solar system (distance to Pluto) | $6 \times 10^{-4}$ |
| Nearest star (Proxima Centauri) | 4.2 |
| Center of our Galaxy | $2.6 \times 10^{4}$ |
| Nearest large galaxy | $2.4 \times 10^{6}$ |
| Farthest galaxies | $13.4 \times 10^{9}$ |

The farthest detectable galaxies are more than $10^{10}$ ly distant. See Table 44–1.

**CONCEPTUAL EXAMPLE 44–2** **Looking back in time.** Astronomers often think of their telescopes as time machines, looking back toward the origin of the universe. How far back do they look?

**RESPONSE** The distance in light-years measures how long in years the light has been traveling to reach us, so Table 44–1 tells us also how far back in time we are looking. For example, if we saw Proxima Centauri explode into a supernova today, then the event would have really occurred about 4.2 years ago. The most distant galaxies emitted the light we see now roughly $13 \times 10^9$ years ago. What we see was how they were then, $13 \times 10^9$ yr ago.

**EXERCISE A** Suppose we could place a huge mirror 1 light-year away from us. What would we see in this mirror if it is facing us on Earth? When did what we see in the mirror take place? (This might be called a "time machine.")

Besides the usual stars, clusters of stars, galaxies, and clusters and super-clusters of galaxies, the universe contains many other interesting objects. Among these are stars known as *red giants, white dwarfs, neutron stars*, exploding stars called *novae* and *supernovae*, and *black holes* whose gravity is so strong that even light cannot escape them. In addition, there is electromagnetic radiation that reaches the Earth but does not come from the bright pointlike objects we call stars: particularly important is the microwave background radiation that arrives nearly uniformly from all directions in the universe.

Finally, there are **active galactic nuclei** (**AGN**), which are very luminous point-like sources of light in the centers of distant galaxies. The most dramatic examples of AGN are **quasars** ("quasistellar objects" or QSOs), which are so luminous that the surrounding starlight of the galaxy is drowned out. Their luminosity is thought to come from matter falling into a giant black hole at a galaxy's center.

## 44–2 Stellar Evolution: Birth and Death of Stars, Nucleosynthesis

The stars appear unchanging. Night after night the night sky reveals no significant variations. Indeed, on a human time scale, the vast majority of stars change very little (except for novae, supernovae, and certain variable stars). Although stars *seem* fixed in relation to each other, many move sufficiently for the motion to be detected. Speeds of stars relative to neighboring stars can be hundreds of km/s, but at their great distance from us, this motion is detectable only by careful measurement. There is also a great range of brightness among stars, due to differences in the rate stars emit energy and to their different distances from us.

### Luminosity and Brightness of Stars

Any star or galaxy has an **intrinsic luminosity**, $L$ (or simply **luminosity**), which is its total power radiated in watts. Also important is the **apparent brightness**, $b$, defined as the power crossing unit area at the Earth perpendicular to the path of the light. Given that energy is conserved, and ignoring any absorption in space, the total emitted power $L$ when it reaches a distance $d$ from the star will be spread over a sphere of surface area $4\pi d^2$. If $d$ is the distance from the star to the Earth, then $L$ must be equal to $4\pi d^2$ times $b$ (power per unit area at Earth). That is,

$$b = \frac{L}{4\pi d^2}. \qquad \textbf{(44–1)}$$

PSE5_CH44_v1.6_23Jun-20

**EXAMPLE 44–3** **Apparent brightness.** Suppose a star has luminosity equal to that of our Sun. If it is 10 ly away from Earth, how much dimmer will it appear?

**APPROACH** We use the inverse square law in Eq. 44–1 to determine the relative brightness $(b \propto 1/d^2)$ since the luminosity $L$ is the same for both stars.

**SOLUTION** Using the inverse square law, the star appears dimmer by a factor

$$\frac{b_{\text{star}}}{b_{\text{Sun}}} = \frac{d_{\text{Sun}}^2}{d_{\text{star}}^2} = \frac{(1.5 \times 10^8\,\text{km})^2}{(10\,\text{ly})^2(10^{13}\,\text{km/ly})^2} \approx 2 \times 10^{-12}.$$

Careful study of nearby stars has shown that the luminosity for most stars depends on the mass: *the more massive the star, the greater its luminosity*.† Another important parameter of a star is its surface temperature, which can be determined from the spectrum of electromagnetic frequencies it emits. As we saw in Chapter 37, as the temperature of a body increases, the spectrum shifts from predominantly lower frequencies (and longer wavelengths, such as red) to higher frequencies (and shorter wavelengths such as blue). Quantitatively, the relation is given by Wien's law (Eq. 37–1): the wavelength $\lambda_P$ at the peak of the spectrum of light emitted by a blackbody (we often approximate stars as blackbodies) is inversely proportional to its Kelvin temperature $T$; that is, $\lambda_P T = 2.90 \times 10^{-3}\,\text{m} \cdot \text{K}$. The surface temperatures of stars typically range from about 3000 K (reddish) to about 50,000 K (UV).

**EXAMPLE 44–4** **Determining star temperature and star size.** Suppose that the distances from Earth to two nearby stars can be reasonably estimated, and that their measured apparent brightnesses suggest the two stars have about the same luminosity, $L$. The spectrum of one of the stars peaks at about 700 nm (so it is reddish). The spectrum of the other peaks at about 350 nm (bluish). Use Wien's law (Eq. 37–1) and the Stefan-Boltzmann equation (Section 19–10) to determine (*a*) the surface temperature of each star, and (*b*) how much larger one star is than the other.

**APPROACH** We determine the surface temperature $T$ for each star using Wien's law and each star's peak wavelength. Then, using the Stefan-Boltzmann equation (power output or luminosity $\propto AT^4$ where $A$ = surface area of emitter), we can find the surface area ratio and relative sizes of the two stars.

**SOLUTION** (*a*) Wien's law (Eq. 37–1) states that $\lambda_P T = 2.90 \times 10^{-3}\,\text{m} \cdot \text{K}$. So the temperature of the reddish star is

$$T_r = \frac{2.90 \times 10^{-3}\,\text{m} \cdot \text{K}}{\lambda_P} = \frac{2.90 \times 10^{-3}\,\text{m} \cdot \text{K}}{700 \times 10^{-9}\,\text{m}} = 4140\,\text{K}.$$

The temperature of the bluish star will be double this because its peak wavelength is half (350 nm vs. 700 nm):

$$T_b = 8280\,\text{K}.$$

(*b*) The Stefan-Boltzmann equation, Eq. 19–18, states that the power radiated *per unit area* of surface from a blackbody is proportional to the fourth power of the Kelvin temperature, $T^4$. The temperature of the bluish star is double that of the reddish star, so the bluish one must radiate $(T_b/T_r)^4 = 2^4 = 16$ times as much energy per unit area. But we are given that they have the same luminosity (the same total power output); so the surface area of the blue star must be $\frac{1}{16}$ that of the red one. The surface area of a sphere is $4\pi r^2$, so the radius of the reddish star is $\sqrt{16} = 4$ times larger than the radius of the bluish star (or $4^3 = 64$ times the volume).

†Applies to "main-sequence" stars (see next page). The mass of a star can be determined by observing its gravitational effects on other visible objects. Many stars are part of a cluster, the simplest being a binary star in which two stars orbit around each other, allowing their masses to be determined using rotational mechanics.

## H–R Diagram

An important astronomical discovery, made around 1900, was that for most stars, the color is related to the intrinsic luminosity and therefore to the mass. A useful way to present this relationship is by the so-called Hertzsprung–Russell (H–R) diagram. On the H–R diagram, the horizontal axis shows the surface temperature $T$ and the vertical axis is the luminosity $L$; each star is represented by a point on the diagram, Fig. 44–6. Most stars fall along the diagonal band termed the **main sequence**. Starting at the lower right we find the coolest stars: by Wien's law, $\lambda_P T = \text{constant}$, their light output peaks at long wavelengths, so they are reddish in color. They are also the least luminous and therefore of low mass. Farther up toward the left we find hotter and more luminous stars that are whitish, like our Sun. Still farther up we find even more luminous and more massive stars, bluish in color. Stars that fall on this diagonal band are called *main-sequence stars*. There are also stars that fall outside the main sequence. Above and to the right we find extremely large stars, with high luminosities but with low (reddish) color temperature: these are called **red giants**. At the lower left, there are a few stars of low luminosity but with high temperature: these are the **white dwarfs**.

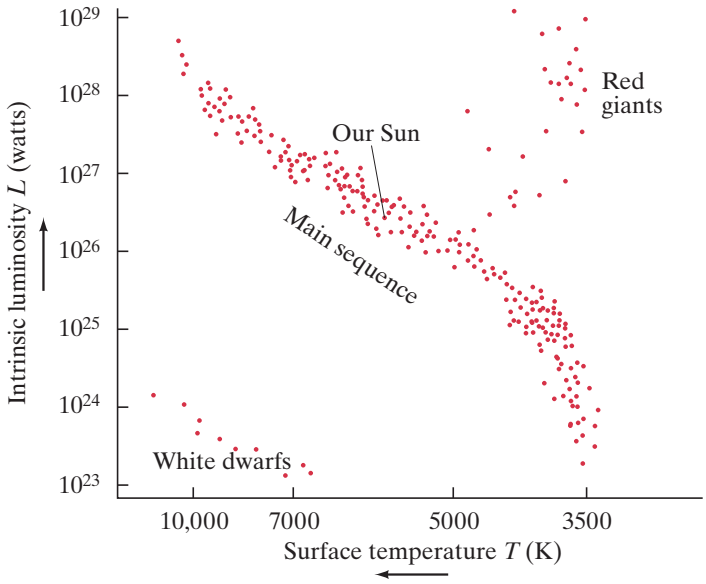

**FIGURE 44–6** Hertzsprung–Russell (H–R) diagram is a logarithmic graph of luminosity vs. surface temperature $T$ of stars (note that $T$ increases to the left).

**EXAMPLE 44–5** **ESTIMATE** **Distance to a star using the H–R diagram and color.** Suppose that detailed study of a certain star suggests that it most likely fits on the main sequence of an H–R diagram. Its measured apparent brightness is $b = 1.0 \times 10^{-12}\,\text{W/m}^2$, and the peak wavelength of its spectrum is $\lambda_P \approx 600\,\text{nm}$. Estimate its distance from us.

**APPROACH** We find the temperature using Wien's law, Eq. 37–1. The luminosity is estimated for a main-sequence star on the H–R diagram of Fig. 44–6, and then the distance is found using the relation between brightness and luminosity, Eq. 44–1.

**SOLUTION** The star's temperature, from Wien's law (Eq. 37–1), is

$$T \approx \frac{2.90 \times 10^{-3}\,\text{m}\cdot\text{K}}{600 \times 10^{-9}\,\text{m}} \approx 4800\,\text{K}.$$

A star on the main sequence of an H–R diagram at this temperature has luminosity of about $L \approx 1 \times 10^{26}\,\text{W}$, read off of Fig. 44–6. Then, from Eq. 44–1,

$$d = \sqrt{\frac{L}{4\pi b}} \approx \sqrt{\frac{1 \times 10^{26}\,\text{W}}{4(3.14)\left(1.0 \times 10^{-12}\,\text{W/m}^2\right)}} \approx 3 \times 10^{18}\,\text{m}.$$

Its distance from us in light-years is

$$d = \frac{3 \times 10^{18}\,\text{m}}{10^{16}\,\text{m/ly}} \approx 300\,\text{ly}.$$

**EXERCISE B** Estimate the distance to a 6000-K main-sequence star with an apparent brightness of $2.0 \times 10^{-12}\,\text{W/m}^2$.

## Stellar Evolution; Nucleosynthesis

Why are there different types of stars, such as red giants and white dwarfs, as well as main-sequence stars? Were they all born this way, in the beginning? Or might each different type represent a different age in the life cycle of a star? Astronomers and astrophysicists today believe the latter is the case. Note, however, that we cannot actually follow any but the tiniest part of the life cycle of any given star because they live for ages vastly greater than ours, on the order of millions or billions of years. Nonetheless, let us follow the process of **stellar evolution** from the birth to the death of a star, as astrophysicists have theoretically reconstructed it today.

Stars are born, it is believed, when gaseous clouds (mostly hydrogen) contract due to the pull of gravity. A huge gas cloud might fragment into numerous contracting masses, each mass centered in an area where the density is only slightly greater than that at nearby points. Once such "globules" form, gravity causes each to contract in toward its center of mass. As the particles of such a *protostar* accelerate inward, their kinetic energy increases. Eventually, when the kinetic energy is sufficiently high, the Coulomb repulsion between the positive charges is not strong enough to keep all the hydrogen nuclei apart, and nuclear fusion can take place.

In a star like our Sun, the fusion of hydrogen (sometimes referred to as "burning")[†] occurs mainly via the *proton–proton chain* (Section 42–4, Eqs. 42–7), in which four protons fuse to form a ${}^4_2\text{He}$ nucleus with the release of $\gamma$ rays, positrons, and neutrinos: $4\,{}^1_1\text{H} \rightarrow {}^4_2\text{He} + 2\text{e}^+ + 2\nu_\text{e} + 2\gamma$. These reactions require a temperature of about $10^7$ K, corresponding to an average kinetic energy ($\approx kT$) of about 1 keV (Eq. 18–4). In more massive stars, the carbon cycle produces the same net effect: four ${}^1_1\text{H}$ produce a ${}^4_2\text{He}$—see Section 42–4. The fusion reactions take place primarily in the core of a star, where $T$ may be on the order of $10^7$ to $10^8$ K. (The surface temperature is much lower—on the order of a few thousand kelvins.) The tremendous release of energy in these fusion reactions produces an outward pressure sufficient to halt the inward gravitational contraction. Our protostar, now really a young *star*, stabilizes on the *main sequence*. Exactly where the star falls along the main sequence depends on its mass. The more massive the star, the farther up (and to the left) it falls on the H–R diagram of Fig. 44–6. Our Sun required perhaps 30 million years to reach the main sequence, and is expected to remain there about 10 billion years ($10^{10}$ yr). Although most stars are billions of years old, evidence is strong that stars are actually being born at this moment. More massive stars have shorter lives, because they are hotter and the Coulomb repulsion is more easily overcome, so they use up their fuel faster. Our Sun may remain on the main sequence for $10^{10}$ years, but a star ten times more massive may reside there for only $10^7$ years.

As hydrogen fuses to form helium, the helium that is formed is denser and tends to accumulate in the central core where it was formed. As the core of helium grows, hydrogen continues to fuse in a shell around it: see Fig. 44–7. When much of the hydrogen within the core has been consumed, the production of energy decreases at the center and is no longer sufficient to prevent the huge gravitational forces from once again causing the core to contract and heat up. The hydrogen in the shell around the core then fuses even more fiercely because of this rise in temperature, allowing the outer envelope of the star to expand and to cool. The surface temperature, thus reduced, produces a spectrum of light that peaks at longer wavelength (reddish).

[†]The word "burn," meaning fusion, is put in quotation marks because these high-temperature fusion reactions occur via a *nuclear* process, and must not be confused with ordinary burning (of, say, paper, wood, or coal) in air, which is a *chemical* reaction, occurring at the *atomic* level (and at a much lower temperature).

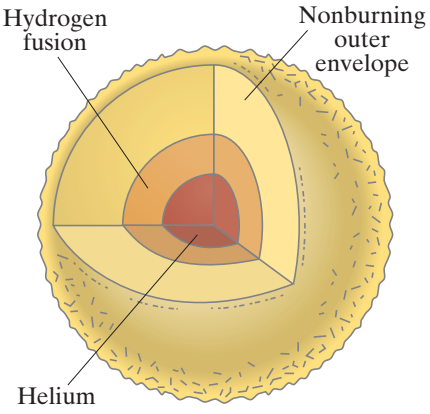

**FIGURE 44–7** A shell of "burning" hydrogen (fusing to become helium) surrounds the core where the newly formed helium gravitates.

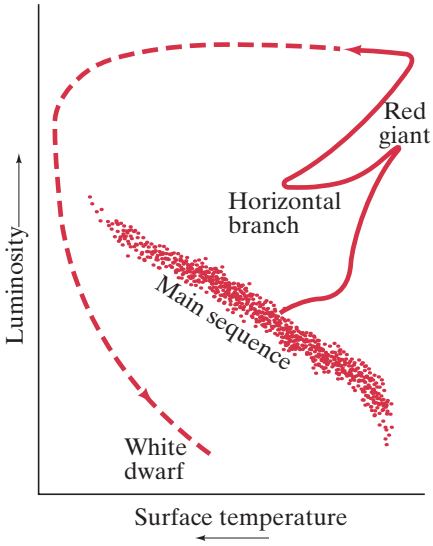

**FIGURE 44–8** Evolutionary "track" of a star like our Sun represented on an H–R diagram.

This process marks a new step in the evolution of a star. The star has become redder, it has grown in size, and it has become more luminous, which means it has left the main sequence. It will have moved to the right and upward on the H–R diagram, as shown in Fig. 44–8. As it moves upward, it enters the **red giant** stage. Thus, theory explains the origin of red giants as a natural step in a star's evolution. Our Sun, for example, has been on the main sequence for about $4\frac{1}{2}$ billion years. It will probably remain there another 5 or 6 billion years. When our Sun leaves the main sequence, it is expected to grow in diameter (as it becomes a red giant) by a factor of 100 or more, perhaps swallowing up inner planets such as Mercury and possibly Venus and even Earth.

If the star is like our Sun, or larger, further fusion can occur. As the star's outer envelope expands, its core continues to shrink and heat up. When the temperature reaches about $10^8$ K, even helium nuclei, in spite of their greater charge and hence greater electrical repulsion, can come close enough to each other to undergo fusion. The reactions are

$$\begin{aligned} {}^4_2\text{He} + {}^4_2\text{He} &\rightarrow {}^8_4\text{Be} \\ {}^4_2\text{He} + {}^8_4\text{Be} &\rightarrow {}^{12}_6\text{C} \end{aligned} \qquad \textbf{(44–2)}$$

with the emission of two $\gamma$ rays. These two reactions must occur in quick succession (because ${}^8_4$Be is very unstable), and the net effect is

$$3\,{}^4_2\text{He} \rightarrow {}^{12}_6\text{C} + 2\gamma. \qquad (Q = 7.3\,\text{MeV})$$

This fusion of helium causes a change in the star which moves rapidly to the "horizontal branch" on the H–R diagram (Fig. 44–8). Further fusion reactions are possible, with ${}^4_2$He fusing with ${}^{12}_6$C to form ${}^{16}_8$O. In more massive stars, higher $Z$ elements like ${}^{20}_{10}$Ne or ${}^{24}_{12}$Mg can be made. This process of creating heavier nuclei from lighter ones (or by absorption of neutrons which tends to occur at higher $Z$) is called **nucleosynthesis**.

## Low Mass Stars—White Dwarfs

The final fate of a star depends on its mass. Stars can lose mass as parts of their outer envelope move off into space. Stars born with a mass less than about 8 solar masses (8× the mass of our Sun) eventually end up with a residual mass less than about 1.4 solar masses. A residual mass of 1.4 solar masses is known as the **Chandrasekhar limit**. For stars smaller than this, no further fusion energy can be obtained because of the large Coulomb repulsion between nuclei. The core of such a "low mass" star (original mass $\lesssim$ 8 solar masses) contracts under gravity. The outer envelope expands again and the star becomes an even brighter and larger red giant, Fig. 44–8. Eventually the outer layers escape into space, and the newly revealed surface is hotter than before. So the star moves to the left in the H–R diagram (horizontal dashed line in Fig. 44–8). Then, as the core shrinks the star cools, and typically follows the downward dashed route shown on the left in Fig. 44–8, becoming a **white dwarf**. A white dwarf with a residual mass equal to that of the Sun would be about the size of the Earth. A white dwarf contracts to the point at which the electrons start to overlap, but no further because, by the Pauli exclusion principle, no two electrons can be in the same quantum state. At this point the star is supported against further collapse by this **electron degeneracy** pressure. A white dwarf continues to lose internal energy by radiation, decreasing in temperature and becoming dimmer until it glows no more. It has then become a cold dark chunk of extremely dense material.

## High Mass Stars—Supernovae, Neutron Stars, Black Holes

Stars whose original mass is greater than about 8 solar masses are thought to follow a very different scenario. A star with this great a mass can contract under gravity and heat up even further. At temperatures $T \approx 3$ or $4 \times 10^9$ K, nuclei as heavy as ${}^{56}_{26}$Fe and ${}^{56}_{28}$Ni can be made. But here the formation of heavy nuclei from lighter ones, by fusion, ends. As we saw in Fig. 41–1, the average binding energy per nucleon begins to decrease for $A$ greater than about 60. Further fusions would *require* energy, rather than release it.

At these extremely high temperatures, well above $10^9$ K, high-energy collisions can cause the breaking apart of iron and nickel nuclei into He nuclei, and eventually into protons and neutrons:

$$^{56}_{26}\text{Fe} \rightarrow 13\,^{4}_{2}\text{He} + 4\text{n}$$
$$^{4}_{2}\text{He} \rightarrow 2\text{p} + 2\text{n}.$$

These are energy-requiring (endothermic) reactions, which rob energy from the core, allowing gravitational contraction to begin. This then can force electrons and protons together to form neutrons in **inverse $\beta$ decay**:

$$\text{e}^- + \text{p} \rightarrow \text{n} + \nu.$$

As a result of these reactions, the pressure in the core drops precipitously. As the core collapses under the huge gravitational forces, the tremendous mass becomes essentially an enormous nucleus made up almost exclusively of neutrons. The size of the star is no longer limited by the exclusion principle applied to electrons, but rather by **neutron degeneracy** pressure, and the star contracts rapidly to form an enormously dense **neutron star**. The core of a neutron star contracts to the point at which all neutrons are as close together as they are in an atomic nucleus. That is, the density of a neutron star is on the order of $10^{14}$ times greater than normal solids and liquids on Earth. A cupful of such dense matter would weigh billions of tons. A neutron star that has a mass 1.5 times that of our Sun would have a diameter of only about 20 km. (Compare this to a white dwarf with 1 solar mass whose diameter would be $\approx 10^4$ km, as mentioned on the previous page.)

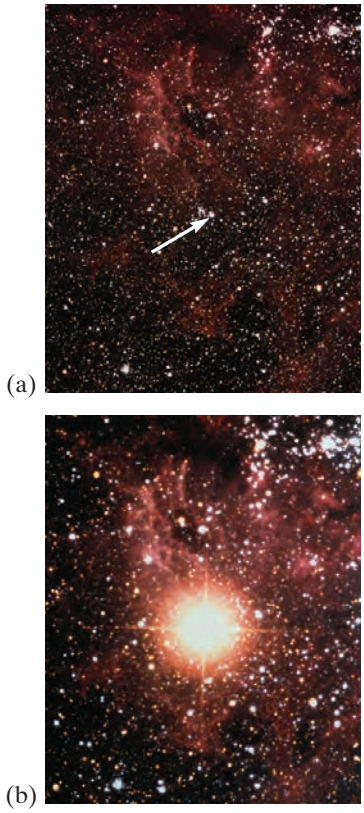
The contraction of the core of a massive star would mean a great reduction in gravitational potential energy. Somehow this energy would have to be released. Indeed, it was suggested in the 1930s that the final core collapse to a neutron star could be accompanied by a catastrophic explosion known as a **supernova** (plural = supernovae). The tremendous energy release (Fig. 44–9) could form virtually all elements of the Periodic Table (see below) and blow away the entire outer envelope of the star, spreading its contents into interstellar space. The presence of heavy elements on Earth and in our solar system suggests that our solar system formed from the debris of many such supernova explosions.

The elements heavier than Ni are thought to form mainly by **neutron capture** in these exploding supernovae (rather than by fusion, as for elements up to Ni). Large numbers of free neutrons, resulting from nuclear reactions, are present inside those highly evolved stars and they can readily combine with, say, a $^{56}_{26}$Fe nucleus to form (if three are captured) $^{59}_{26}$Fe, which decays to $^{59}_{27}$Co. The $^{59}_{27}$Co can capture neutrons, also becoming neutron rich and decaying by $\beta^-$ to the next higher $Z$ element, and so on to the highest $Z$ elements.

The final state of a neutron star depends on its mass. If the final mass is less than about three solar masses, the subsequent evolution of the neutron star is thought to resemble that of a white dwarf. If the mass is greater than this (original mass $\gtrsim 40$ solar masses), the neutron star collapses under gravity, overcoming even neutron degeneracy. Gravity would then be so strong that emitted light could not escape—it would be pulled back in by the force of gravity. Since no radiation could escape from such a "star," we could not see it—it would be black. An object may pass by it and be deflected by its gravitational field, but if the object came too close it would be swallowed up, never to escape. This is a **black hole**.

## Novae and Supernovae

**Novae** (singular is *nova*, meaning "new" in Latin) are faint stars that have suddenly increased in brightness by as much as a factor of $10^6$ and last for a month or two before fading. Novae are thought to be faint white dwarfs that have pulled mass from a nearby companion (they make up a *binary* system), as illustrated in Fig. 44–10. The captured mass of hydrogen suddenly fuses into helium at a high rate for a few weeks. Many novae (maybe all) are *recurrent*—they repeat their bright glow years later.



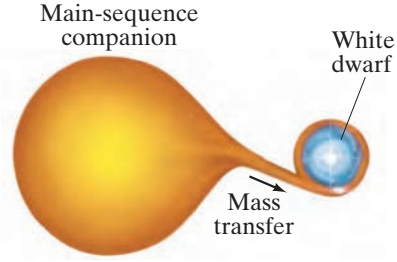


**FIGURE 44–9** The star indicated by the arrow in (a) exploded as a supernova, as shown in (b). It was detected in 1987, and named SN1987A. The large bright spot in (b) indicates a huge release of energy but does not represent the physical size.

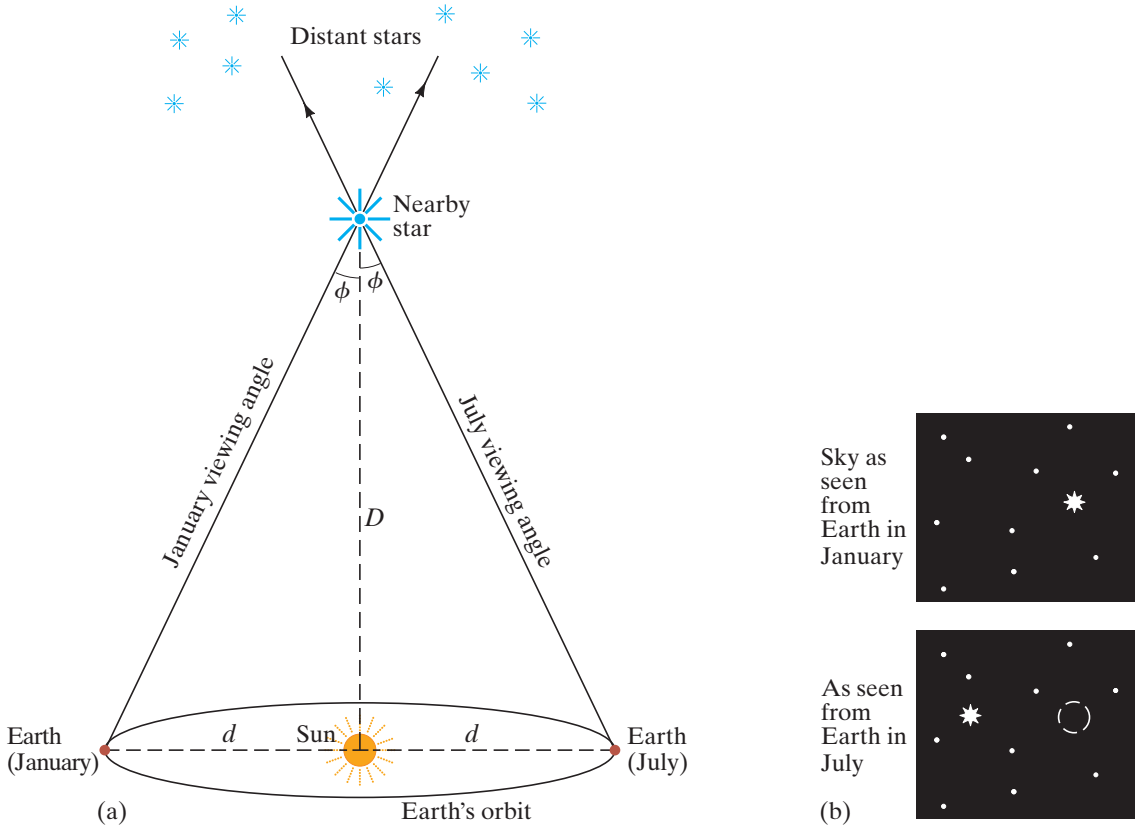
**FIGURE 44–10** Hypothetical model for novae and Type Ia supernovae, showing how a white dwarf could pull mass from its normal companion.

**Supernovae** are also brief explosive events, but release millions of times more energy than novae, up to $10^{10}$ times more luminous than our Sun. The peak of brightness may exceed that of the entire galaxy in which they are located, but lasts only a few days or weeks. They slowly fade over a few months. Many supernovae form by core collapse to a neutron star as described above. See Fig. 44–9.



**Type Ia supernovae** are different. They all seem to have very nearly the same luminosity. They are believed to be binary stars, one of which is a white dwarf that pulls mass from its companion, much like for a nova, Fig. 44–10. The mass is higher, and as mass is captured and the total mass approaches the Chandrasekhar limit of 1.4 solar masses, it explodes as a "white-dwarf" supernova by undergoing a "thermonuclear runaway"—an uncontrolled chain of nuclear reactions that entirely destroys the white dwarf. Type Ia supernovae are useful to us as "standard candles" in the night sky to help us determine distance—see next Section.

# 44–3 Distance Measurements

## Parallax

We have talked about the vast distances of objects in the universe. But how do we measure these distances? One basic technique employs simple geometry to measure the **parallax** of a star. By parallax we mean the apparent motion of a star, against the background of much more distant stars, due to the Earth's motion around the Sun. As shown in Fig. 44–11, we can measure the angle $2\phi$ that the star appears to shift, relative to very distant stars, when viewed 6 months apart. If we know the distance $d$ from Earth to Sun, we can reconstruct the right triangles shown in Fig. 44–11 and can then determine the distance $D$ to the star. This is essentially the way the heights of mountains are determined, by "triangulation": see Example 1–7.

**FIGURE 44–11** (a) Determining the distance $D$ to a relatively nearby star using parallax. Horizontal distances are greatly exaggerated: in reality $\phi$ is a very small angle (less than $\frac{1}{3600}° = 1'' = 1$ second of arc). (b) Diagram of the sky showing the apparent position of the "nearby" star relative to more distant stars, at two different times (January and July). The viewing angle in January puts the star more to the right relative to distant stars, whereas in July it is more to the left (dashed circle shows January location).

PSE5_CH44_v1.6_23Jun-20

**EXAMPLE 44–6** **ESTIMATE** **Distance to a star using parallax.** Estimate the distance $D$ to a star if the angle $2\phi$ in Fig. 44–11a is measured to be $2\phi = 0.00012°$.

**APPROACH** From trigonometry, $\tan\phi = d/D$ in Fig. 44–11a. The Sun–Earth distance is $d = 1.5 \times 10^8$ km (inside front cover).

**SOLUTION** The angle $\phi = 0.00006°$, or about $(0.00006°)(2\pi \text{ rad}/360°) = 1.0 \times 10^{-6}$ radians. We can use $\tan\phi \approx \phi$ because $\phi$ is very small. We solve for $D$ in $\tan\phi = d/D$. The distance $D$ to the star is

$$D = \frac{d}{\tan\phi} \approx \frac{d}{\phi} = \frac{1.5 \times 10^8 \text{ km}}{1.0 \times 10^{-6} \text{ rad}} = 1.5 \times 10^{14} \text{ km},$$

or about 15 ly.

## *Parsec

Distances to stars are often specified in terms of parallax angle ($\phi$ in Fig. 44–11a) given in seconds of arc: 1 second $(1'')$ is $\frac{1}{60}$ of one minute $(1')$ of arc, which is $\frac{1}{60}$ of a degree, so $1'' = \frac{1}{3600}$ of a degree. The distance is then specified in **parsecs** (pc) (meaning *par*allax angle in *sec*onds of arc): $D = 1/\phi$ with $\phi$ in seconds of arc. In Example 44–6, $\phi = (6 \times 10^{-5})°(3600) = 0.22''$ of arc, so we would say the star is at a distance of $1/0.22'' = 4.5$ pc. One parsec is given by (recall $D = d/\phi$, and we set the Sun–Earth distance (Fig. 44–11a) as $d = 1.496 \times 10^{11}$ m):

$$1 \text{ pc} = \frac{d}{1''} = \frac{1.496 \times 10^{11} \text{ m}}{(1'')\left(\frac{1'}{60''}\right)\left(\frac{1°}{60'}\right)\left(\frac{2\pi \text{ rad}}{360°}\right)} = 3.086 \times 10^{16} \text{ m}$$

$$1 \text{ pc} = (3.086 \times 10^{16} \text{ m})\left(\frac{1 \text{ ly}}{9.46 \times 10^{15} \text{ m}}\right) = 3.26 \text{ ly}.$$

## Distant Stars and Galaxies

Parallax can be used to determine the distance to stars as far away as about 100 light-years from Earth, and from an orbiting spacecraft perhaps 5 to 10 times farther. Beyond that distance, parallax angles are too small to measure. For greater distances, more subtle techniques must be employed. We might compare the apparent brightnesses of two stars, or two galaxies, and use the *inverse square law* (apparent brightness drops off as the square of the distance) to roughly estimate their relative distances. We can't expect this technique to be very precise because we don't expect any two stars, or two galaxies, to have the same intrinsic luminosity.

When comparing galaxies, a better estimate assumes that the *brightest* stars in all galaxies (or the brightest galaxies in galaxy clusters) are similar and have about the same intrinsic luminosity. Consequently, their *apparent brightness* would be a measure of how far away they were.

Another technique makes use of the H–R diagram. Measurement of a star's surface temperature (from its spectrum) places it at a certain point (within 20%) on the H–R diagram, assuming it is a main-sequence star, and then its luminosity can be estimated from the vertical axis (Fig. 44–6). Its apparent brightness and Eq. 44–1 give its approximate distance; see Example 44–5.

A better estimate comes from comparing *variable stars*, especially *Cepheid variables* whose luminosity varies over time with a period that is found to be related to their average luminosity. Thus, from their period and apparent brightness we get their distance.

## Distance via SNIa, Redshift

The largest distances are estimated by comparing the apparent brightnesses of Type Ia supernovae ("SNIa"). Type Ia supernovae all have a similar origin (as described on the previous page and Fig. 44–10), and their brief explosive burst of light when the Chandrasekhar limit (1.4 solar masses) is reached leads us to believe they have nearly the same luminosity. They are thus sometimes referred to as "standard candles."

Another important technique for estimating the distance of very distant galaxies is from the "redshift" in the line spectra of elements and compounds. The amount of redshift is related to the expansion of the universe, as we shall discuss in Section 44–5. It is useful for objects farther than $10^7$ to $10^8$ ly away.

As we look farther and farther away, measurement techniques are less and less reliable, so there is more uncertainty in the measurements of large distances.

## 44–4 General Relativity: Gravity and the Curvature of Space

We have seen that the force of gravity plays an important role in the processes that occur in stars. Gravity too is important for the evolution of the universe as a whole. The reasons gravity plays a dominant role in the universe, and not one of the other of the four forces in nature, are (1) it is long-range and (2) it is always attractive. The strong and weak nuclear forces act over very short distances only, on the order of the size of a nucleus; hence they do not act over astronomical distances (they do act between nuclei and nucleons in stars to produce nuclear reactions). The electromagnetic force, like gravity, acts over great distances. But it can be either attractive or repulsive. And since the universe does not seem to contain large areas of net electric charge, a large net force does not occur. But gravity acts only as an *attractive* force between *all* masses, and there are large accumulations of mass in the universe. The force of gravity as Newton described it in his law of universal gravitation was modified by Einstein. In his general theory of relativity, Einstein developed a theory of gravity that now forms the basis of cosmological dynamics.

In the *special theory of relativity* (Chapter 36), Einstein concluded that there is no way for an observer to determine whether a given frame of reference is at rest or is moving at constant velocity in a straight line. Thus the laws of physics must be the same in different inertial reference frames. But what about the more general case of motion where reference frames can be *accelerating*?

Einstein tackled the problem of accelerating reference frames in his **general theory of relativity** and in it also developed a theory of gravity. The mathematics of General Relativity is complex, so our discussion will be mainly qualitative.

We begin with Einstein's **principle of equivalence**, which states that

> **no experiment can be performed that could distinguish between a uniform gravitational field and an equivalent uniform acceleration.**

If observers sensed that they were accelerating (as in a vehicle speeding around a sharp curve), they could not prove by any experiment that in fact they weren't simply experiencing the pull of a gravitational field. Conversely, we might think we are being pulled by gravity when in fact we are undergoing an acceleration having nothing to do with gravity.

As a thought experiment, consider a person in a freely falling elevator near the Earth's surface. If our observer held out a book and let go of it, what would happen? Gravity would pull it downward toward the Earth, but at the same rate $(g = 9.8\,\text{m/s}^2)$ at which the person and elevator were falling. So the book would hover right next to the person's hand (Fig. 44–12). The effect is exactly the same as if this reference frame was at rest and *no* forces were acting. On the other hand, if the elevator was out in space where the gravitational field is essentially zero, the released book would float, just as it does in Fig. 44–12. Next, if the elevator (out in space) is accelerated upward (using rockets) at an acceleration of $9.8\,\text{m/s}^2$, the book as seen by our observer would fall to the floor with an acceleration of $9.8\,\text{m/s}^2$, just as if it were falling due to gravity at the surface of the Earth. According to the principle of equivalence, the observer could not determine whether the book fell because the elevator was accelerating upward, or because a gravitational field was acting downward and the elevator was at rest. The two descriptions are equivalent.

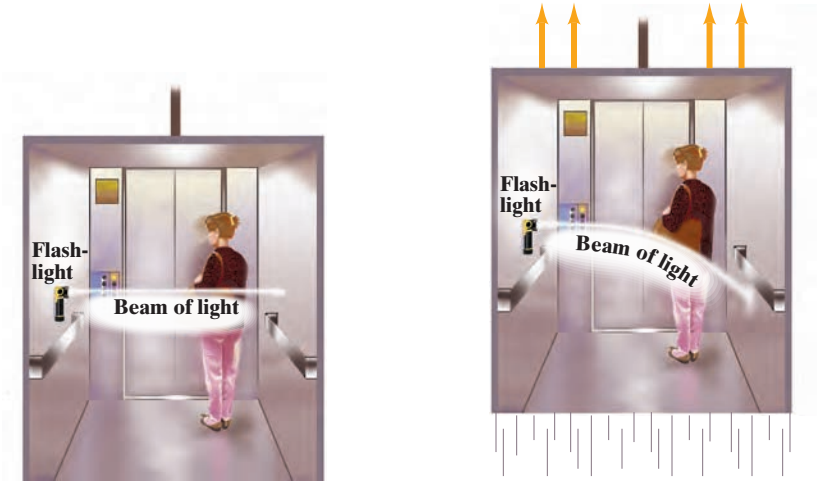


**FIGURE 44–12** In an elevator falling freely under gravity, (a) a person releases a book; (b) the released book hovers next to the owner's hand; (b) is a few moments after (a).

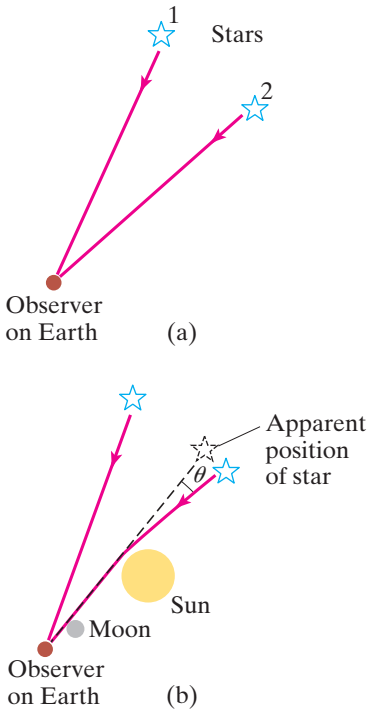
PSE5_CH44_v1.6_23Jun-20

The principle of equivalence is related to the concept that there are two types of mass. Newton's second law, $F = ma$, uses **inertial mass**. We might say that inertial mass represents "resistance" to being accelerated by any type of force. The second type of mass is **gravitational mass**. When one object attracts another by the gravitational force (Newton's law of universal gravitation, $F = Gm_1 m_2/r^2$, Chapter 6), the strength of the force is proportional to the product of the *gravitational masses* of the two objects. This is much like Coulomb's law for the electric force between two objects which is proportional to the product of their electric charges. The electric charge on an object is not related to its inertial mass; so why should we expect that an object's gravitational mass (call it gravitational charge if you like) be related to its inertial mass? All along we have assumed they were the same. Why? Because no experiment—not even of high precision—has been able to discern any measurable difference between inertial mass and gravitational mass. (For example, in the absence of air resistance, all objects fall at the same acceleration, $g$, on Earth.) This is another way to state the equivalence principle: *gravitational mass is equivalent to inertial mass*.



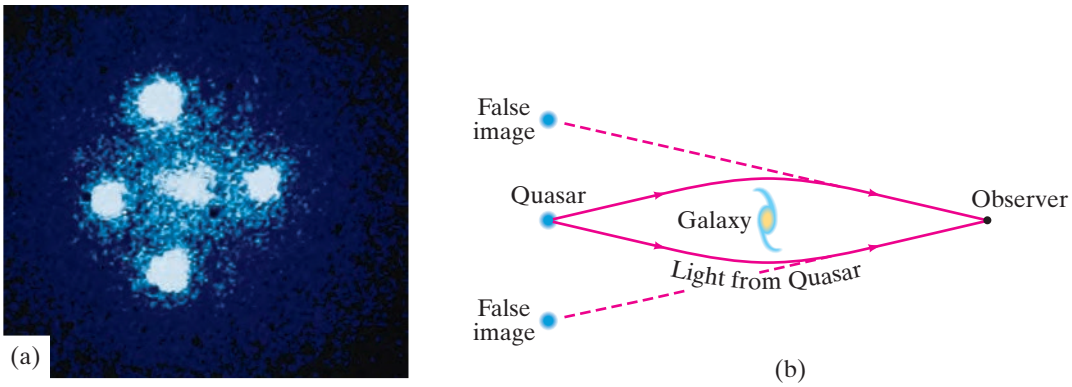
(a) (b)

**FIGURE 44–13** (a) Light beam goes straight across an elevator which is not accelerating. (b) The light beam bends (exaggerated) according to an observer in an accelerating elevator whose speed increases in the upward direction.

The principle of equivalence can be used to predict that light ought to be deflected by the gravitational force due to a massive object. Consider another thought experiment, in which an elevator is in free space where virtually no gravity acts. If a light beam is emitted by a flashlight attached to the side of the elevator, the beam travels straight across the elevator and makes a spot on the opposite side if the elevator is at rest or moving at constant velocity (Fig. 44–13a). If instead the elevator is accelerating upward, as in Fig. 44–13b, the light beam still travels straight across in a reference frame at rest. In the upwardly accelerating elevator, however, the beam is observed to curve downward. Why? Because during the time the light travels from one side of the elevator to the other, the elevator is moving upward at a vertical speed that is increasing relative to the light. Next we note that according to the equivalence principle, an upwardly accelerating reference frame is equivalent to a downward gravitational field. Hence, we can picture the curved light path in Fig. 44–13b as being due to the effect of a gravitational field. Thus, from the principle of equivalence, we expect gravity to exert a force on a beam of light and to bend it out of a straight-line path!

That light is affected by gravity is an important prediction of Einstein's general theory of relativity. And it can be tested. The amount a light beam would be deflected from a straight-line path must be small even when passing a massive object. (For example, light near the Earth's surface after traveling 1 km is predicted to drop only about $10^{-10}$ m, which is equal to the diameter of a small atom and not detectable.) The most massive object near us is the Sun, and it was calculated that light from a distant star would be deflected by 1.75″ of arc (tiny but detectable) as it passed by the edge of the Sun (Fig. 44–14).

**FIGURE 44–14** (a) Two stars in the sky observed from Earth. (b) If the light from one of these stars passes very near the Sun, whose gravity bends the rays, the star will appear higher than it actually is (follow the ray backwards). [Not to scale.]



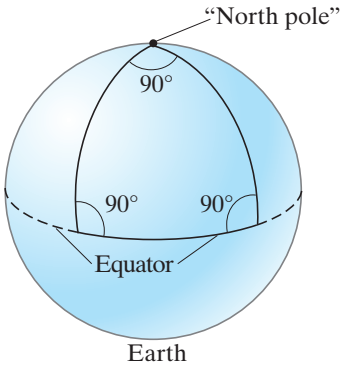


**FIGURE 44–15** (a) Hubble Space Telescope photograph of the so-called "Einstein cross", thought to represent "gravitational lensing": the central spot is a relatively nearby galaxy, whereas the four other spots are thought to be images of a single quasar *behind* the galaxy. (b) Diagram showing how the galaxy could bend the light coming from the quasar behind it to produce the four images. See also Fig. 44–14. [If the shape of the nearby galaxy and distant quasar were perfect spheres and perfectly aligned, we would expect the "image" of the distant quasar to be a circular ring or halo instead of the four separate images seen here. Such a ring is called an "Einstein ring."]

However, such a measurement could be made only during a total eclipse of the Sun, so that the Sun's tremendous brightness would not obscure the starlight passing near its edge. An opportune eclipse occurred in 1919, and scientists journeyed to the South Atlantic to observe it. Their photos of stars just behind the Sun revealed shifts in accordance with Einstein's prediction. Another example of gravitational deflection of light is **gravitational lensing**, as described in Fig. 44–15. The very distant galaxies shown in the XDF photo at the start of this Chapter, page 1322, are thought to be visible only because of gravitational lensing (and magnification of their emitted light) by nearer galaxies—as if the nearby galaxies acted as a magnifying glass.

The mathematician Fermat showed in the 1600s that optical phenomena, including reflection, refraction, and effects of lenses, can be derived from a simple principle: that light traveling between two points follows the shortest path in space. Thus if gravity curves the path of light, then gravity must be able to curve space itself. That is, *space itself can be curved*, and it is gravitational mass that causes the curvature. Indeed, the curvature of space—or rather, of four-dimensional space-time—is a basic aspect of Einstein's General Relativity.

What is meant by **curved space**? To understand, recall that our normal method of viewing the world is via Euclidean plane geometry. In Euclidean geometry, there are many axioms and theorems we take for granted, such as that the sum of the angles of any triangle is 180°. Non-Euclidean geometries, which involve curved space, have also been imagined by mathematicians. It is hard enough to imagine three-dimensional curved space, much less curved four-dimensional space-time. So let us try to understand the idea of curved space by using two-dimensional surfaces.

**FIGURE 44–16** On a two-dimensional curved surface, the sum of the angles of a triangle may not be 180°.

Consider, for example, the two-dimensional surface of a sphere. It is clearly curved, Fig. 44–16, at least to us who view it from the outside—from our three-dimensional world. But how would hypothetical two-dimensional creatures determine whether their two-dimensional space was flat (a plane) or curved? One way would be to measure the sum of the angles of a triangle. If the surface is a plane, the sum of the angles is 180°, as we learn in plane geometry. But if the space is curved, and a sufficiently large triangle is constructed, the sum of the angles will *not* be 180°. To construct a triangle on a curved surface, say the sphere of Fig. 44–16, we must use the equivalent of a straight line: that is, the shortest distance between two points, which is called a **geodesic**. On a sphere, a geodesic is an arc of a great circle (an arc in a plane passing through the center of the sphere) such as the Earth's equator and the Earth's longitude lines. Consider, for example, the large triangle of Fig. 44–16: its sides are two longitude lines passing from the north pole to the equator, and the third side is a section of the equator as shown. The two longitude lines make 90° angles with the equator (look at a world globe to see this more clearly). They make an angle with each other at the north pole, which could be, say, 90° as shown; the sum of these angles is $90° + 90° + 90° = 270°$. This is clearly *not* a Euclidean space. Note, however, that if the triangle is small in comparison to the radius of the sphere, the angles will add up to nearly 180°, and the triangle (and space) will seem flat.

Another way to test the curvature of space is to measure the radius $r$ and circumference $C$ of a large circle. On a plane surface, $C = 2\pi r$. But on a two-dimensional spherical surface, $C$ is *less* than $2\pi r$, as can be seen in Fig. 44–17. The proportionality between $C$ and $r$ is *less* than $2\pi$. Such a surface is said to have *positive curvature*. On the saddlelike surface of Fig. 44–18, the circumference of a circle is greater than $2\pi r$, and the sum of the angles of a triangle is less than 180°. Such a surface is said to have a *negative curvature*.

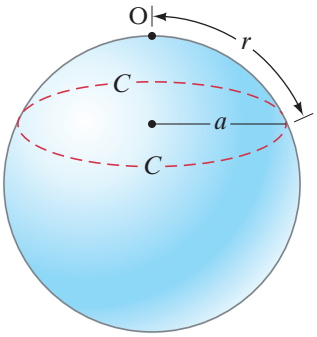

**FIGURE 44–17** On a spherical surface (a two-dimensional world) a circle of circumference $C$ is drawn (red) about point O as the center. The radius of the circle (not the sphere) is the distance $r$ along the surface. (Note that in our three-dimensional view, we can tell that $C = 2\pi a$. Since $r > a$, then $C < 2\pi r$.)

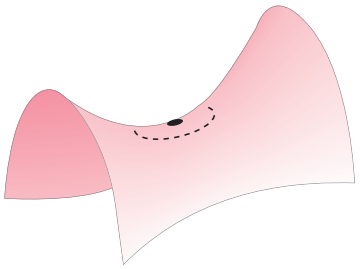
## Curvature of the Universe



What about our universe? On a large scale (not just near a large mass), what is the overall curvature of the universe? Does it have positive curvature, negative curvature, or is it flat (zero curvature)? We perceive our world as Euclidean (flat), but we can not exclude the possibility that space could have a curvature so slight that we don't normally notice it. This is a crucial question in cosmology, and it can be answered only by precise experimentation.

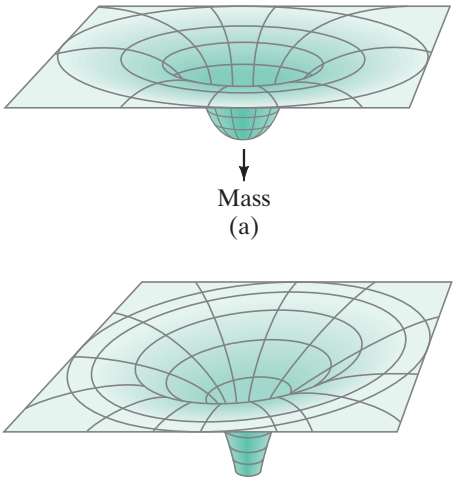
If the universe had a positive curvature, the universe would be *closed*, or *finite* in volume. This would *not* mean that the stars and galaxies extended out to a certain boundary, beyond which there is empty space. There is no boundary or edge in such a universe. The universe is all there is. If a particle were to move in a straight line in a particular direction, it would eventually return to the starting point—perhaps eons of time later.

On the other hand, if the curvature of space was zero or negative, the universe would be *open*. It could just go on forever. An open universe could be *infinite*; but according to recent research, even that may not necessarily be so.

Today the evidence is very strong that the universe on a large scale is very close to being flat. Indeed, it is so close to being flat that we can't tell if it might have very slightly positive or very slightly negative curvature.

**FIGURE 44–18** Example of a two-dimensional surface with negative curvature.

## Black Holes



According to Einstein's theory of general relativity (sometimes abbreviated GR), space-time is curved near massive objects. We might think of space as being like a thin rubber sheet: if a heavy weight is placed on the sheet, it sags as shown in Fig. 44–19a. The weight corresponds to a huge mass that causes space (space itself!) to curve. Thus, in the context of general relativity[†] we do not speak of the "force" of gravity acting on objects. Instead we say that objects and light rays move as they do because space-time is curved. An object starting at rest or moving slowly near the great mass of Fig. 44–19a would follow a geodesic (the equivalent of a straight line in plane geometry) toward that great mass.

The extreme curvature of space-time shown in Fig. 44–19b could be produced by a **black hole**. A black hole, as we mentioned in Section 44–2, has such strong gravity that even light cannot escape from it. To become a black hole, an object of mass $M$ must undergo **gravitational collapse**, contracting by gravitational self-attraction to within a radius called the **Schwarzschild radius**,

$$R = \frac{2GM}{c^2},$$

where $G$ is the gravitational constant and $c$ the speed of light. If an object collapses to within this radius, it is predicted by general relativity to collapse to a point at $r = 0$, forming an infinitely dense singularity. This prediction is uncertain, however, because in this realm we need to combine quantum mechanics with gravity, a unification of theories not yet achieved (Section 44–12).

**FIGURE 44–19** (a) Rubber-sheet analogy for space-time curved by matter. (b) Same analogy for a black hole, which can "swallow up" objects that pass near.

**I EXERCISE C** What is the Schwarzschild radius for an object with 10 solar masses?

[†]Alexander Pope (1688–1744) wrote an epitaph for Newton:
"Nature, and Nature's laws lay hid in night:
God said, *Let Newton be!* and all was light."

Sir John Squire (1884–1958), perhaps uncomfortable with Einstein's profound thoughts, added:
"It did not last: the Devil howling '*Ho!*
*Let Einstein be!*' restored the status quo."

The Schwarzschild radius also represents the event horizon of a black hole. By **event horizon** we mean the surface beyond which no emitted signals can ever reach us, and thus inform us of events that happen beyond that surface. As a star collapses toward a black hole, the light it emits is pulled harder and harder by gravity, but we can still see it. Once the matter passes within the event horizon, the emitted light cannot escape but is pulled back in by gravity (= curvature of space-time).

All we can know about a black hole is its mass, its angular momentum (rotating black holes), and its electric charge. No other information, no details of its structure or the kind of matter it was formed of, can be known because no information can escape.

How might we observe black holes? We cannot see them because no light can escape from them. They would be black objects against a black sky. But they do exert a gravitational force on nearby objects, and also on light rays (or photons) that pass nearby (just like in Fig. 44–15). The black hole believed to be at the center of our Galaxy $\left(M \approx 4 \times 10^6\, M_{\text{Sun}}\right)$ was discovered by examining the motion of matter in its vicinity. Another technique is to examine stars which appear to move as if they were one member of a *binary system* (two stars rotating about their common center of mass), but without a visible companion. If the unseen star is a black hole, it might be expected to pull off gaseous material from its visible companion (as in Fig. 44–10). As this matter approached the black hole, it would be highly accelerated and should emit X-rays of a characteristic type before plunging inside the event horizon. Such X-rays, plus a sufficiently high mass estimate from the rotational motion, can provide evidence for a black hole. One of the many candidates for a black hole is in the binary-star system Cygnus X-1. It is widely believed that the center of most galaxies is occupied by a black hole with a mass $10^6$ to $10^9$ times the mass of a typical star like our Sun.

**EXERCISE D** A black hole has radius $R$. Its mass is proportional to (*a*) $R$, (*b*) $R^2$, (*c*) $R^3$. Justify your answer.

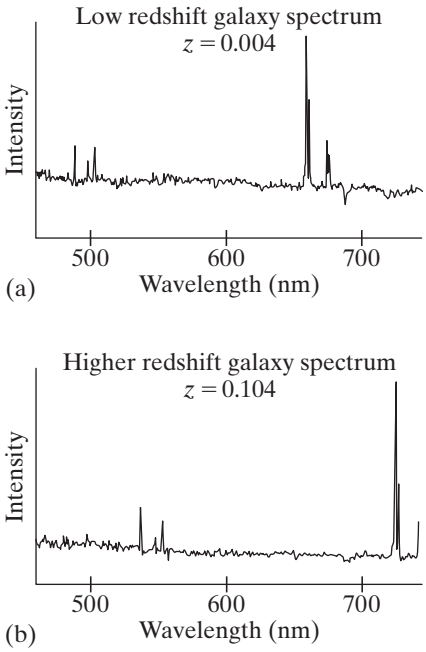


**FIGURE 44–20** Atoms and molecules emit and absorb light of particular frequencies depending on the spacing of their energy levels, as we saw in Chapters 37 to 40. (a) The spectrum of light received from a relatively slow-moving galaxy. (b) Spectrum of a galaxy moving away from us at a much higher speed. Note how the peaks (or lines) in the spectrum have moved to longer wavelengths. The redshift is $z = (\lambda_{\text{obs}} - \lambda_{\text{rest}})/\lambda_{\text{rest}}$.

## 44–5 The Expanding Universe: Redshift and Hubble's Law

We discussed in Section 44–2 how individual stars evolve from their birth to their death as white dwarfs, neutron stars, or black holes. But what about the universe as a whole: is it static, or does it change? One of the most important scientific discoveries of the twentieth century was that distant galaxies are racing away from us, and that the farther they are from us at a given time, the faster they are moving away. How astronomers arrived at this astonishing idea, and what it means for the past history of the universe as well as its future, will occupy us for the remainder of the book.

Evidence that the universe is expanding was first put forth by Georges Lemaître (1894–1966), a Belgian physicist and Catholic priest, in 1927 and also by Edwin Hubble in 1929. This idea was based on distance measurements of galaxies (Section 44–3), and determination of their velocities by the Doppler shift of spectral lines in the light received from them (Fig. 44–20). In Chapter 16 we saw how the frequency of sound is higher and the wavelength shorter if the source and observer move toward each other. If the source moves away from the observer, the frequency is lower and the wavelength longer. The **Doppler effect** occurs also for light, but the formula for light is slightly different than for sound and is given by[†]

$$\lambda_{\text{obs}} = \lambda_{\text{rest}} \sqrt{\frac{1 + v/c}{1 - v/c}}, \qquad \left[\begin{array}{l}\text{source and observer moving}\\ \text{away from each other}\end{array}\right] \qquad \textbf{(44–3)}$$

where $\lambda_{\text{rest}}$ is the emitted wavelength as seen in a reference frame at rest with respect to the source, and $\lambda_{\text{obs}}$ is the wavelength observed in a frame moving with velocity $v$ away from the source along the line of sight. (For relative motion

[†]For light there is no medium and we can make no distinction between motion of the source and motion of the observer (special relativity), as we did for sound which travels in a medium.

PSE5_CH44_v1.6_23Jun-20

*toward* each other, $v < 0$ in this formula.) When a distant source emits light of a particular wavelength, and the source is moving away from us, the wavelength appears longer to us: the color of the light (if it is visible) is shifted toward the red end of the visible spectrum, an effect known as a **redshift**. (If the source moves toward us, the color shifts toward the blue or shorter wavelength.)

In the spectra of stars in other galaxies, lines are observed that correspond to lines in the known spectra of particular atoms (see Section 37–10 and Figs. 35–22 and 37–20). What Hubble found was that the lines seen in the spectra from distant galaxies were generally *redshifted*, and that the amount of shift seemed to be approximately proportional to the distance of the galaxy from us. That is, the velocity $v$ of a galaxy moving away from us is proportional to its distance $d$ from us:

$$v = H_0 d. \qquad \textbf{(44–4)}$$

*HUBBLE'S LAW*

This is **Hubble's law**, one of the most fundamental astronomical ideas. It was first suggested, in 1927, by Georges Lemaître, who also first proposed what later came to be called the Big Bang. The constant $H_0$ is called the **Hubble constant**.

The value of $H_0$ until recently was uncertain by over 20%, and thought to be between 15 and 25 km/s/Mly. But recent measurements now put its value more precisely at

$$H_0 = 21 \text{ km/s/Mly}$$

(that is, 21 km/s per million light-years of distance). The current uncertainty is close to 1%, or $\pm 0.2$ km/s/Mly. [$H_0$ can be written in terms of parsecs (Section 44–3) as $H_0 = 68$ km/s/Mpc (that is, 68 km/s per megaparsec of distance) with an uncertainty of about $\pm 1$ km/s/Mpc.]

## Redshift Origins

Galaxies very near us seem to be moving randomly relative to us: some move towards us (blueshifted), others away from us (redshifted); their speeds are on the order of $0.001c$. But for more distant galaxies, the velocity of recession is much greater than the velocity of local random motion, and so is dominant and Hubble's law (Eq. 44–4) holds very well. More distant galaxies have higher recession velocity and a larger redshift, and we call their redshift a **cosmological redshift**. We interpret this redshift today as due to the *expansion of space* itself. We can think of the originally emitted wavelength $\lambda_{\text{rest}}$ as being stretched out (becoming longer) along with the expanding space around it, as suggested in Fig. 44–21. Although Hubble thought of the redshift as a Doppler shift, now we prefer to understand it in this sense of expanding space. (But note that atoms in galaxies do not expand as space expands; they keep their regular size.)

There is a third way to produce a redshift, which we mention for completeness: a **gravitational redshift**. Light leaving a massive star is gaining in gravitational potential energy (just like a stone thrown upward from Earth). So the kinetic energy of each photon, $hf$, must be getting smaller (to conserve energy). A smaller frequency $f$ means a larger (longer) wavelength $\lambda$ ($= c/f$), which is a redshift.

The amount of a redshift is specified by the **redshift parameter**, $z$, defined as

$$z = \frac{\lambda_{\text{obs}} - \lambda_{\text{rest}}}{\lambda_{\text{rest}}} = \frac{\Delta\lambda}{\lambda_{\text{rest}}}, \qquad \textbf{(44–5a)}$$

where $\lambda_{\text{rest}}$ is a wavelength as seen by an observer at rest relative to the source, and $\lambda_{\text{obs}}$ is the wavelength measured by a moving observer. Equation 44–5a can be written as

$$z = \frac{\lambda_{\text{obs}}}{\lambda_{\text{rest}}} - 1 \qquad \textbf{(44–5b)}$$

and

$$z + 1 = \frac{\lambda_{\text{obs}}}{\lambda_{\text{rest}}}. \qquad \textbf{(44–5c)}$$

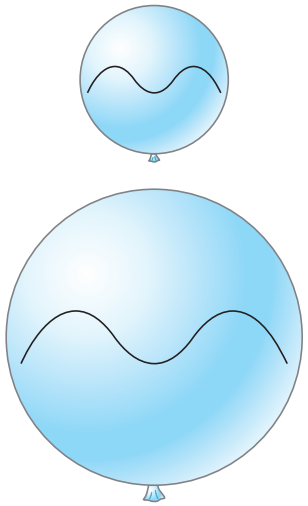

**FIGURE 44–21** Simplified model of a 2-dimensional universe, imagined as a balloon. As you blow up the balloon (= expanding universe), the wavelength of a wave on its surface gets longer (redshifted).

For low speeds not close to the speed of light ($v \lesssim 0.1\,c$), the Doppler formula (Eq. 44–3) can be used to show (Problem 36) that $z$ is proportional to the speed of the source toward or away from us:

$$z = \frac{\lambda_{\text{obs}} - \lambda_{\text{rest}}}{\lambda_{\text{rest}}} = \frac{\Delta\lambda}{\lambda_{\text{rest}}} \approx \frac{v}{c}. \qquad [v \ll c] \quad \textbf{(44–6)}$$

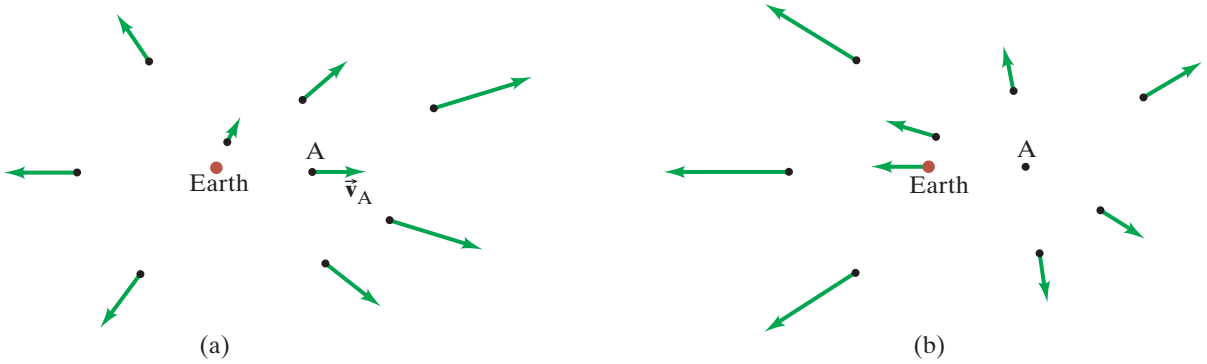
But redshifts are not always small, in which case the approximation of Eq. 44–6 is not valid. For high $z$ galaxies, not even Eq. 44–3 applies because the redshift is due to the expansion of space (cosmological redshift), not the Doppler effect. Our Chapter-Opening Photograph, page 1322, shows two very distant high $z$ galaxies, $z = 8.8$ and 11.9, which are also shown enlarged.

## Scale Factor

The expansion of space can be described as a scaling of the typical distance between two points or objects in the universe. If two distant galaxies are a distance $d_0$ apart at some initial time, then a time $t$ later they will be separated by a greater distance $d(t)$. The **scale factor** is the same as for light, expressed in Eq. 44–5a:

$$\frac{d(t) - d_0}{d_0} = \frac{\Delta\lambda}{\lambda} = z$$

or



$$\frac{d(t)}{d_0} = 1 + z.$$

Thus, for example, if a galaxy has $z = 3$, then the scale factor is now $(1 + 3) = 4$ times larger than when the light was emitted from that galaxy. That is, the average distance between galaxies has become 4 times larger. Thus the factor by which the wavelength has increased since it was emitted tells us by what factor the universe (or the typical distance between objects) has increased.

## Expansion, and the Cosmological Principle

What does it mean that distant galaxies are all moving away from us, and with ever greater speed the farther they are from us? It seems to suggest some kind of explosive expansion that started at some very distant time in the past. And at first sight we seem to be in the middle of it all. But we aren't. The expansion appears the same from any other point in the universe. To understand why, see Fig. 44–22. In Fig. 44–22a we have the view from Earth (or from our Galaxy). The velocities of surrounding galaxies are indicated by arrows, pointing away from us, and the arrows are longer (faster speeds) for galaxies more distant from us. Now, what if we were on the galaxy labeled A in Fig. 44–22a? From Earth, galaxy A appears to be moving to the right at a velocity, call it $\vec{\mathbf{v}}_A$, represented by the arrow pointing to the right. If we were *on* galaxy A, Earth would appear to be moving to the left at velocity $-\vec{\mathbf{v}}_A$.

**FIGURE 44–22** Expansion of the universe looks the same from any point in the universe. If you are on Earth as shown in part (a), or you are instead at galaxy A (which is at rest in the reference frame shown in (b)), all other galaxies appear to be racing away from you.

PSE5_CH44_v1.6_23Jun-20

To determine the velocities of other galaxies relative to A, we vectorially add the velocity vector, $-\vec{\mathbf{v}}_A$, to all the velocity arrows shown in Fig. 44–22a. This yields Fig. 44–22b, where we see that the universe is expanding away from galaxy A as well; and the velocities of galaxies receding from A are proportional to their current distance from A. *The universe looks pretty much the same from different points.*

Thus the expansion of the universe can be stated as follows: all galaxies are racing away from *each other* at an average rate of about 21 km/s per million light-years of distance between them. The ramifications of this idea are profound, and we discuss them in a moment.

A basic assumption in cosmology has been that on a large scale, the universe would look the same to observers at different places at the same time. In other words, the universe is both *isotropic* (looks the same in all directions) and *homogeneous* (would look the same if we were located elsewhere, say in another galaxy). This assumption is called the **cosmological principle**. On a local scale, say in our solar system or within our Galaxy, it clearly does not apply (the sky looks different in different directions). But it has long been thought to be valid if we look on a large enough scale, so that the average population density of galaxies and clusters of galaxies ought to be the same in different areas of the sky. This seems to be valid on distances greater than about 700 Mly. The expansion of the universe (Fig. 44–22) is consistent with the cosmological principle; and the near uniformity of the cosmic microwave background radiation (discussed in Section 44–6) supports it. Another way to state the cosmological principle is that *our place in the universe is not special.*

The expansion of the universe, as described by Hubble's law, strongly suggests that galaxies must have been closer together in the past than they are now. This is, in fact, the basis of the *Big Bang* theory of the origin of the universe, which pictures the universe as a relentless expansion starting from a very hot and compressed beginning. We discuss the Big Bang in detail shortly, but first let us see what can be said about the age of the universe.

One way to estimate the age of the universe uses the Hubble constant. With $H_0 \approx 21$ km/s per $10^6$ light-years, the time required for the galaxies to arrive at their present separations would be approximately (starting with $v = d/t$ and using Hubble's law, Eq. 44–4),

$$t = \frac{d}{v} = \frac{d}{H_0 d} = \frac{1}{H_0} \approx \frac{(10^6 \text{ ly})(0.95 \times 10^{13} \text{ km/ly})}{(21 \text{ km/s})(3.16 \times 10^7 \text{ s/yr})} \approx 14 \times 10^9 \text{ yr},$$

or 14 billion years. The age of the universe calculated in this way is called the *characteristic expansion time* or "Hubble age." It is a very rough estimate and assumes the rate of expansion of the universe was constant (which today we are quite sure is not true). Today's best measurements give the age of the universe as about $13.8 \times 10^9$ yr, in remarkable agreement with the rough Hubble age estimate.

## *Steady-State Model

Before discussing the Big Bang in detail, we mention one alternative to the Big Bang—the **steady-state model**—which assumed that the universe is infinitely old and on average looks the same now as it always has. (This assumed uniformity in time as well as space was called the *perfect cosmological principle.*) According to the steady-state model, no large-scale changes have taken place in the universe as a whole, particularly no Big Bang. To maintain this view in the face of the recession of galaxies away from each other, matter would need to be created continuously to maintain the assumption of uniformity. The rate of mass creation required is very small—about one nucleon per cubic meter every $10^9$ years.

The steady-state model provided the Big Bang model with healthy competition in the mid-twentieth century. But the discovery of the cosmic microwave background radiation (next Section), as well as other observations of the universe, has made the Big Bang model universally accepted.

## 44–6 The Big Bang and the Cosmic Microwave Background

The expansion of the universe suggests that typical objects in the universe were once much closer together than they are now. This is the basis for the idea that the universe began about 14 billion years ago as an expansion from a state of very high density and temperature known affectionately as the **Big Bang**.

The birth of the universe was not an explosion, because an explosion blows pieces out into the surrounding space. Instead, the Big Bang was the start of an expansion of space itself. The observable universe was relatively very small at the start and has been expanding, getting ever larger, ever since. The initial tiny universe of extremely dense matter is not to be thought of as a concentrated mass in the midst of a much larger space around it. The initial tiny but dense universe was the *entire universe*. There wouldn't have been anything else. When we say that the universe was once smaller than it is now, we mean that the average separation between objects (such as electrons or galaxies) was less. The universe may have been infinite in extent even then, and it may still be now (only bigger). The **observable universe** (that which we have the possibility of observing because light has had time to reach us) is, however, finite.

A major piece of evidence supporting the Big Bang is the **cosmic microwave background** radiation (or CMB) whose discovery came about as follows.

In 1964, Arno Penzias and Robert Wilson pointed their horn antenna for detecting radio waves (Fig. 44–23) into the sky. With it they detected widespread emission, and became convinced that it was coming from outside our Galaxy. They made precise measurements at a wavelength $\lambda = 7.35$ cm, in the microwave region of the electromagnetic spectrum (Fig. 31–12). The intensity of this radiation was found initially not to vary by day or night or time of year, nor to depend on direction. It came from all directions in the universe with equal intensity, to a precision of better than 1%. It could only be concluded that this radiation came from the universe as a whole.

The intensity of this CMB measured at $\lambda = 7.35$ cm corresponds to blackbody radiation (see Section 37–1) at a temperature of about 3 K. When radiation at other wavelengths was measured by the COBE satellite (COsmic Background Explorer), the intensities were found to fall on a nearly perfect blackbody curve as shown in Fig. 44–24, corresponding to a temperature of 2.725 K ($\pm 0.002$ K).

The remarkable uniformity of the CMB was in accordance with the cosmological principle. But theorists felt that there needed to be some small

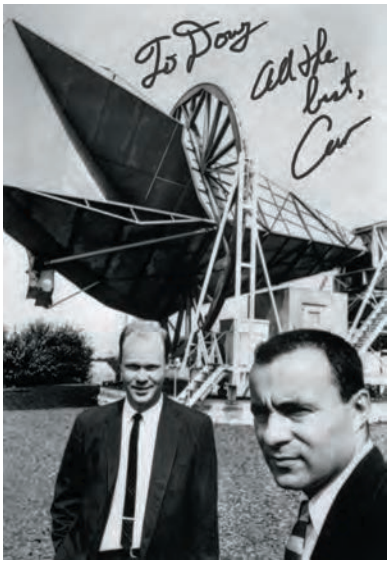


**FIGURE 44–23** Photo of Arno Penzias (right, who signed it "Arno") and Robert Wilson. Behind them their "horn antenna."

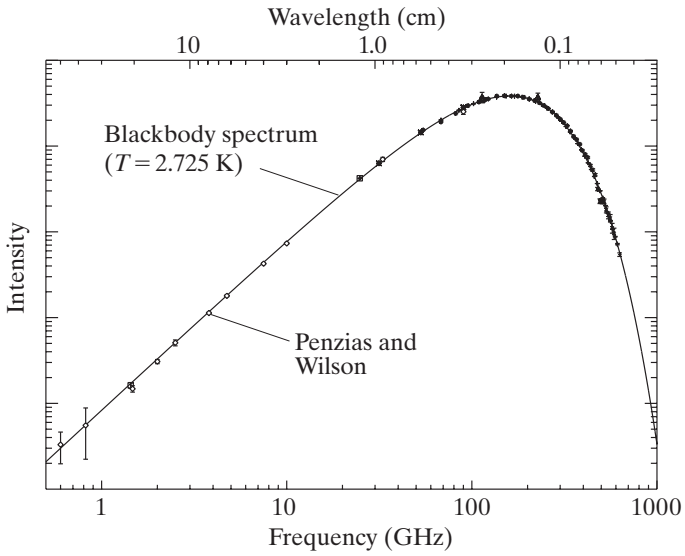

**FIGURE 44–24** Spectrum of cosmic microwave background radiation, showing blackbody curve and experimental measurements including at the frequency detected by Penzias and Wilson. (Thanks to G. F. Smoot and D. Scott. The vertical bars represent the most recent experimental uncertainty in a measurement.)

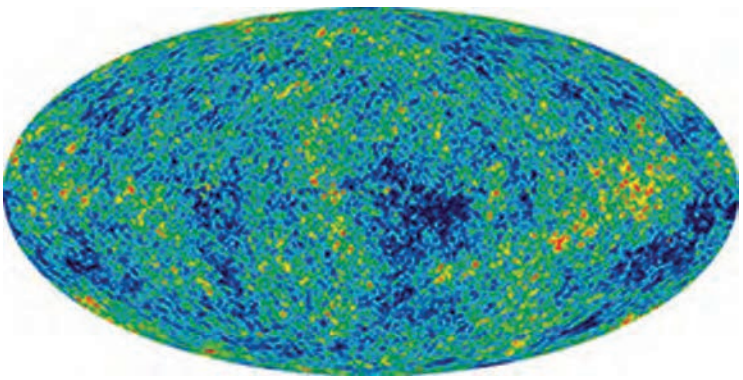
inhomogeneities, or "anisotropies," in the CMB that would have provided "seeds" at which galaxy formation could have started. Small areas of slightly higher density, which could have contracted under gravity to form clusters of galaxies, were indeed found. These tiny inhomogeneities in density and temperature were detected first by the COBE satellite experiment in 1992, led by George Smoot and John Mather (Fig. 44–25).

This discovery of the **anisotropy** of the CMB ranks with the discovery of the CMB itself in the history of cosmology. The blackbody fit and the anisotropy were the culmination of decades of research by pioneers such as Richard Muller, Paul Richards, and David Wilkinson. Subsequent experiments gave us greater detail with the WMAP (Wilkinson Microwave Anisotropy Probe) results from 2003–2012, Fig. 44–26, and even more recently with the European Planck satellite results in 2013.

The CMB provides strong evidence in support of the Big Bang, and gives us information about conditions in the very early universe. In fact, in the late 1940s, George Gamow and his collaborators calculated that a Big Bang origin of the universe should have generated just such a microwave background radiation.



To understand why, let us look at what a Big Bang might have been like. (Today we usually use the term "Big Bang" to refer to the *process*, starting from a moment after the birth of the universe through the subsequent expansion.) The temperature must have been extremely high at the start, so high that there could not have been any atoms in the very early stages of the universe (high energy collisions would have broken atoms apart into nuclei and free electrons). Instead, the universe would have consisted solely of radiation (photons) and a plasma of charged electrons and other elementary particles. The universe would have been opaque—the photons in a sense "trapped," traveling very short distances before being scattered again, primarily by electrons. Indeed, the details of the microwave background radiation provide strong evidence that matter and radiation were once in equilibrium at a very high temperature. As the universe expanded, the energy spread out over an increasingly larger volume and the temperature dropped. When the temperature approached ~3000 K, some 380,000 years later, could nuclei and electrons combine together as stable atoms. With the disappearance of free electrons, as they combined with nuclei to form atoms, the radiation would have been freed—**decoupled** from matter, we say. The universe became *transparent* because photons were now free to travel nearly unimpeded straight through the universe.

It is this radiation, from 380,000 years after the birth of the universe, that we now see as the CMB. As the universe expanded, so too the wavelengths of the radiation lengthened, thus redshifting to longer wavelengths that correspond to lower temperature (recall Wien's law, $\lambda_P T = \text{constant}$, Section 37–1), until they would have reached the 2.7-K background radiation we observe today.

**FIGURE 44–25** COBE scientists John Mather (chief scientist and responsible for measuring the blackbody form of the spectrum) and George Smoot (chief investigator for anisotropy experiment) shown here during celebrations for their Dec. 2006 Nobel Prize, given for their discovery of the spectrum and anisotropy of the CMB using the COBE instrument.

**FIGURE 44–26** Measurements of the cosmic microwave background radiation over the entire sky, color-coded to represent differences in temperature from the average 2.725 K: the color scale ranges from $+200\,\mu$K (red) to $-200\,\mu$K (dark blue), representing slightly hotter and colder spots (associated with variations in density). Results are from the WMAP satellite in 2012: the angular resolution is 0.2°.

## Looking Back Toward the Big Bang—Lookback Time

Figure 44–27 shows our Earth point of view, looking out in all directions back toward the Big Bang and the brief (380,000-year-long) period when radiation was trapped in the early plasma (yellow band). The time it takes light to reach us from an event is called its **lookback time**. The "close-up" insert in Fig. 44–27 shows a photon scattering repeatedly inside that early plasma and then exiting the plasma in a straight line. No matter what direction we look, our view of the very early universe is blocked by this wall of plasma. It is like trying to look into a very thick fog or into the surface of the Sun—we can see only as far as its surface, called the **surface of last scattering**, but not into it. Wavelengths from there are redshifted by $z \approx 1100$. Time $\Delta t'$ in Fig. 44–27 is the lookback time (not real time that goes forward).

Recall that when we view an object far away, we are seeing it as it was then, when the light was emitted, not as it would appear today.

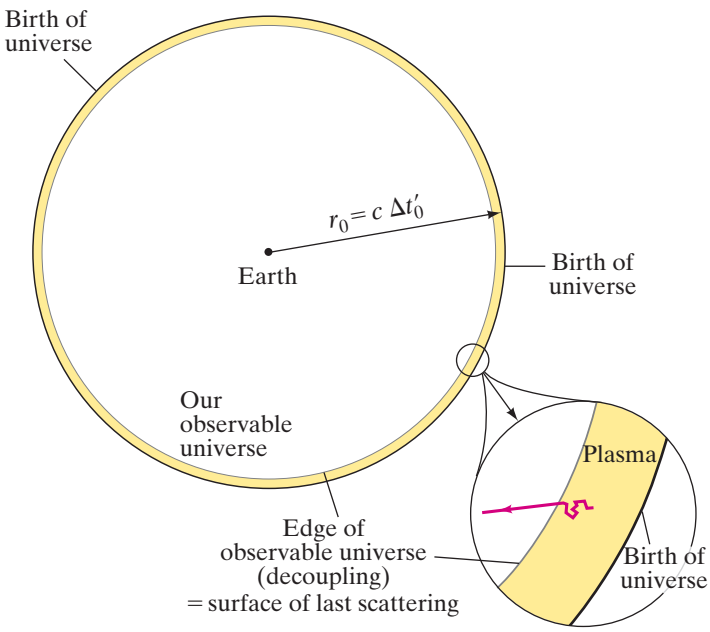


**FIGURE 44–27** When we look out from the Earth, we look back in time. Any other observer in the universe would see more or less the same thing. The farther an object is from us, the longer ago the light we see had to have left it. We cannot see quite as far as the Big Bang because our view is blocked; we can see only as far as the "surface of last scattering," which radiated the CMB. The insert on the lower right shows the earliest 380,000 years of the universe when it was opaque: a photon is shown scattering many times and then (at decoupling, 380,000 yr after the birth of the universe) becoming free to travel in a straight line. If this photon wasn't heading our way when "liberated," many others were. Galaxies are not shown, but would be concentrated close to Earth in this diagram because they were created relatively recently. *Note*: This diagram is not a normal map. Maps show a section of the world as might be seen all *at a given time*. This diagram shows space (like a map), but each point is *not* at the same time. The light coming from a point a distance $r$ from Earth took a time $\Delta t' = r/c$ to reach Earth, and thus shows an event that took place long ago, a time $\Delta t' = r/c$ in the past, which we call its "lookback time." The universe began $\Delta t'_0 = 13.8\,\text{Gyr}$ ago.

## The Observable Universe

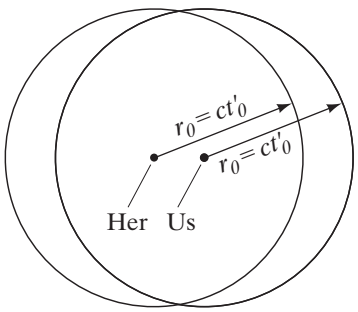

Figure 44–27 can easily be misinterpreted: it is not a picture of the universe at a given instant, but is intended to suggest how we look out in all directions from our observation point (the Earth, or near it). Be careful not to think that the birth of the universe took place in a circle or a sphere surrounding us as if Fig. 44–27 were a photo taken at a given moment. What Fig. 44–27 does show is what we can see, the *observable universe*. Better yet, it shows the *most* we could see.

We would undoubtedly be arrogant to think that we could see the entire universe. Indeed, theories assume that we cannot see everything, that the **entire universe** is greater than the **observable universe**, which is a sphere of radius $r_0 = ct_0$ centered on the observer, with $t_0$ being the age of the universe. We can never see further back than the time it takes light to reach us.

Consider, for example, an observer in another galaxy, very far from us, located to the left of our observation point in Fig. 44–27. That observer would not yet have seen light coming from the far right of the large circle in Fig. 44–27 that we see—it will take some time for that light to reach her. But she will have already, some time ago, seen the light coming from the left that we are seeing now. In fact, her observable universe, superimposed on ours, is suggested by Fig. 44–28.

The edge of our observable universe is called the **horizon**. We could, in principle, see as far as the horizon, but not beyond it. An observer in another galaxy, far from us, will have a different horizon.

**FIGURE 44–28** Two observers, on widely separated galaxies, have different horizons, different observable universes.

PSE5_CH44_v1.6_23Jun-20

# 44–7 The Standard Cosmological Model: Early History of the Universe

In the last decade or two, a convincing theory of the origin and evolution of the universe has been developed, now called the **Standard Cosmological Model**. Part of this theory is based on recent theoretical and experimental advances in elementary particle physics, and part from observations of the universe including COBE, WMAP, and Planck satellites. Indeed, cosmology and elementary particle physics have cross-fertilized to a surprising extent.

Let us go back to the earliest of times—as close as possible to the Big Bang—and follow a Standard Model theoretical scenario of events as the universe expanded and cooled after the Big Bang. Initially we talk of extremely small time intervals as well as extremely high temperatures, far higher than any temperature in the universe today. Figure 44–29 is a compressed graphical representation of the events, and it may be helpful to consult it as we go along.

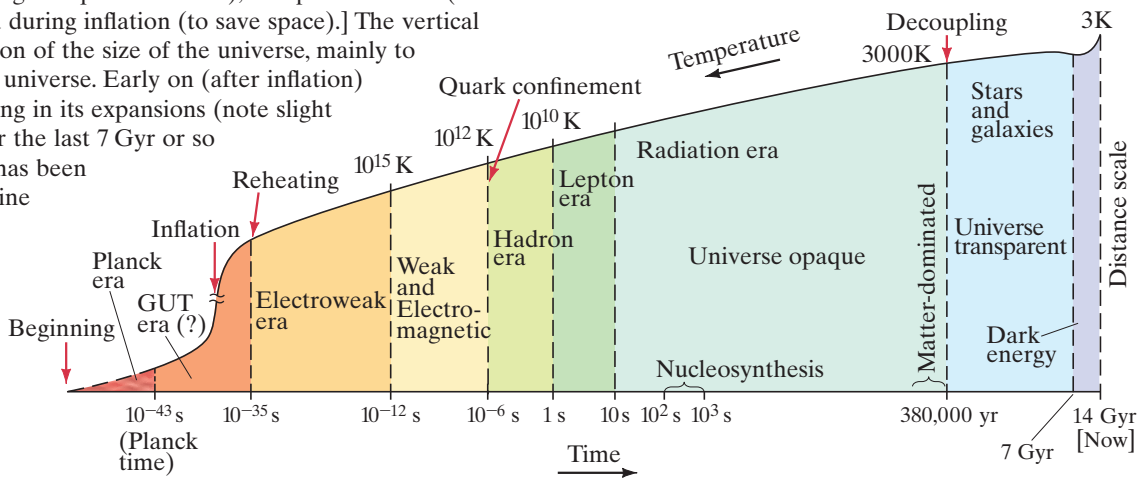

**FIGURE 44–29** Compressed graphical representation of the development of the universe after the Big Bang, according to modern cosmology. [The time scale is mostly logarithmic (each factor of 10 in time gets equal treatment), except at the start (there can be no $t = 0$ on a log scale), and during inflation (to save space).] The vertical height is a rough indication of the size of the universe, mainly to suggest expansion of the universe. Early on (after inflation) the universe is decelerating in its expansions (note slight downward curve); but for the last 7 Gyr or so (= thin strip on right) it has been accelerating, so the size line on the top curves upward at upper right.

## The History

We begin at a time only a minuscule fraction of a second after the "beginning" of the universe, $10^{-43}$ s. This time (sometimes referred to as the **Planck time**) is an unimaginably short time, and predictions can be only speculative. Earlier, we can say nothing because we do not have a theory of quantum gravity which would be needed for the incredibly high densities and temperatures during this "Planck era."

The first theories of the Big Bang assumed the universe was extremely hot in the beginning, maybe $10^{32}$ K, and then gradually cooled down while expanding. In those first moments after $10^{-43}$ s, the four forces of nature were thought to be united—there was only one force (Chapter 43, Fig. 43–22). Then a kind of "phase transition" would have occurred during which the gravitational force would have "condensed out" as a separate force. This and subsequent phase transitions, as shown in Fig. 43–22, are analogous to phase transitions water undergoes as it cools from a gas condensing into a liquid, and with further cooling freezes into ice.[†] The *symmetry* of the four forces would have been broken leaving the strong, weak, and electromagnetic forces still unified, and the universe would have entered the **grand unified era** (GUT—see Section 43–11).

[†]It may be interesting to point out that this story of origins here bears some resemblance to ancient accounts (nonscientific) that mention the "void," "formless wasteland" (or "darkness over the deep"), "abyss," "divide the waters" (= a phase transition?), not to mention the sudden appearance of light.

This scenario of a *hot* Big Bang is now doubted by some important theorists, such as Andreí Linde, whose theories suggest the universe was much cooler at the Planck time. But what happened next to the universe, though very strange, is accepted by most cosmologists: a brilliant idea, suggested by Linde and Alan Guth in the early 1980s, proposed that the universe underwent an incredible exponential expansion, increasing in size by a factor of $10^{30}$ or maybe much more, in a tiny fraction of a second, perhaps $10^{-35}$ s or $10^{-32}$ s. The usefulness of this **inflationary scenario** is that it solved major problems with earlier Big Bang models, such as explaining why the universe is flat, as well as the thermal equilibrium to provide the nearly uniform CMB, as discussed below.

When inflation ended, whatever energy caused it then ended up being transformed into elementary particles with very high kinetic energy, corresponding to very high temperature $\left(\text{Eq. 18–4, } \overline{K} = \frac{3}{2}kT\right)$. That process is referred to as **reheating**, and the universe was now a "soup" of leptons, quarks, and other particles. We can think of this "soup" as a plasma of particles and antiparticles, as well as photons—all in roughly equal numbers—colliding with one another frequently and exchanging energy.

The temperature of the universe at the end of inflation was much lower than that expected by the hot Big Bang theory. But it would have been high enough so that the weak and electromagnetic forces were unified into a single force, and this stage of the universe is sometimes called the **electroweak era**. Approximately $10^{-12}$ s after the Big Bang, the temperature dropped to about $10^{15}$ K corresponding to randomly moving particles with an average kinetic energy $K$ of about 100 GeV (see Eq. 18–4):

$$K \approx kT \approx \frac{(1.4 \times 10^{-23}\,\text{J/K})(10^{15}\,\text{K})}{1.6 \times 10^{-19}\,\text{J/eV}} \approx 10^{11}\,\text{eV} = 100\,\text{GeV}.$$

(We usually ignore the factor $\frac{3}{2}$ in Eq. 18–4, as these are order-of-magnitude quantities. Also, be careful to distinguish $K$ (italic) from K.) At that time, symmetry between weak and electromagnetic forces would have broken down, and the weak force separated from the electromagnetic.

As the universe cooled down to about $10^{12}$ K ($K \approx 100$ MeV), approximately $10^{-6}$ s after the Big Bang, quarks stop moving freely and begin to "condense" into more normal particles: nucleons and the other hadrons and their antiparticles. With this **confinement of quarks**, the universe entered the **hadron era**. But it did not last long. Very soon the vast majority of hadrons disappeared. To see why, let us focus on the most familiar hadrons: nucleons and their antiparticles. When the average kinetic energy of particles was somewhat higher than 1 GeV, protons, neutrons, and their antiparticles were continually being created out of the energies of collisions involving photons and other particles, such as

$$\begin{aligned} \text{photons} &\rightarrow \text{p} + \overline{\text{p}} \\ &\rightarrow \text{n} + \overline{\text{n}}. \end{aligned}$$

But just as quickly, particles and antiparticles would annihilate: for example

$$\text{p} + \overline{\text{p}} \rightarrow \text{photons or leptons.}$$

So the processes of creation and annihilation of nucleons were in equilibrium. The numbers of nucleons and antinucleons were high—roughly as many as there were electrons, positrons, or photons. But as the universe expanded and cooled, and the average kinetic energy of particles dropped below about 1 GeV, which is the minimum energy needed in a typical collision to create nucleons and antinucleons (about 940 MeV each), the process of nucleon creation could not continue. Annihilation could continue, however, with antinucleons annihilating nucleons, until almost no nucleons were left. But not quite zero. Somehow we need to explain our present world of matter (nucleons and electrons) with very little antimatter in sight.

PSE5_CH44_v1.6_23Jun-20

To explain our world of matter, we might suppose that earlier in the universe, after the inflationary period, a slight excess of quarks over antiquarks was formed.[†] This would have resulted in a slight excess of nucleons over antinucleons. And it is these "leftover" nucleons that we are made of today. The excess of nucleons over antinucleons was probably about one part in $10^9$. During the hadron era, there should have been about as many nucleons as photons. After it ended, the "leftover" nucleons thus numbered only about one nucleon per $10^9$ photons, and this ratio has persisted to this day. Protons, neutrons, and all other heavier particles were thus tremendously reduced in number by about $10^{-6}$ s after the Big Bang. The lightest hadrons, the pions, soon disappeared, about $10^{-4}$ s after the Big Bang; because they are the lightest mass hadrons (140 MeV), pions were the last hadrons able to be created as the temperature (and average kinetic energy) dropped. Lighter particles, including electrons and neutrinos, were the dominant form of matter, and the universe entered the **lepton era**.

By the time the first full second had passed (clearly the most eventful second in history!), the universe had cooled to about 10 billion degrees, $10^{10}$ K. The average kinetic energy was about 1 MeV. This was still sufficient energy to create electrons and positrons and balance their annihilation reactions, since their masses correspond to about 0.5 MeV. So there were about as many $e^+$ and $e^-$ as there were photons. But within a few more seconds, the temperature had dropped sufficiently so that $e^+$ and $e^-$ could no longer be formed. Annihilation $(e^+ + e^- \rightarrow \text{photons})$ continued. And, like nucleons before them, electrons and positrons all but disappeared from the universe—except for a slight excess of electrons over positrons (later to join with nuclei to form atoms). Thus, about $t = 10$ s after the Big Bang, the universe entered the **radiation era** (Fig. 44–29). Its major constituents were photons and neutrinos. But the neutrinos, partaking only in the weak force, rarely interacted. So the universe, until then experiencing significant amounts of energy in matter and in radiation, now became **radiation-dominated**: much more energy was contained in radiation than in matter, a situation that would last more than 50,000 years.

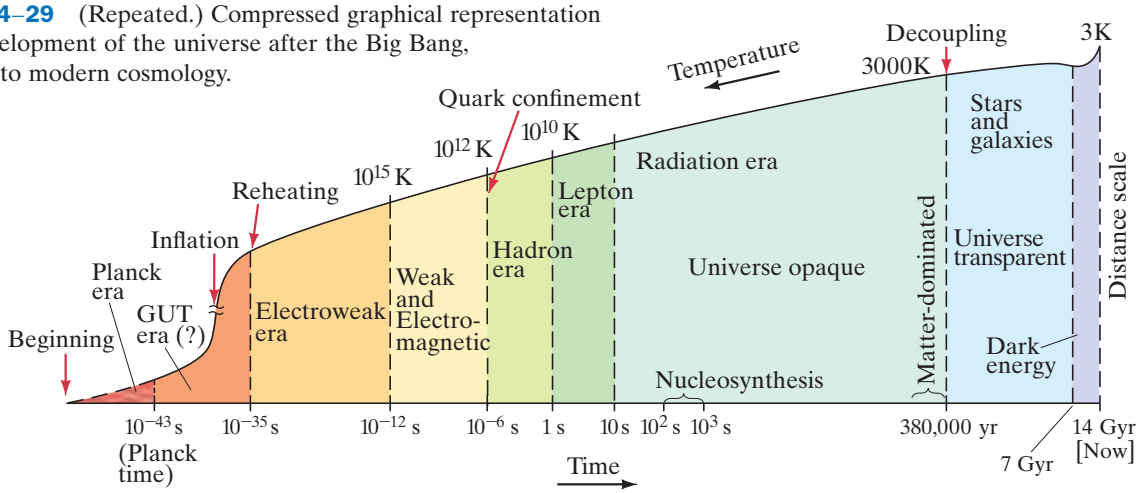

**FIGURE 44–29** (Repeated.) Compressed graphical representation of the development of the universe after the Big Bang, according to modern cosmology.

Meanwhile, during the next few minutes, crucial events were taking place. Beginning about 2 or 3 minutes after the Big Bang, nuclear fusion began to occur. The temperature had dropped to about $10^9$ K, corresponding to an average kinetic energy $K \approx 100$ keV, where nucleons could strike each other and be able to fuse (Section 42–4), but now cool enough so newly formed nuclei would not be immediately broken apart by subsequent collisions. Deuterium, helium, and very tiny amounts of lithium nuclei were made. But the universe was cooling too quickly, and larger nuclei were not made. After only a few minutes, probably not even a quarter of an hour after the Big Bang, the temperature dropped far enough that nucleosynthesis stopped, not to start again for millions of years (in stars).

[†]Why this could have happened is a question for which we are seeking an answer today.

Thus, after the first quarter hour or so of the universe, matter consisted mainly of bare nuclei of hydrogen (about 75%) and helium (about 25%)[†] as well as electrons. But radiation (photons) continued to dominate.

Our story is almost complete. The next important event is thought to have occurred 380,000 years later. The universe had expanded to about $\frac{1}{1000}$ of its present scale, and the temperature had cooled to about 3000 K. The average kinetic energy of nuclei, electrons, and photons was less than an electron volt. Since ionization energies of atoms are on the order of eV, then as the temperature dropped below this point, electrons could orbit the bare nuclei and remain there (without being ejected by collisions), thus forming atoms. This period is often called the **recombination** epoch (a misnomer since electrons had never before been combined with nuclei to form atoms). With the disappearance of free electrons and the birth of atoms, the photons—which had been continually scattering from the free electrons—now became free to spread throughout the universe. As mentioned in the previous Section, we say that the photons became **decoupled** from matter. Thus *decoupling* occurred at *recombination*. The energy contained in radiation had been decreasing (lengthening in wavelength as the universe expanded); and at about $t = 56{,}000$ yr (even before decoupling) the energy contained in matter became dominant over radiation. The universe was said to have become **matter-dominated** (marked on Fig. 44–29). As the universe continued to expand, the electromagnetic radiation cooled further, to 2.7 K today, forming the cosmic microwave background radiation we detect from everywhere in the universe.

After the birth of atoms, then stars and galaxies could begin to form: by self-gravitation around mass concentrations (inhomogeneities). Stars began to form about 200 million years after the Big Bang, galaxies after almost $10^9$ years. The universe continued to evolve until today, some 14 billion years after it started.

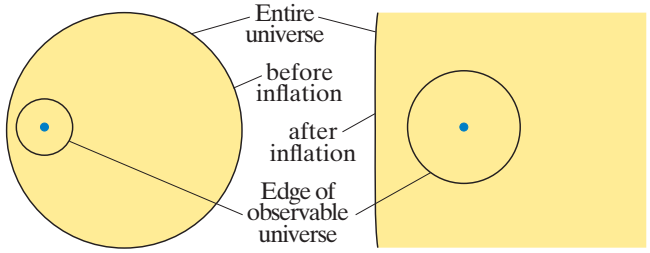
* * *

This scenario, like other scientific models, cannot be said to be "proven." Yet this model is remarkably effective in explaining the evolution of the universe we live in and the observations made up to now; it also makes predictions which can be tested against the next generation of observations.

A major event, and something only discovered recently, is that when the universe was about half as old as it is now (about 7 Gyr ago), its expansion began to accelerate. This was a big surprise because it was assumed the expansion of the universe would slow down due to gravitational attraction of all objects toward each other. This acceleration in the expansion of the universe is said to be due to "dark energy," as we discuss in Section 44–9. On the right in Fig. 44–29 is a narrow vertical strip that represents the most recent 7 billion years or so of the universe, during which *dark energy* seems to have dominated.

## 44–8 Inflation: Explaining Flatness, Uniformity, and Structure

The idea that the universe underwent a period of exponential inflation early in its life, expanding by a factor of $10^{30}$ or more (previous Section), was first put forth by Alan Guth and Andreí Linde. Many sophisticated models based on this general idea have since been proposed. The energy required for this wild expansion may have been due to fields somewhat like the Higgs field (Section 42–10). So far, the evidence for inflation is indirect; yet it is a feature of most viable cosmological models because it alone is able to provide natural explanations for several remarkable features of our universe.



[†]This Standard Model prediction of a 25% primordial production of helium agrees with what we observe today—the universe *does* contain about 25% He—and it is strong evidence in support of the Standard Big Bang Model. Furthermore, the theory says that 25% He abundance is fully consistent with there being three neutrino types, which is the number we observe. And it sets an upper limit of four to the maximum number of possible neutrino types. This is a striking example of the powerful connection between particle physics and cosmology.

PSE5_CH44_v1.6_23Jun-20

## Flatness

First of all, our best measurements suggest that the universe is flat, that it has zero curvature. As scientists, we would like some reason for this remarkable result. To see how inflation explains flatness, consider a simple 2-dimensional model of the universe as we did earlier in Figs. 44–16 and 44–21. A circle in this 2-dimensional universe (= surface of a sphere, Fig. 44–30a) represents the *observable* universe as seen by an observer at the blue dot. A possible hypothesis is that inflation occurred over a time interval that very roughly doubled the age of the universe from, let us say, $t = 1 \times 10^{-35}\,\text{s}$ to $t = 2 \times 10^{-35}\,\text{s}$. The size of the *observable* universe $(r = ct)$ would have increased by a factor of two during inflation, while the radius of curvature of the *entire* universe increased by an enormous factor of $10^{30}$ or more. Thus the edge of our 2-D sphere representing the entire universe would have seemed flat to a high degree of precision, as shown in Fig. 44–30b. Even if the time of inflation was a factor of 10 or 100 (instead of 2), the expansion factor of $10^{30}$ or more would have blotted out any possibility of observing anything but a flat universe.

(a) Before inflation (b) After inflation

**FIGURE 44–30** (a) Simple 2-D model of the entire universe; the observable universe is suggested by the small circle centered on us (blue dot). (b) Edge of universe is essentially flat after the $10^{30}$-fold expansion during inflation.

## CMB Uniformity

Inflation also explains why the Cosmic Background Radiation is so uniform. Without inflation, the tiny universe at $10^{-35}\,\text{s}$ would not have been small enough for all parts of it to have been in contact and so reach the same temperature (information cannot travel faster than $c$). To see this, suppose that the currently observable universe came from a region of space about 1 cm in diameter at $t = 10^{-36}\,\text{s}$, as per original Big Bang theory. In that $10^{-36}\,\text{s}$, light could have traveled $d = ct = (3 \times 10^8\,\text{m/s})(10^{-36}\,\text{s}) = 10^{-27}\,\text{m}$, way too small for the opposite sides of a 1-cm-wide "universe" to have been in communication. But if that region had been $10^{30}$ times smaller $(= 10^{-32}\,\text{m})$, as proposed by the inflation model, there could have been contact and thermal equilibrium to produce the observed nearly uniform CMB. Inflation, by making the very early universe extremely small, assures that all parts of that region which is today's observable universe could have been in thermal equilibrium. And after inflation the universe could be large enough to give us today's observable universe.

## Galaxy Seeds, Fluctuations, Magnetic Monopoles

Inflation also gives us a clue as to how the present structure of the universe (galaxies and clusters of galaxies) came about. We saw earlier that, according to the uncertainty principle, energy might be not conserved by an amount $\Delta E$ for a time $\Delta t \approx \hbar/\Delta E$. Forces, whether electromagnetic or other types, can undergo such tiny **quantum fluctuations** according to quantum theory, but they are so tiny they are not detectable unless magnified in some way. That is what inflation might have done: it could have magnified those fluctuations perhaps $10^{30}$ times in size, which would give us the density irregularities seen in the cosmic microwave background (Planck, Fig. 44–26). That would be very nice, because the density variations we see in the CMB are what we believe were the seeds that later coalesced under gravity into galaxies and galaxy clusters, and our models fit the data extremely well.

Sometimes it is said that the quantum fluctuations occurred in the **vacuum state** or vacuum energy. This could be possible because the vacuum is no longer considered to be empty, as we discussed in Section 43–3 relative to positrons as holes in a negative energy sea of electrons. Indeed, the vacuum is thought to be filled with fields and particles occupying all the possible negative energy states.

Also, the virtual exchange particles that carry the forces, as discussed in Chapter 43, could leave their brief virtual states and actually become real as a result of the $10^{30}$ magnification of space (according to inflation) and the very short time over which it occurred $(\Delta t = \hbar/\Delta E)$.

Inflation helps us too with the puzzle of why **magnetic monopoles** (Section 27–1) have never been observed, yet isolated magnetic poles may well have been copiously produced at the start. After inflation, they would have been so far apart that we have never stumbled on one.

Inflation may solve outstanding problems, but we may need new physics to understand how inflation occurred. Many predictions of inflationary theory have been confirmed by recent cosmological observations.

## 44–9 Dark Matter and Dark Energy

According to the Standard Big Bang Model, the universe is evolving and changing. Individual stars are being created, evolving, and then dying to become white dwarfs, neutron stars, or black holes. At the same time, the universe as a whole is expanding. One important question is whether the universe will continue to expand forever. Until the late 1990s, the universe was thought to be dominated by matter which interacts by gravity, and the fate of the universe was connected to the curvature of space-time (Section 44–4). If the universe had *negative* curvature, the expansion of the universe would never stop, although the rate of expansion would decrease due to the gravitational attraction of its parts. Such a universe would be *open* and infinite. If the universe is *flat* (no curvature), it would still be open and infinite but its expansion would slowly approach a zero rate. If the universe had *positive* curvature, it would be *closed* and finite; the effect of gravity would be strong enough that the expansion would eventually stop and the universe would begin to contract, collapsing back onto itself in a **big crunch**.

### Critical Density

According to the above scenario (which does not include inflation or the recently discovered acceleration of the universe), the fate of the universe would depend on the average mass–energy density in the universe. For an average mass density greater than a critical value known as the **critical density**, estimated to be about

$$\rho_c \approx 10^{-26}\,\text{kg/m}^3$$

(i.e., a few nucleons/m$^3$ on average throughout the universe), space-time would have a positive curvature and gravity would prevent expansion from continuing forever. Eventually (if $\rho > \rho_c$) gravity would pull the universe back into a big crunch. If instead the actual density was equal to the critical density, $\rho = \rho_c$, the universe would be flat and open, just barely expanding forever. If the actual density was less than the critical density, $\rho < \rho_c$, the universe would have negative curvature and would easily expand forever. See Fig. 44–31. Today we believe the universe is very close to flat.

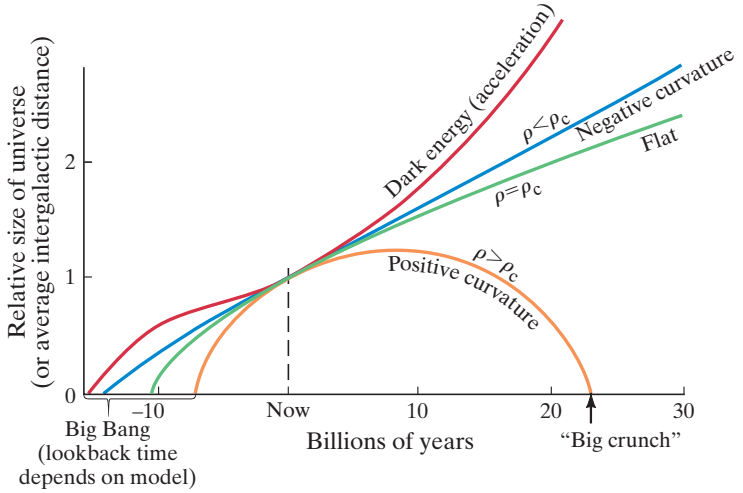


**FIGURE 44–31** Three future possibilities for the universe, depending on the density $\rho$ of ordinary matter, plus a fourth possibility that includes dark energy. Note that all curves have been chosen to have the same slope ($= H_0$, the Hubble parameter) right now. Looking back in time, the Big Bang occurs where each curve touches the horizontal (time) axis.

PSE5_CH44_v1.6_23Jun-20

But recent evidence suggests the universe is expanding at an *accelerating* rate, as discussed below.

**EXAMPLE 44–7** **ESTIMATE** **Critical density of the universe.** Use energy conservation and escape velocity (Section 8–7) to estimate the critical density of the universe.

**APPROACH** At the critical density, $\rho_c$, any given galaxy of mass $m$ will just be able to "escape" away from our Galaxy. As we saw in Section 8–7, escape can just occur if the total energy $E$ of the galaxy satisfies

$$E = K + U = \tfrac{1}{2}mv^2 - G\frac{mM}{R} = 0.$$

Here $R$ is the distance of that galaxy $m$ from us. We approximate the total mass $M$ that pulls inward on $m$ as the total mass within a sphere of radius $R$ around us (Appendix E). If we assume the density of galaxies is roughly constant, then $M = \frac{4}{3}\pi\rho_c R^3$.

**SOLUTION** Substituting this $M$ into the equation above, and setting $v = HR$ (Hubble's law, Eq. 44–4), we obtain

$$\frac{GM}{R} = \tfrac{1}{2}v^2$$

or

$$\frac{G\left(\frac{4}{3}\pi\rho_c R^3\right)}{R} = \tfrac{1}{2}(HR)^2.$$

We solve for $\rho_c$:

$$\rho_c = \frac{3H^2}{8\pi G} \approx \frac{3\left[(22\,\text{km/s/Mly})\,(1\,\text{Mly}/10^{19}\,\text{km})\right]^2}{8(3.14)\left(6.67\times10^{-11}\,\text{N}\cdot\text{m}^2/\text{kg}^2\right)} \approx 10^{-26}\,\text{kg/m}^3.$$

**EXERCISE E** Return to the Chapter-Opening Questions, page 1322, and answer them again. Try to explain why you may have answered differently the first time.

## Dark Matter

COBE, WMAP, Planck, and other experiments have convinced scientists that the universe is flat and $\rho = \rho_c$. But this $\rho$ cannot be only normal baryonic matter (atoms are 99.9% baryons—protons and neutrons—by weight). These recent experiments put the amount of normal baryonic matter in the universe at only about 5% of the critical density. What is the other 95%? There is strong evidence for a significant amount of nonluminous matter in the universe referred to as **dark matter**, which acts normally under gravity, but does not absorb or radiate light sufficiently to be visible. For example, observations of the rotation of galaxies suggest that they rotate as if they had considerably more mass than we can see. Recall from Chapter 5, Eq. 5–6, that for a satellite of mass $m$ revolving around Earth (mass $M$)

$$m\frac{v^2}{r} = G\frac{mM}{r^2}$$

and hence $v = \sqrt{GM/r}$. If we apply this equation to stars in a galaxy, we see that their speed depends on galactic mass. Observations show that stars farther from the galactic center revolve much faster than expected if there is only the pull of visible matter, suggesting a great deal of invisible matter. Similarly, observations of the motion of galaxies within clusters also suggest that they have considerably more mass than can be seen. In fact, dark matter was first proposed in the 1930s, based on such observations.

Furthermore, theory suggests that without dark matter, galaxies and stars probably would not have formed and would not exist. Dark matter seems to hold the universe together.

What might this nonluminous matter in the universe be? We don't know yet. But we hope to find out soon. It cannot be made of ordinary baryonic matter (protons and neutrons), so it must consist of some other sort of elementary particle, perhaps created at a very early time. Perhaps it is made up of previously undetected *weakly interacting massive particles* (**WIMP**s), possibly supersymmetric particles (Section 43–12) such as neutralinos. We are anxiously awaiting the results of intense searches for such particles, looking both at what arrives from far out in the cosmos with underground detectors[†] and satellites, and by producing them in particle colliders (the LHC, Section 43–1).

Dark matter makes up roughly 25% of the mass–energy of the universe, according to the latest observations and models. Thus the total mass–energy is 25% dark matter plus 5% baryons for a total of about 30%, which does not bring $\rho$ up to $\rho_c$. What is the other 70%? We are not sure about that either, but we have given it a name: "dark energy."

## Dark Energy—Cosmic Acceleration

**FIGURE 44–32** Saul Perlmutter, center, flanked by Adam G. Riess (left) and Brian P. Schmidt, at the Nobel Prize celebrations, December 2011.

In 1998, just before the turn of the millennium, two groups, one led by Saul Perlmutter and the other by Brian Schmidt and Adam Riess (Fig. 44–32), reported a huge surprise. Gravity was assumed to be the predominant force on a large scale in the universe, and it was thought that the expansion of the universe ought to be slowing down in time because gravity acts as an attractive force between objects. But measurements of Type Ia supernovae (our best standard candles—see Section 44–3) unexpectedly showed that very distant (high $z$) supernovae were dimmer than expected. That is, given their great distance $d$ as determined from their low brightness, their speed $v$ as determined from the measured $z$ was less than expected according to Hubble's law. This result suggests that nearer galaxies are moving away from us relatively faster than those very distant ones, meaning the expansion of the universe in more recent epochs has sped up. This **acceleration** in the expansion of the universe (in place of the expected deceleration due to gravitational attraction between masses) seems to have begun roughly 7 billion years ago (7 Gyr, which would be about halfway back to what we call the Big Bang).

What could be causing the universe to accelerate in its expansion, against the attractive force of gravity? Does our understanding of gravity need to be revised? We don't yet know the answers to these questions. There are several speculations. But somehow there seems to be a long-range *repulsive* effect on space, like a negative gravity, causing objects to speed away from each other ever faster. Whatever it is, it has been given the name **dark energy**. Many scientists say dark energy is the biggest mystery facing physical science today. The name "dark energy" doesn't tell us much: As the poet[‡] sang a half century ago, "Something is happening but we don't know what it is… ." Here are some thoughts:

One idea is a sort of quantum field given the name **quintessence**. Another possibility suggests an energy latent in space itself (**vacuum energy**) and relates to an aspect of General Relativity known as the **cosmological constant** (symbol $\Lambda$). When Einstein developed his equations, he found that they offered no solutions for a static universe. In those days (1917) it was thought the universe was static—unchanging and everlasting. Einstein added an arbitrary constant ($\Lambda$) to his equations to provide solutions for a static universe.[§] A decade later, when Hubble showed us an expanding universe, Einstein discarded his cosmological constant as no longer needed ($\Lambda = 0$). But today, measurements are consistent

[†]In deep mines and under mountains to block out most other particles.

[‡]Bob Dylan, "Ballad of a Thin Man." "Dark matter," on the other hand, is a good name because it refers to something we can't see but that acts gravitationally, like regular matter.

[§]It seems strange that Einstein and other scientists believed in a static universe. The ancients, including the Roman Lucretius argued against it: *If there was no birth-time of earth and heaven and they have been from everlasting, why before the* [Trojan] *war …. have not other poets as well sung other themes?* [The reference is to Homer being the oldest known writings.] The ancient Hebrews also argued for a beginning (like our Big Bang): see Genesis.

PSE5_CH44_v1.6_23Jun-20

with dark energy being due to a nonzero cosmological constant, although further measurements are needed to see subtle differences among theories.

There is increasing evidence that the effects of some form of dark energy are very real. Observations of the CMB, supernovae, and large-scale structure (Section 44–10) agree well with theories and computer models when they input dark energy as providing about 70% of the mass–energy in the universe, and when the total mass–energy density equals the critical density $\rho_c$.

Today's best estimate of how the mass–energy in the universe is distributed is approximately, rounded off (but see also Fig. 44–33):

70% dark energy

30% matter, subject to the known gravitational force.

Of this 30%, about

25% is dark matter

5% is baryons (what atoms are made of); of this 5% only $\frac{1}{10}$ is readily visible matter—stars and galaxies (that is, 0.5% of the total); the other $\frac{9}{10}$ of ordinary matter, which is not visible, is mainly gaseous plasma.

It is remarkable that only 0.5% of all the mass–energy in the universe is visible as stars and galaxies.

The idea that the universe is dominated by completely unknown forms of matter and energy seems bizarre. Nonetheless, the ability of our present model to precisely explain observations of the CMB anisotropy, cosmic expansion, and large-scale structure (next Section) presents a compelling case.

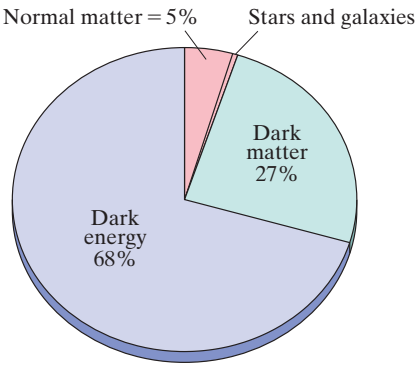

**FIGURE 44–33** Portions of total mass–energy in the universe today (approximate).

## 44–10 Large-Scale Structure of the Universe

The beautiful Planck pictures of the sky (Fig. 44–26) show small but significant inhomogeneities in the temperature of the cosmic microwave background (CMB). These anisotropies reflect compressions and expansions in the primordial plasma just before decoupling (Fig. 44–29), from which galaxies and clusters of galaxies formed. Analyses of the irregularities in the CMB using mammoth computer simulations predict a large-scale distribution of galaxies very similar to what is seen today (Fig. 44–34). These simulations are very successful if they contain dark energy and dark matter; and the dark matter needs to be *cold* (slow speed—think of Eq. 18–4, $\frac{1}{2}m\overline{v^2} = \frac{3}{2}kT$. where $T$ is temperature), rather than "hot" dark matter such as neutrinos which move at or very near the speed of light. Indeed, the modern **cosmological model** is called the **ΛCDM** model, where lambda (**Λ**) stands for the cosmological constant, and CDM is **cold dark matter**.

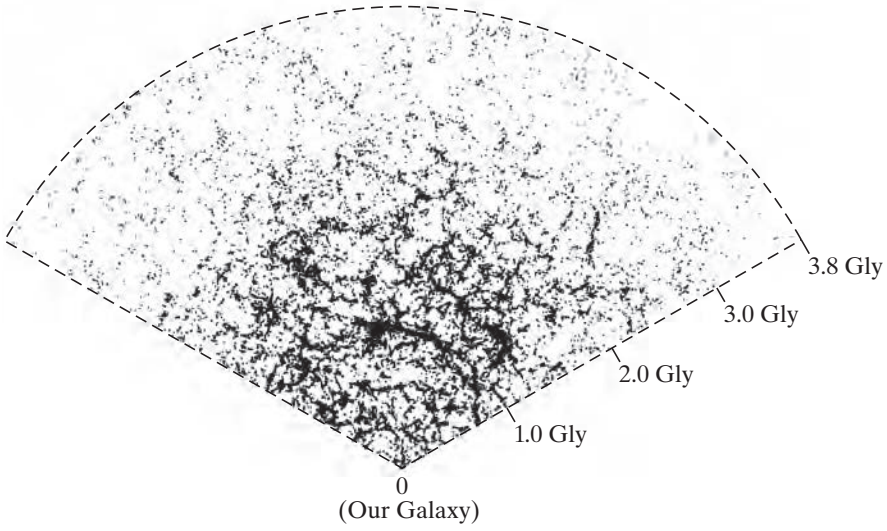

**FIGURE 44–34** Distribution of some 50,000 galaxies in a 2.5° slice through almost half of the sky above the equator, as measured by the Sloan Digital Sky Survey (SDSS). Each dot represents a galaxy. The distance from us is obtained from the redshift and Hubble's law, and is given in units of $10^9$ light-years (Gly). The point 0 represents us, our observation point. This diagram may seem to put us at the center, but remember that at greater distances, fewer galaxies are bright enough to be detected, thus resulting in an apparent thinning out of galaxies. Note the "walls" and "voids" of galaxies.

Cosmologists have gained substantial confidence in this cosmological model from such a precise fit between observations and theory. They can also extract very precise values for cosmological parameters which previously were only known with low accuracy. The CMB is such an important cosmological observable that every effort is being made to extract all of the information it contains. A new generation of ground, balloon, and satellite experiments is observing the CMB with greater resolution and sensitivity. They may detect interaction of *gravity waves* (produced in the inflationary epoch) with the CMB and thereby provide direct evidence for cosmic inflation, and also provide information about elementary particle physics at energies far beyond the reach of man-made accelerators and colliders.

## 44–11 Gravitational Waves—LIGO

Einstein, in his General Theory of Relativity (Section 44–4) predicted that there could be **gravitational waves**. That is, space itself could support waves: space itself could be "wavy" as waves moved along. Any wave needs a source, such as a rock thrown into a lake causes circular waves to move outward from the rock's point of entry. See photos in Fig. 15–1, page 428.

Gravitational waves are expected to be very tiny ripples in the fabric of space-time; tiny and difficult to detect. Very sensitive instruments have been developed over the last few decades to detect gravitational waves, and use them as a tool to understand the universe.

In early 2016, their direct detection was announced by LIGO, the Laser Interferometer Gravitational-wave Observatory. How did they do it? They used very large interferometers. Recall the Michelson interferometer with 2 perpendicular arms (Section 34–6, Fig. 34–24) which could sit on a large table-top and was used to detect (unsuccessfully) the "ether" assumed to be the medium to carry light waves. See the Special Theory of Relativity, especially Section 36–2, and Fig. 36–3.

LIGO uses interferometers whose two perpendicular arms are vastly longer, 4 km each. A passing gravitational wave changes the relative lengths of the two arms and causes a phase difference in the light beams (from a laser source) traveling along the two arms. Because LIGO has large interferometers at two distant locations (Louisiana and Washington state), and both detected a $\frac{1}{4}$-second long pulse of gravitational waves pass by on September 14, 2015, they could estimate (by triangulation—see Section 1–6 and Fig. 44–11) that the source of the tiny ripples they detected was 1.3 billion light-years away.

What was the source? Analysis of the frequencies present in the pulse allowed them to judge that 2 black holes orbiting each other had spiraled closer and closer until they collided and merged into one, releasing a tremendous amount of energy $\left(\approx 3M_{\text{Sun}}c^2\right)$. That energy warped space-time, like a rock striking a lake. The change in length of the interferometer arms was only about $10^{-18}$ m. Astonishing instruments!

To finally make a direct detection of gravitational waves was a triumph. But there is more. For the first time, the possibility that binary black holes exist, and could merge, was confirmed. (Like binary stars, they would orbit each other, slowly moving closer, and possibly merging given enough time.)

Additional large interferometers are already in place near Pisa, Italy (Virgo), and being constructed in India and Japan. With more, and more sensitive, detectors in place, gravitational waves should help us to observe details about the universe that would otherwise be invisible and unknown.

## 44–12 Finally . . .

When we look up into the night sky, we see stars; and with the best telescopes, we see galaxies and the exotic objects we discussed earlier, including rare supernovae. But even with our best instruments we do not see the processes going on inside stars and supernovae that we hypothesized (and believe to exist).

PSE5_CH44_v1.6_23Jun-20

We are dependent on brilliant theorists who come up with viable theories and verifiable models. We depend on complicated computer models whose parameters are varied until the outputs compare favorably with our observations and analyses of Planck or WMAP and other experiments. And we now have a surprisingly precise idea about some aspects of our universe: it is nearly or completely flat, it is about 14 billion years old, it contains only 5% "normal" baryonic matter (for atoms), and so on.

The questions raised by cosmology are difficult and profound, and may seem removed from everyday "reality." We can always say, "the Sun is shining, it's going to shine on for an unimaginably long time, all is well." Nonetheless, the questions of cosmology are deep ones that fascinate the human intellect. One aspect that is especially intriguing is this: calculations on the formation and evolution of the universe have been performed that deliberately varied the values—just slightly—of certain fundamental physical constants. The result would be a universe in which life as we know it and possibly life of any kind could not exist. [For example, if the difference in mass between a proton and a neutron were zero, or less than the mass of the electron, $0.511\,\text{MeV}/c^2$, there would be no atoms: electrons would be captured by protons to make neutrons.] Such results have contributed to a philosophical idea called the **anthropic principle**, which says that if the universe were even a little different than it is, we could not be here. We physicists are trying to find out if there are some undiscovered fundamental laws that determined those conditions that allowed us to exist. A poet might say that the universe is exquisitely tuned, almost as if to accommodate us.

## Summary

The night sky contains myriads of stars including those in the Milky Way, which is a "side view" of our **Galaxy** looking along the plane of the disk. Our Galaxy includes over $10^{11}$ stars. Beyond our Galaxy are billions of other galaxies.

Astronomical distances are measured in **light-years** $(1\,\text{ly} \approx 10^{13}\,\text{km})$. The nearest star is about 4 ly away and the nearest large galaxy is 2 million ly away. Our Galactic disk has a diameter of about 100,000 ly. [Distances are sometimes specified in **parsecs**, where 1 parsec = 3.26 ly.]

Stars are believed to begin life as collapsing masses of gas (protostars), largely hydrogen. As they contract, they heat up (potential energy is transformed to kinetic energy). When the temperature reaches about 10 million degrees, nuclear fusion begins and forms heavier elements (**nucleosynthesis**), mainly helium at first. The energy released during these reactions heats the gas so its outward pressure balances the inward gravitational force, and the young star stabilizes as a **main-sequence** star. The tremendous luminosity of stars comes from the energy released during these thermonuclear reactions. After billions of years, as helium is collected in the core and hydrogen is used up, the core contracts and heats further. The outer envelope expands and cools, and the star becomes a **red giant** (larger diameter, redder color).

The next stage of stellar evolution depends on the mass of the star, which may have lost much of its original mass as its outer envelope escaped into space. Stars of residual mass less than about 1.4 solar masses cool further and become **white dwarfs**, eventually fading and going out altogether. Heavier stars contract further due to their greater gravity: the density approaches nuclear density, the huge pressure forces electrons to combine with protons to form neutrons, and the star becomes essentially a huge nucleus of neutrons. This is a **neutron star**, and the energy released during its final core collapse is believed to produce **supernova** explosions. If the star is very massive, it may contract even further and form a **black hole**, which is so dense that no matter or light can escape from it.

In the **general theory of relativity**, the **equivalence principle** states that an observer cannot distinguish acceleration from a gravitational field. Said another way, gravitational and inertial masses are the same. The theory predicts gravitational bending of light rays to a degree consistent with experiment. Gravity is treated as a curvature in space and time, the curvature being greater near massive objects. The universe as a whole may be curved. With sufficient mass (and no dark energy), the curvature of the universe would be positive, and the universe is *closed* and *finite*; otherwise, it would be *open* and *infinite*. Today we believe the universe is **flat**.

Distant galaxies display a **redshift** in their spectral lines, originally interpreted as a Doppler shift. The universe is observed to be **expanding**, its galaxies racing away from each other at speeds $(v)$ proportional to the distance $(d)$ between them:

$$v = H_0 d, \qquad \textbf{(44–4)}$$

which is known as **Hubble's law** $(H_0$ is the **Hubble constant**$)$. This expansion of the universe suggests an explosive origin, the **Big Bang**, which occurred about 13.8 billion years ago. It is not like an ordinary explosion, but rather an expansion of space itself.

The **cosmological principle** assumes that the universe, on a large scale, is homogeneous and isotropic.

Important evidence for the Big Bang model of the universe was the discovery of the **cosmic microwave background** radiation (CMB), which conforms to a blackbody radiation curve at a temperature of 2.725 K.

PSE5_CH44_v1.6_23Jun-20

The **Standard Model** of the Big Bang provides a possible scenario as to how the universe developed as it expanded and cooled after the Big Bang. Starting at $10^{-43}$ seconds after the Big Bang, according to this model, the universe underwent a brief but rapid exponential expansion, referred to as **inflation**. Shortly thereafter, quarks were **confined** into hadrons (the **hadron era**). About $10^{-4}$ s after the Big Bang, the majority of hadrons disappeared, having combined with anti-hadrons, producing photons, leptons, and energy, leaving mainly photons and leptons to freely move, thus introducing the **lepton era**. By the time the universe was about 10 s old, the electrons too had mostly disappeared, having combined with their antiparticles; the universe was **radiation-dominated**. A couple of minutes later, nucleosynthesis began, but lasted only a few minutes. It then took almost four hundred thousand years before the universe was cool enough for electrons to combine with nuclei to form atoms (**recombination**). Photons, up to then continually being scattered off of free electrons, could now move freely—they were **decoupled** from matter and the universe became transparent. The background radiation had expanded and cooled so much that its total energy became less than the energy in matter, and **matter dominated** increasingly over radiation. Then stars and galaxies formed, producing a universe not much different than it is today—some 14 billion years later.

Recent observations indicate that the universe is essentially flat, that it contains an as-yet unknown type of **dark matter**, and that it is dominated by a mysterious **dark energy** which exerts a sort of negative gravity causing the expansion of the universe to accelerate. The total contributions of baryonic (normal) matter, dark matter, and dark energy sum up to the **critical density**.

# Questions

1. The Milky Way was once thought to be "murky" or "milky" but is now considered to be made up of point sources. Explain.
2. A star is in equilibrium when it radiates at its surface all the energy generated in its core. What happens when it begins to generate more energy than it radiates? Less energy? Explain.
3. Describe a red giant star. List some of its properties.
4. Does the H–R diagram directly reveal anything about the core of a star?
5. Why do some stars end up as white dwarfs, and others as neutron stars or black holes?
6. If you were measuring star parallaxes from the Moon instead of Earth, what corrections would you have to make? What changes would occur if you were measuring parallaxes from Mars?
7. *Cepheid variable* stars change in luminosity with a typical period of several days. The period has been found to have a definite relationship with the average intrinsic luminosity of the star. How could these stars be used to measure the distance to galaxies?
8. What is a geodesic? What is its role in General Relativity?
9. If it were discovered that the redshift of spectral lines of galaxies was due to something other than expansion, how might our view of the universe change? Would there be conflicting evidence? Discuss.
10. Almost all galaxies appear to be moving away from us. Are we therefore at the center of the universe? Explain.
11. If you were located in a galaxy near the boundary of our observable universe, would galaxies in the direction of the Milky Way appear to be approaching you or receding from you? Explain.
12. Compare an explosion on Earth to the Big Bang. Consider such questions as: Would the debris spread at a higher speed for more distant particles, as in the Big Bang? Would the debris come to rest? What type of universe would this correspond to, open or closed?
13. If nothing, not even light, escapes from a black hole, then how can we tell if one is there?
14. The Earth's age is often given as about 4.6 billion years. Find that time on Fig. 44–29. Modern humans have lived on Earth on the order of 200,000 years. Where is that on Fig. 44–29?
15. Why were atoms, as opposed to bare nuclei, unable to exist until hundreds of thousands of years after the Big Bang?
16. (*a*) Why are Type Ia supernovae so useful for determining the distances of galaxies? (*b*) How are their distances actually measured?
17. Under what circumstances would the universe eventually collapse in on itself?
18. (*a*) Why did astronomers expect that the expansion rate of the universe would be decreasing (decelerating) with time? (*b*) How, in principle, could astronomers hope to determine whether the universe used to expand faster than it does now?
19. Describe how we can estimate the distance from us to other stars. Which methods can we use for nearby stars, and which can we use for very distant stars? Which method gives the most accurate distance measurements for the most distant stars?
20. (*a*) Describe some of the evidence that the universe began with a "Big Bang." (*b*) How does the curvature of the universe affect its future destiny? (*c*) How does dark energy affect the possible future of the universe?
21. Explain what the 2.7-K cosmic microwave background radiation is. Where does it come from? Why is its temperature now so low?

PSE5_CH44_v1.6_23Jun-20

# MisConceptual Questions

1. Which one of the following is *not* expected to occur on an H–R diagram during the lifetime of a single star?
   (*a*) The star will move off the main sequence toward the upper right of the diagram.
   (*b*) Low-mass stars will become white dwarfs and end up toward the lower left of the diagram.
   (*c*) The star will move along the main sequence from one place to another.
   (*d*) All of the above.
2. When can parallax be used to determine the approximate distance from the Earth to a star?
   (*a*) Only during January and July.
   (*b*) Only when the star's distance is relatively small.
   (*c*) Only when the star's distance is relatively large.
   (*d*) Only when the star appears to move directly toward or away from the Earth.
   (*e*) Only when the star is the Sun.
   (*f*) Always.
   (*g*) Never.
3. Observations show that all galaxies tend to move away from Earth, and that more distant galaxies move away from Earth at faster velocities than do galaxies closer to the Earth. These observations imply that
   (*a*) the Earth is the center of the universe.
   (*b*) the universe is expanding.
   (*c*) the expansion of the universe will eventually stop.
   (*d*) All of the above.
4. Which process results in a tremendous amount of energy being emitted by the Sun?
   (*a*) Hydrogen atoms burn in the presence of oxygen—that is, hydrogen atoms oxidize.
   (*b*) The Sun contracts, decreasing its gravitational potential energy.
   (*c*) Protons in hydrogen atoms fuse, forming helium nuclei.
   (*d*) Radioactive atoms such as uranium, plutonium, and cesium emit gamma rays with high energy.
   (*e*) None of the above.
5. Which of the following methods can be used to find the distance from us to a star outside our galaxy? Choose all that apply.
   (*a*) Parallax.
   (*b*) Using luminosity and temperature from the H–R diagram and measuring the apparent brightness.
   (*c*) Using supernova explosions as a "standard candle."
   (*d*) Redshift in the line spectra of elements and compounds.
6. The history of the universe can be determined by observing astronomical objects at various (large) distances from the Earth. This method of discovery works because
   (*a*) time proceeds at different rates in different regions of the universe.
   (*b*) light travels at a finite speed.
   (*c*) matter warps space.
   (*d*) older galaxies are farther from the Earth than are younger galaxies.
7. Where did the Big Bang occur?
   (*a*) Near the Earth.
   (*b*) Near the center of the Milky Way Galaxy.
   (*c*) Several billion light-years away.
   (*d*) Throughout all space.
   (*e*) Near the Andromeda Galaxy.
8. When and how were virtually all of the elements of the Periodic Table formed?
   (*a*) In the very early universe a few seconds after the Big Bang.
   (*b*) At the centers of stars during their main-sequence phases.
   (*c*) At the centers of stars during novae.
   (*d*) At the centers of stars during supernovae.
   (*e*) On the surfaces of planets as they cooled and hardened.
9. We know that there must be dark matter in the universe because
   (*a*) we see dark dust clouds.
   (*b*) we see that the universe is expanding.
   (*c*) we see that stars far from the galactic center are moving faster than can be explained by visible matter.
   (*d*) we see that the expansion of the universe is accelerating.
10. Acceleration of the universe's expansion rate is due to
    (*a*) the repulsive effect of dark energy.
    (*b*) the attractive effect of dark matter.
    (*c*) the attractive effect of gravity.
    (*d*) the thermal expansion of stellar cores.

# Problems

### 44–1 to 44–3 Stars, Galaxies, Stellar Evolution, Distances

1. (I) The parallax angle of a star is 0.00035°. How far away is the star?
2. (I) A star exhibits a parallax of 0.23 seconds of arc. How far away is it?
3. (I) If one star is twice as far away from us as a second star, will the parallax angle of the farther star be greater or less than that of the nearer star? By what factor?
4. (II) What is the relative brightness of the Sun as seen from Jupiter, as compared to its brightness from Earth? (Jupiter is 5.2 times farther from the Sun than the Earth is.)
5. (II) When our Sun becomes a red giant, what will be its average density if it expands out to the orbit of Mercury ($6 \times 10^{10}$ m from the Sun)?

6. (II) We saw earlier (Chapter 19) that the rate energy reaches the Earth from the Sun (the "solar constant") is about $1.3 \times 10^3\ \text{W/m}^2$. What is (*a*) the apparent brightness *b* of the Sun, and (*b*) the intrinsic luminosity *L* of the Sun?

7. (II) Estimate the angular width that our Galaxy would subtend if observed from the nearest galaxy to us (Table 44–1). Compare to the angular width of the Moon from Earth.

8. (II) Assuming our Galaxy represents a good average for all other galaxies, how many stars are in the observable universe?

9. (II) Calculate the density of a white dwarf whose mass is equal to the Sun's and whose radius is equal to the Earth's. How many times larger than Earth's density is this?

10. (II) A neutron star whose mass is 1.5 solar masses has a radius of about 11 km. Calculate its average density and compare to that for a white dwarf (Problem 9) and to that of nuclear matter.

*11. (II) A star is 48 pc away. What is its parallax angle? State (*a*) in seconds of arc, and (*b*) in degrees.

*12. (II) What is the parallax angle for a star that is 74 ly away? How many parsecs is this?

*13. (II) A star is 77 pc away. How long does it take for its light to reach us?

14. (II) Calculate the *Q*-values for the He burning reactions of Eq. 44–2. (The mass of the very unstable $^8_4\text{Be}$ is 8.005305 u.)

15. (II) When our Sun becomes a while dwarf, it is expected to be about the size of the Moon. What angular width would it subtend from the present distance to Earth?

16. (II) Suppose that three main-sequence stars could undergo the three changes represented by the three arrows, A, B, and C, in the H–R diagram of Fig. 44–35. For each case, describe the changes in temperature, intrinsic luminosity, and size.

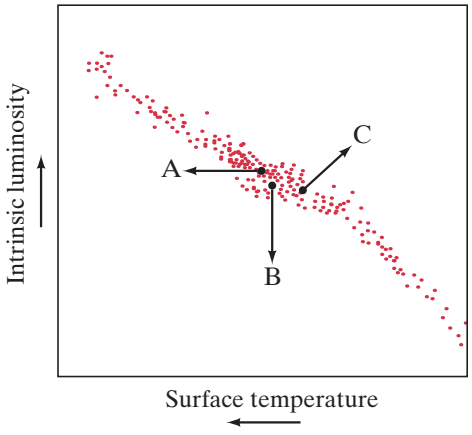

**FIGURE 44–35** Problem 16.

17. (III) Suppose two stars of the same apparent brightness *b* are also believed to be the same size. The spectrum of one star peaks at 750 nm whereas that of the other peaks at 450 nm. Use Wien's law and the Stefan-Boltzmann equation (Eq. 19–17) to estimate their relative distances from us. [*Hint:* See Examples 44–4 and 44–5.]

18. (III) Stars located in a certain cluster are assumed to be about the same distance from us. Two such stars have spectra that peak at $\lambda_1 = 470\ \text{nm}$ and $\lambda_2 = 720\ \text{nm}$, and the ratio of their apparent brightness is $b_1/b_2 = 0.091$. Estimate their relative sizes (give ratio of their diameters) using Wien's law and the Stefan-Boltzmann equation, Eq. 19–17.

## 44–4 General Relativity, Gravity and Curved Space

19. (I) Show that the Schwarzschild radius for Earth is 8.9 mm.

20. (II) What is the Schwarzschild radius for a typical galaxy (like ours)?

21. (II) What mass will give a Schwarzschild radius equal to that of the hydrogen atom in its ground state?

22. (II) What is the maximum sum-of-the-angles for a triangle on a sphere?

23. (II) Describe a triangle, drawn on the surface of a sphere, for which the sum of the angles is (*a*) 359°, and (*b*) 179°.

24. (II) Calculate the escape velocity, using Newtonian mechanics, from an object that has collapsed to its Schwarzschild radius.

25. (II) What is the apparent deflection of a light beam in an elevator (Fig. 44–13) which is 3.2 m wide if the elevator is accelerating downward at $9.8\ \text{m/s}^2$?

## 44–5 Redshift, Hubble's Law

26. (I) The redshift of a galaxy indicates a recession velocity of 2250 km/s. How far away is it?

27. (I) If a galaxy is traveling away from us at 2.2% of the speed of light, roughly how far away is it?

28. (II) A galaxy is moving away from Earth. The "blue" hydrogen line at 434 nm emitted from the galaxy is measured on Earth to be 455 nm. (*a*) How fast is the galaxy moving? (*b*) How far is it from Earth based on Hubble's law?

29. (II) Estimate the wavelength shift for the 656.3-nm line in the Balmer series of hydrogen emitted from a galaxy whose distance from us is (*a*) $6.0 \times 10^6$ ly, (*b*) $6.0 \times 10^7$ ly.

30. (II) If an absorption line of calcium is normally found at a wavelength of 393.4 nm in a laboratory gas, and you measure it to be at 419.7 nm in the spectrum of a galaxy, what is the approximate distance to the galaxy?

31. (II) What is the speed of a galaxy with $z = 0.068$?

32. (II) What would be the redshift parameter *z* for a galaxy traveling away from us at $v = 0.068c$?

33. (II) Estimate the distance *d* from the Earth to a galaxy whose redshift parameter $z = 1$.

34. (II) Estimate the speed of a galaxy, and its distance from us, if the wavelength for the hydrogen line at 434 nm is measured on Earth as being 625 nm.

35. (II) Radiotelescopes are designed to observe 21-cm waves emitted by atomic hydrogen gas. A signal from a distant radio-emitting galaxy is found to have a wavelength that is 0.10 cm longer than the normal 21-cm wavelength. Estimate the distance to this galaxy.

36. (III) Starting from Eq. 44–3, show that the Doppler shift in wavelength is $\Delta\lambda/\lambda_{\text{rest}} \approx v/c$ (Eq. 44–6) for $v \ll c$. [*Hint:* Use the binomial expansion.]

### 44–6 to 44–8 The Big Bang, CMB, Universe Expansion

**37.** (I) Calculate the wavelength at the peak of the blackbody radiation distribution at 2.7 K using Wien's law.

**38.** (II) (*a*) What temperature would correspond to 13-TeV collisions at the LHC? (*b*) Estimate the time after the Big Bang probed by this energy. (*c*) To what era in cosmological history does this correspond? [*Hint*: See Fig. 44–29.]

**39.** (II) Calculate the peak wavelength of the CMB at 1.0 s after the birth of the universe. In what part of the EM spectrum is this radiation?

**40.** (II) The critical density for closure of the universe is $\rho_c \approx 10^{-26}\,\text{kg/m}^3$ (see Example 44–7). State $\rho_c$ in terms of the average number of nucleons per cubic meter.

**41.** (II) The scale factor of the universe (average distance between galaxies) at any given time is believed to have been inversely proportional to the absolute temperature. Estimate the size of the universe, compared to today, at (*a*) $t = 10^6$ yr, (*b*) $t = 1$ s, (*c*) $t = 10^{-6}$ s, and (*d*) $t = 10^{-35}$ s.

**42.** (II) At approximately what time had the universe cooled below the threshold temperature for producing (*a*) kaons $(M \approx 500\,\text{MeV}/c^2)$, (*b*) $\Upsilon$ $(M \approx 9500\,\text{MeV}/c^2)$, and (*c*) muons $(M \approx 100\,\text{MeV}/c^2)$?

### 44–9 Dark Matter, Dark Energy

**43.** (II) Only about 5% of the energy in the universe is composed of baryonic matter. (*a*) Estimate the average density of baryonic matter in the observable universe with a radius of 14 billion light-years that contains $10^{11}$ galaxies, each with about $10^{11}$ stars like our Sun. (*b*) Estimate the density of dark matter in the universe.

### 44–10 Structure of Universe

**44.** (II) Two identical black holes form a binary system and are orbiting one another. Assume they are a distance apart which is twice the Schwartzchild radius in each. Then, assuming Newton mechanics is still valid, how fast are they moving with respect to the center of mass?

## General Problems

**45.** Use conservation of angular momentum to estimate the angular velocity of a neutron star which has collapsed to a diameter of 16 km, from a star whose core radius was equal to that of Earth $(6 \times 10^6\,\text{m})$. Assume its mass is 1.5 times that of the Sun, and that it rotated (like our Sun) about once a month.

**46.** By what factor does the rotational kinetic energy change when the star in Problem 45 collapses to a neutron star?

**47.** Assume that the nearest stars to us have an intrinsic luminosity about the same as the Sun's. Their apparent brightness, however, is about $10^{11}$ times fainter than the Sun. From this, estimate the distance to the nearest stars.

**48.** A certain pulsar, believed to be a neutron star of mass 1.5 times that of the Sun, with diameter 16 km, is observed to have a rotation speed of 1.0 rev/s. If it loses rotational kinetic energy at the rate of 1 part in $10^9$ per day, which is all transformed into radiation, what is the power output of the star?

**49.** The nearest large galaxy to our Galaxy is about $2 \times 10^6$ ly away. If both galaxies have a mass of $4 \times 10^{41}$ kg, with what gravitational force does each galaxy attract the other? Ignore dark matter.

**50.** How large would the Sun be if it had its current mass but had a density equal to the critical density of the universe, $\rho_c \approx 10^{-26}\,\text{kg/m}^3$? Express your answer in light-years and compare with the Earth–Sun distance and the diameter of our Galaxy.

**51.** Two stars, whose spectra peak at 660 nm and 480 nm, respectively, both lie on the main sequence. Use Wien's law, the Stefan-Boltzmann equation, and the H–R diagram (Fig. 44–6) to estimate the ratio of their diameters.

**52.** (*a*) In order to measure distances with parallax at 100 ly, what minimum angular resolution (in degrees) is needed? (*b*) What diameter mirror or lens would be needed?

**53.** In the later stages of stellar evolution, a star (if massive enough) will begin fusing carbon nuclei to form, for example, magnesium:

$$^{12}_{6}\text{C} + {}^{12}_{6}\text{C} \rightarrow {}^{24}_{12}\text{Mg} + \gamma.$$

(*a*) How much energy is released in this reaction (see Appendix G)? (*b*) How much kinetic energy must each carbon nucleus have (assume equal) in a head-on collision if they are just to "touch" (use Eq. 41–1) so that the strong force can come into play? (*c*) What temperature does this kinetic energy correspond to?

**54.** Consider the reaction

$$^{16}_{8}\text{O} + {}^{16}_{8}\text{O} \rightarrow {}^{28}_{14}\text{Si} + {}^{4}_{2}\text{He},$$

and answer the same questions as in Problem 53.

**55.** Use *dimensional analysis* with the fundamental constants $c$, $G$, and $\hbar$ to estimate the value of the so-called *Planck time*. It is thought that physics as we know it can say nothing about the universe before this time.

**56.** Estimate the mass of our observable universe using the following assumptions: Our universe is spherical in shape, it has been expanding at the speed of light since the Big Bang, and its density is the critical density.

**57.** Estimate what neutrino mass $(\text{in eV}/c^2)$ would provide the critical density to close the universe. Assume the neutrino density is, like photons, about $10^9$ times that of nucleons, and that nucleons make up only (*a*) 2% of the mass needed, or (*b*) 5% of the mass needed.

**58.** The evolution of stars, as discussed in Section 44–2, can lead to a white dwarf, a neutron star, or even a black hole, depending on the mass. (*a*) Referring to Sections 44–2 and 44–4, give the radius of (i) a white dwarf of 1 solar mass, (ii) a neutron star of 1.5 solar masses, and (iii) a black hole of 3 solar masses. (*b*) Express these three radii as ratios $(r_i : r_{ii} : r_{iii})$.

**59.** When stable nuclei first formed, about 3 minutes after the Big Bang, there were about 7 times more protons than neutrons. Explain how this leads to a ratio of the mass of hydrogen to the mass of helium of 3:1. This is about the actual ratio observed in the universe.

**60.** Astronomers use an **apparent magnitude** ($m$) scale to describe apparent brightness. It uses a logarithmic scale, where a higher number corresponds to a less bright star. (For example, the Sun has magnitude $-27$, whereas most stars have positive magnitudes.) On this scale, a change in apparent magnitude by $+5$ corresponds to a decrease in apparent brightness by a factor of 100. If Venus has an apparent magnitude of $-4.4$, whereas Sirius has an apparent magnitude of $-1.4$, which is brighter? What is the ratio of the apparent brightness of these two objects?

**61.** Astronomers have measured the rotation of gas around a possible supermassive black hole of about 2 billion solar masses at the center of a galaxy. If the radius from the galactic center to the gas clouds is 68 light-years, estimate the value of $z$.

**62.** Calculate the Schwarzschild radius using a semi-classical (Newtonian) gravitational theory, by calculating the minimum radius $R$ for a sphere of mass $M$ such that a photon can escape from the surface. (General Relativity gives $R = 2GM/c^2$.)

**63.** (*a*) Use special relativity and Newton's law of gravitation to show that a photon of mass $m = E/c^2$ just grazing the Sun will be deflected by an angle $\Delta\theta$ given by

$$\Delta\theta = \frac{2GM}{c^2R}$$

where $G$ is the gravitational constant, $R$ and $M$ are the radius and mass of the Sun, and $c$ is the speed of light. (*b*) Put in values and show $\Delta\theta = 0.87''$. (General Relativity predicts an angle twice as large, $1.74''$.)

**64.** We cannot use Hubble's law to measure the distances to nearby galaxies, because their random motions are larger than the overall expansion. Indeed, the closest galaxy to us, the Andromeda Galaxy, 2.5 million light-years away, is approaching us at a speed of about 130 km/s. (*a*) What is the shift in wavelength of the 656-nm line of hydrogen emitted from the Andromeda Galaxy, as seen by us? (*b*) Is this a redshift or a blueshift? (*c*) Ignoring the expansion, how soon will it and the Milky Way Galaxy collide?

**65.** Estimate the radius of a white dwarf whose mass is equal to that of the Sun by the following method, assuming there are $N$ nucleons and $\frac{1}{2}N$ electrons (why $\frac{1}{2}$?): (*a*) Use Fermi-Dirac statistics (Section 40–6) to show that the total energy of all the electrons is

$$E_e = \frac{3}{5}\left(\frac{1}{2}N\right)\frac{h^2}{8m_e}\left(\frac{3}{\pi}\frac{N}{2V}\right)^{\frac{2}{3}}.$$

[*Hint:* See Eqs. 40–12 and 40–13; we assume electrons fill energy levels from 0 up to the Fermi energy.] (*b*) The nucleons contribute to the total energy mainly via the gravitational force (note that the Fermi energy for nucleons is negligible compared to that for electrons—why?). Use a gravitational form of Gauss's law to show that the total gravitational potential energy of a uniform sphere of radius $R$ is

$$-\frac{3}{5}\frac{GM^2}{R},$$

by considering the potential energy of a spherical shell of radius $r$ due only to the mass inside it (why?) and integrate from $r = 0$ to $r = R$. (See also Appendix E.) (*c*) Write the total energy as a sum of these two terms, and set $dE/dR = 0$ to find the equilibrium radius, and evaluate it for a mass equal to the Sun's $(2.0 \times 10^{30}\,\text{kg})$.

**66.** Determine the radius of a neutron star using the same argument as in Problem 65 but for $N$ neutrons only. Show that the radius of a neutron star, of 1.5 solar masses, is about 11 km.

## ANSWERS TO EXERCISES

**A:** Our Earth and ourselves, 2 years ago.

**B:** 600 ly (estimating $L$ from Fig. 44–6 as $L \approx 8 \times 10^{26}\,\text{W}$; note that on a log scale, 6000 K is closer to 7000 K than it is to 5000 K).

**C:** 30 km.

**D:** (*a*); not the usual $R^3$, but $R$: see formula for the Schwarzschild radius.

**E:** (*c*); (*d*).

APPENDIX

# A Mathematical Formulas

## A–1 Quadratic Formula

If $ax^2 + bx + c = 0$

then $$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

## A–2 Binomial Expansion†

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{2!}x^2 \pm \frac{n(n-1)(n-2)}{3!}x^3 + \cdots$$

$$\approx 1 \pm nx \qquad (\text{if } x \ll 1) \qquad \text{[Binomial approximation]}$$

$$(x + y)^n = x^n\left(1 + \frac{y}{x}\right)^n = x^n\left(1 + n\frac{y}{x} + \frac{n(n-1)}{2!}\frac{y^2}{x^2} + \cdots\right)$$

## A–3 Other Expansions†

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots$$

$$\ln(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \cdots$$

$$\sin\theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \cdots \qquad [\theta \text{ in radians}]$$

$$\cos\theta = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \cdots \qquad [\theta \text{ in radians}]$$

$$\tan\theta = \theta + \frac{\theta^3}{3} + \frac{2}{15}\theta^5 + \cdots \qquad \left[|\theta| < \frac{\pi}{2}\text{ rad}\right]$$

In general: $$f(x) = f(0) + \left(\frac{df}{dx}\right)_0 x + \left(\frac{d^2f}{dx^2}\right)_0 \frac{x^2}{2!} + \cdots$$

## A–4 Exponents

$$(a^n)(a^m) = a^{n+m} \qquad \frac{1}{a^n} = a^{-n}$$

$$(a^n)(b^n) = (ab)^n \qquad a^n a^{-n} = a^0 = 1$$

$$(a^n)^m = a^{nm} \qquad a^{\frac{1}{2}} = \sqrt{a}$$

[Any number ($\neq 0$) raised to the $0^{\text{th}}$ power is 1.]

## A–5 Areas and Volumes

| Object | Surface area | Volume |
|---|---|---|
| Circle, radius $r$ | $\pi r^2$ | — |
| Sphere, radius $r$ | $4\pi r^2$ | $\frac{4}{3}\pi r^3$ |
| Right circular cylinder, radius $r$, height $h$ | $2\pi r^2 + 2\pi rh$ | $\pi r^2 h$ |
| Right circular cone, radius $r$, height $h$ | $\pi r^2 + \pi r\sqrt{r^2 + h^2}$ | $\frac{1}{3}\pi r^2 h$ |

†The exclamation point used after a number, such as 4!, is called a **factorial** number, and means you multiply that number by all the integers smaller than it. That is, $4! = 4 \times 3 \times 2 \times 1 = 24$ and $3! = 3 \times 2 \times 1 = 6$. The quantity $x$ in all these expansions should be unitless, just like the 1.

# A–6 Plane Geometry

**1.** *Equal angles*:

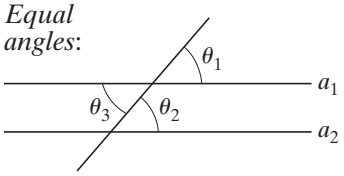

**FIGURE A–1** If line $a_1$ is parallel to line $a_2$, then $\theta_1 = \theta_2 = \theta_3$.

**2.** *Equal angles*:

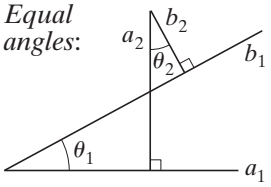

**FIGURE A–2** If $a_1 \perp a_2$ and $b_1 \perp b_2$, then $\theta_1 = \theta_2$.

**3.** The sum of the angles in any plane triangle is 180°.

**4.** *Pythagorean theorem*:

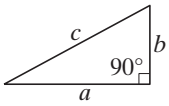

**FIGURE A–3**

In any right triangle (one angle = 90°) of sides $a$, $b$, and $c$:

$$a^2 + b^2 = c^2$$

where $c$ is the length of the hypotenuse (opposite the 90° angle).

**5.** *Similar triangles*: Two triangles are said to be similar if all three of their angles are equal (in Fig. A–4, $\theta_1 = \phi_1$, $\theta_2 = \phi_2$, and $\theta_3 = \phi_3$). Similar triangles can have different sizes and different orientations.

(*a*) Two triangles are similar if any two of their angles are equal. (This follows because the third angles must also be equal since the sum of the angles of a triangle is 180°.)

(*b*) The ratios of corresponding sides of two similar triangles are equal (Fig. A–4):

$$\frac{a_1}{b_1} = \frac{a_2}{b_2} = \frac{a_3}{b_3}.$$

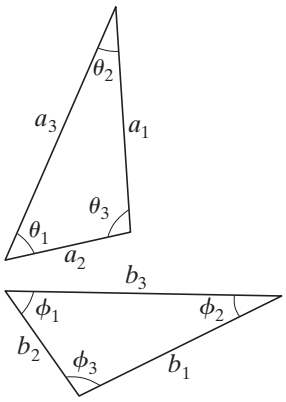

**FIGURE A–4**

**6.** *Congruent triangles*: Two triangles are congruent if one can be placed precisely on top of the other. That is, they are similar triangles and they have the same size. Two triangles are congruent if any of the following holds:

(*a*) The three corresponding sides are equal.

(*b*) Two sides and the enclosed angle are equal ("side-angle-side").

(*c*) Two angles and the enclosed side are equal ("angle-side-angle").

# A–7 Logarithms

Logarithms are defined in the following way:

$$\text{if } \quad y = A^x, \quad \text{then} \quad x = \log_A y.$$

That is, the logarithm of a number $y$ to the base $A$ is that number which, as the exponent of $A$, gives back the number $y$. For **common logarithms**, the base is 10, so

$$\text{if } \quad y = 10^x, \quad \text{then} \quad x = \log y.$$

The subscript 10 on $\log_{10}$ is usually omitted when dealing with common logs. Another important base is the exponential base $e = 2.718\ldots$, a natural number (originating in the integral $\int \frac{1}{x}dx = \ln x$, Section B–4). Such logarithms are called **natural logarithms** and are written ln. Thus,

$$\text{if } \quad y = e^x, \quad \text{then} \quad x = \ln y.$$

For either type, we can take the logarithm of only positive numbers,[†] $y > 0$. For any number $y$, the two types of logarithm are related by

$$\ln y = 2.3026 \log y.$$

Some simple rules for logarithms are as follows:

$$\log(ab) = \log a + \log b, \tag{i}$$

which is true because if $a = 10^n$ and $b = 10^m$, then $ab = 10^{n+m}$. From the

[†]If $y < 0$, no value of $x$ satisfies $y = 10^x$ (try it) nor $y = e^x$. And if $y = 0$, then $x$ must be $-\infty$, which is hardly useful. Thus we can take $\log y$ only if $y > 0$. Note also that both $y$ and $x$ should in principle be *dimensionless*, without units, just like $\theta$ in $\sin\theta$ or $\cos\theta$. Consider the expansions in Appendix A–3 with terms in $x$, $x^2$, $x^3$, etc., whose units would be inconsistent and nonsense.

definition of logarithm, $\log a = n$, $\log b = m$, and $\log(ab) = n + m$; hence, $\log(ab) = n + m = \log a + \log b$. In a similar way, we can show that

$$\log a^n = n \log a \tag{ii}$$

and

$$\log\left(\frac{a}{b}\right) = \log a - \log b \tag{iii}$$

and also, since $\log(b/a) = \log b - \log a$, then

$$\log\left(\frac{b}{a}\right) = -\log\left(\frac{a}{b}\right). \tag{iv}$$

These four rules apply to any kind of logarithm.

If you do not have a calculator that calculates logs, you can easily use a **log table**, such as the small one shown here (Table A–1): the number $N$ whose log we want is given to two digits. The first digit is in the vertical column to the left, and the second digit is in the horizontal row across the top. For example, Table A–1 tells us that $\log 1.0 = 0.000$, $\log 1.1 = 0.041$, and $\log 4.1 = 0.613$. The Table gives logs for numbers between 1.0 and 9.9. For larger or smaller numbers, we use rule (i) above, $\log(ab) = \log a + \log b$. For example, $\log(380) = \log(3.8 \times 10^2) = \log(3.8) + \log(10^2)$. From the Table, $\log 3.8 = 0.580$; and from rule (ii) above $\log(10^2) = 2\log(10) = 2$, since $\log(10) = 1$ by the definition of the logarithm: if $10 = 10^1$, then $1 = \log(10)$. Thus,

$$\begin{aligned}\log(380) &= \log(3.8) + \log(10^2)\\ &= 0.580 + 2\\ &= 2.580.\end{aligned}$$

Similarly,

$$\begin{aligned}\log(0.081) &= \log(8.1) + \log(10^{-2})\\ &= 0.908 - 2 = -1.092.\end{aligned}$$

The reverse process of finding the number $N$ whose log is, say, 2.670, is called "taking the **antilogarithm**." To do so, we separate our number 2.670 into two parts, making the separation at the decimal point:

$$\begin{aligned}\log N = 2.670 &= 2 + 0.670\\ &= \log(10^2) + 0.670.\end{aligned}$$

We now look at Table A–1 to see what number has its log equal to 0.670; none does, so we must **interpolate**: we see that $\log 4.6 = 0.663$ and $\log 4.7 = 0.672$. So the number we want is between 4.6 and 4.7, and closer to the latter by $\frac{7}{9}$, or 4.68. Approximately we can say that $\log 4.68 = 0.670$. Thus

$$\begin{aligned}\log N &= 2 + 0.670\\ &= \log(10^2) + \log(4.68) = \log(4.68 \times 10^2),\end{aligned}$$

so $N = 4.68 \times 10^2 = 468$.

If the given logarithm is negative, say, $-2.180$, we proceed as follows:

$$\begin{aligned}\log N = -2.180 &= -3 + 0.820\\ &= \log(10^{-3}) + \log(6.6) = \log(6.6 \times 10^{-3}),\end{aligned}$$

so $N = 6.6 \times 10^{-3}$. Notice that we added to our given logarithm the next largest integer (3 in this case) so that we have an integer, plus a decimal number between 0 and 1.0 whose antilogarithm can be looked up in the Table.

**TABLE A–1 Short Table of Common Logarithms**

| *N* | 0.0 | 0.1 | 0.2 | 0.3 | 0.4 | 0.5 | 0.6 | 0.7 | 0.8 | 0.9 |
|---|---|---|---|---|---|---|---|---|---|---|
| 1 | 0.000 | 0.041 | 0.079 | 0.114 | 0.146 | 0.176 | 0.204 | 0.230 | 0.255 | 0.279 |
| 2 | 0.301 | 0.322 | 0.342 | 0.362 | 0.380 | 0.398 | 0.415 | 0.431 | 0.447 | 0.462 |
| 3 | 0.477 | 0.491 | 0.505 | 0.519 | 0.531 | 0.544 | 0.556 | 0.568 | 0.580 | 0.591 |
| 4 | 0.602 | 0.613 | 0.623 | 0.633 | 0.643 | 0.653 | 0.663 | 0.672 | 0.681 | 0.690 |
| 5 | 0.699 | 0.708 | 0.716 | 0.724 | 0.732 | 0.740 | 0.748 | 0.756 | 0.763 | 0.771 |
| 6 | 0.778 | 0.785 | 0.792 | 0.799 | 0.806 | 0.813 | 0.820 | 0.826 | 0.833 | 0.839 |
| 7 | 0.845 | 0.851 | 0.857 | 0.863 | 0.869 | 0.875 | 0.881 | 0.886 | 0.892 | 0.898 |
| 8 | 0.903 | 0.908 | 0.914 | 0.919 | 0.924 | 0.929 | 0.934 | 0.940 | 0.944 | 0.949 |
| 9 | 0.954 | 0.959 | 0.964 | 0.968 | 0.973 | 0.978 | 0.982 | 0.987 | 0.991 | 0.996 |

# A–8 Vectors: see Sections 3–2 to 3–5, 7–2, 11–2.

# A–9 Trigonometric Functions and Identities

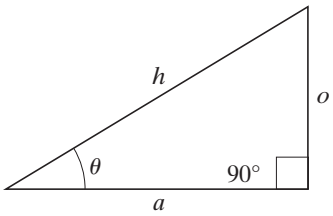

**FIGURE A–5**

The trigonometric functions are defined as follows (see Fig. A–5, $o$ = side opposite, $a$ = side adjacent, $h$ = hypotenuse. Values are given in Table A–2):

$$\sin\theta = \frac{o}{h} \qquad \csc\theta = \frac{1}{\sin\theta} = \frac{h}{o}$$

$$\cos\theta = \frac{a}{h} \qquad \sec\theta = \frac{1}{\cos\theta} = \frac{h}{a}$$

$$\tan\theta = \frac{o}{a} = \frac{\sin\theta}{\cos\theta} \qquad \cot\theta = \frac{1}{\tan\theta} = \frac{a}{o}$$

and recall that

$$a^2 + o^2 = h^2 \qquad \text{[\textbf{Pythagorean theorem}].}$$

**FIGURE A–6**

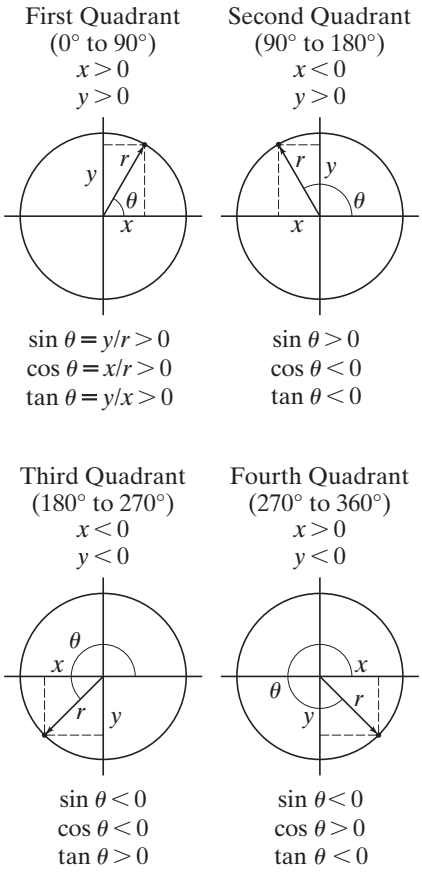

Figure A–6 shows the signs (+ or −) that cosine, sine, and tangent take on for angles $\theta$ in the four quadrants (0° to 360°, or 0 to $2\pi$ radians). Note that angles are measured counterclockwise from the $+x$ axis as shown; negative angles are measured clockwise from *below* the $+x$ axis: for example, $-30° = +330°$, and so on.

The following are some useful identities among the trigonometric functions:

$$\sin^2\theta + \cos^2\theta = 1$$

$$\sec^2\theta - \tan^2\theta = 1, \qquad \csc^2\theta - \cot^2\theta = 1$$

$$\sin 2\theta = 2\sin\theta\cos\theta$$

$$\cos 2\theta = \cos^2\theta - \sin^2\theta = 2\cos^2\theta - 1 = 1 - 2\sin^2\theta$$

$$\tan 2\theta = \frac{2\tan\theta}{1 - \tan^2\theta}$$

$$\sin(A \pm B) = \sin A\cos B \pm \cos A\sin B$$

$$\cos(A \pm B) = \cos A\cos B \mp \sin A\sin B$$

$$\tan(A \pm B) = \frac{\tan A \pm \tan B}{1 \mp \tan A\tan B}$$

$$\sin(180° - \theta) = \sin\theta \qquad [\text{in radians, } \sin(\pi - \theta) = \sin\theta]$$

$$\cos(180° - \theta) = -\cos\theta$$

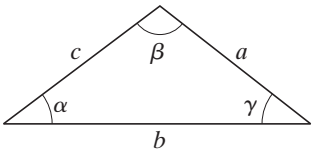
$$\sin(90° - \theta) = \cos\theta$$

$$\cos(90° - \theta) = \sin\theta$$

$$\sin(-\theta) = -\sin\theta$$

$$\cos(-\theta) = \cos\theta$$

$$\tan(-\theta) = -\tan\theta$$



$$\sin\tfrac{1}{2}\theta = \sqrt{\frac{1 - \cos\theta}{2}}, \quad \cos\tfrac{1}{2}\theta = \sqrt{\frac{1 + \cos\theta}{2}}, \quad \tan\tfrac{1}{2}\theta = \sqrt{\frac{1 - \cos\theta}{1 + \cos\theta}}$$

$$\sin A \pm \sin B = 2\sin\left(\frac{A \pm B}{2}\right)\cos\left(\frac{A \mp B}{2}\right).$$

$$\cos A + \cos B = 2\cos\left(\frac{A + B}{2}\right)\cos\left(\frac{A - B}{2}\right)$$

$$\cos A - \cos B = -2\sin\left(\frac{A + B}{2}\right)\sin\left(\frac{A - B}{2}\right)$$

**FIGURE A–7**

For any triangle (see Fig. A–7):

$$\frac{\sin\alpha}{a} = \frac{\sin\beta}{b} = \frac{\sin\gamma}{c} \qquad \text{[\textbf{Law of sines}]}$$

$$c^2 = a^2 + b^2 - 2ab\cos\gamma. \qquad \text{[\textbf{Law of cosines}]}$$

Values of sine, cosine, tangent are given in Table A–2.

**TABLE A–2 Trigonometric Table: Numerical Values of Sin, Cos, Tan**

| Angle in Degrees | Angle in Radians | Sine | Cosine | Tangent | Angle in Degrees | Angle in Radians | Sine | Cosine | Tangent |

APPENDIX

# B Derivatives and Integrals

## B–1 Derivatives: General Rules

(See also Section 2–3.)

$$\frac{dx}{dx} = 1$$

$$\frac{d}{dx}[af(x)] = a\frac{df}{dx} \qquad [a = \text{constant}]$$

$$\frac{d}{dx}[f(x) + g(x)] = \frac{df}{dx} + \frac{dg}{dx}$$

$$\frac{d}{dx}[f(x)g(x)] = \frac{df}{dx}g + f\frac{dg}{dx}$$

$$\frac{d}{dx}\left[\frac{f(x)}{g(x)}\right] = \frac{g\frac{df}{dx} - f\frac{dg}{dx}}{g^2}$$

$$\frac{d}{dx}\left[\frac{1}{g(x)}\right] = -\frac{1}{g^2}\frac{dg}{dx}$$

$$\frac{d}{dx}[f(y)] = \frac{df}{dy}\frac{dy}{dx} \qquad \textbf{[chain rule]}$$

$$\frac{dx}{dy} = \frac{1}{\left(\frac{dy}{dx}\right)} \qquad \left[\text{if } \frac{dy}{dx} \neq 0.\right]$$

## B–2 Derivatives: Particular Functions

$$\frac{da}{dx} = 0 \qquad [a = \text{constant}]$$

$$\frac{d}{dx}x^n = nx^{n-1}$$

$$\frac{d}{dx}\sin ax = a\cos ax$$

$$\frac{d}{dx}\cos ax = -a\sin ax$$

$$\frac{d}{dx}\tan ax = a\sec^2 ax = \frac{a}{\cos^2 ax}$$

$$\frac{d}{dx}\ln ax = \frac{1}{x}$$

$$\frac{d}{dx}e^{ax} = ae^{ax}$$

## B–3 Indefinite Integrals: General Rules

(See also Section 7–3.)

$$\int dx = x$$

$$\int af(x)\,dx = a\int f(x)\,dx \qquad [a = \text{constant}]$$

$$\int [f(x) + g(x)]dx = \int f(x)\,dx + \int g(x)\,dx$$

$$\int u\,dv = uv - \int v\,du \qquad \textbf{[integration by parts}: \text{see also Section B–6]}$$

# B–4 Indefinite Integrals: Particular Functions

(An arbitrary constant can be added to the right side of each equation.)

$$\int a\,dx = ax \qquad [a = \text{constant}]$$

$$\int x^m\,dx = \frac{1}{m+1}x^{m+1} \qquad [m \neq -1]$$

$$\int \sin ax\,dx = -\frac{1}{a}\cos ax$$

$$\int \cos ax\,dx = \frac{1}{a}\sin ax$$

$$\int \tan ax\,dx = -\frac{1}{a}\ln|\cos ax|$$

$$\int \sin^2 ax\,dx = \frac{x}{2} - \frac{\sin 2ax}{4a}$$

$$\int \frac{1}{x}\,dx = \ln x \qquad [x > 0]^{\dagger}$$

$$\int \frac{1}{c+ax}\,dx = \frac{1}{a}\ln(c+ax) \qquad [(c+ax) > 0]$$

$$\int e^{ax}\,dx = \frac{1}{a}e^{ax}$$

$$\int \frac{dx}{x^2+a^2} = \frac{1}{a}\tan^{-1}\frac{x}{a} \qquad [a \neq 0]$$

$$\int \frac{dx}{x^2-a^2} = \frac{1}{2a}\ln\left|\frac{x-a}{x+a}\right| \qquad [a \neq 0,\ x \neq \pm a]$$

$$\int \frac{dx}{\sqrt{x^2 \pm a^2}} = \ln\left(x + \sqrt{x^2 \pm a^2}\right)$$

$$\int \frac{dx}{\sqrt{a^2-x^2}} = \sin^{-1}\left(\frac{x}{a}\right) \qquad [\text{if } x^2 \leq a^2]$$

$$\int \frac{dx}{(x^2 \pm a^2)^{\frac{3}{2}}} = \frac{\pm x}{a^2\sqrt{x^2 \pm a^2}}$$

$$\int \frac{x\,dx}{(x^2 \pm a^2)^{\frac{3}{2}}} = \frac{-1}{\sqrt{x^2 \pm a^2}}$$

$$\int xe^{-ax}\,dx = -\frac{e^{-ax}}{a^2}(ax+1)$$

$$\int x^2e^{-ax}\,dx = -\frac{e^{-ax}}{a^3}(a^2x^2 + 2ax + 2)$$

[†]The natural logarithm, and thus also the natural number $e = 2.718\ldots$, originates from this integral.

# B–5 A Few Definite Integrals $[a > 0]$

$$\int_0^\infty x^n e^{-ax}\,dx = \frac{n!}{a^{n+1}}$$

$$\int_0^\infty e^{-ax^2}\,dx = \sqrt{\frac{\pi}{4a}}$$

$$\int_0^\infty xe^{-ax^2}\,dx = \frac{1}{2a}$$

$$\int_0^\infty x^2e^{-ax^2}\,dx = \sqrt{\frac{\pi}{16a^3}}$$

$$\int_0^\infty x^3e^{-ax^2}\,dx = \frac{1}{2a^2}$$

$$\int_0^\infty x^{2n}e^{-ax^2}\,dx = \frac{1\cdot 3\cdot 5\cdots(2n-1)}{2^{n+1}a^n}\sqrt{\frac{\pi}{a}} \qquad [n = 1, 2, 3, \cdots]$$

# B–6 Integration by Parts

Sometimes a difficult integral can be simplified by carefully choosing the functions $u$ and $v$ in the identity:

$$\int u\,dv = uv - \int v\,du. \qquad \text{[Integration by parts]}$$

This identity follows from the property of derivatives

$$\frac{d}{dx}(uv) = u\frac{dv}{dx} + v\frac{du}{dx}$$

or as differentials: $d(uv) = u\,dv + v\,du$.

For example $\int xe^{-x}\,dx$ can be integrated by choosing $u = x$ and $dv = e^{-x}\,dx$ in the "integration by parts" equation above:

$$\int xe^{-x}\,dx = (x)(-e^{-x}) + \int e^{-x}\,dx$$
$$= -xe^{-x} - e^{-x} = -(x+1)e^{-x}.$$

APPENDIX C

# Numerical Integration

This Appendix discusses how to solve certain Problems numerically, often needing a computer to do the sums. Some of this material is also covered in Chapter 7, Section 7–3. Here we discuss its use in kinematics (Chapter 2).

If we are given the velocity $v$ of an object as a function of time $t$, we can obtain the displacement, $x$. Suppose the velocity as a function of time, $v(t)$, is given as a graph (rather than as an equation that could be integrated as discussed in Section 2–8), as shown in Fig. C–1a. If we are interested in the time interval from $t_1$ to $t_2$, as shown, we divide the time axis into many small subintervals, $\Delta t_1, \Delta t_2, \Delta t_3, \ldots$, which are indicated by the dashed vertical lines. For each subinterval, a horizontal dashed line is drawn to indicate the average velocity during that time interval. The displacement during any subinterval is given by $\Delta x_i$, where the subscript $i$ represents the particular subinterval $(i = 1, 2, 3, \ldots)$. From the definition of average velocity (Eq. 2–2) we have

$$\Delta x_i = \bar{v}_i \, \Delta t_i.$$

Thus the displacement during each subinterval equals the product of $\bar{v}_i$ and $\Delta t_i$, and equals the area of the dark rectangle in Fig. C–1a for that subinterval. The total displacement between times $t_1$ and $t_2$ is the sum of the displacements over all the subintervals:

$$x_2 - x_1 = \sum_{t_1}^{t_2} \bar{v}_i \, \Delta t_i, \qquad \textbf{(C–1a)}$$

where $x_1$ is the position at $t_1$ and $x_2$ is the position at $t_2$. This sum equals the area of all the rectangles shown.

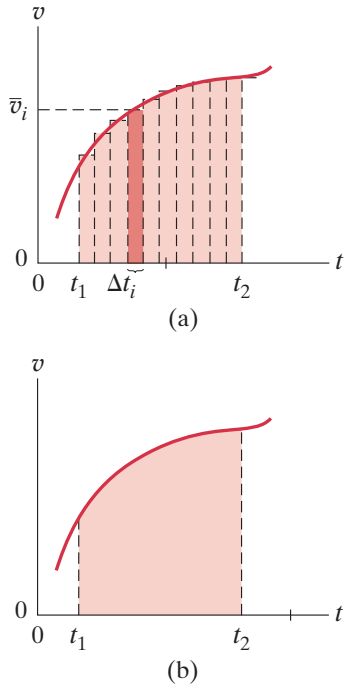

**FIGURE C–1** Graph of $v$ vs. $t$ for a particular motion of a particle. In (a), the time axis is broken into subintervals of width $\Delta t_i$, the average velocity during each $\Delta t_i$ is $\bar{v}_i$, and the area of all the rectangles, $\Sigma \bar{v}_i \, \Delta t_i$, closely approximates the total displacement $(x_2 - x_1)$ during the total time $(t_2 - t_1)$. In (b), $\Delta t_i \to 0$ and the total area under the curve between $t_1$ and $t_2$ is equal to $(x_2 - x_1)$.

It is often difficult to estimate $\bar{v}_i$ with precision for each subinterval from the graph. We can get greater accuracy in our calculation of $x_2 - x_1$ by breaking the time interval $t_2 - t_1$ into more, but narrower, subintervals. Ideally, we can let each $\Delta t_i$ approach zero, so we approach (in principle) an infinite number of subintervals. In this limit, the area of all these infinitesimally thin rectangles becomes exactly equal to the area under the curve (Fig. C–1b). Thus *the total displacement between any two times is equal to the area between the velocity curve and the t axis between the two times* $t_1$ *and* $t_2$. This limit can be written

$$x_2 - x_1 = \lim_{\Delta t \to 0} \sum_{t_1}^{t_2} \bar{v}_i \, \Delta t_i$$

or, using standard calculus notation,

$$x_2 - x_1 = \int_{t_1}^{t_2} v(t) \, dt. \qquad \textbf{(C–1b)}$$

We have let $\Delta t \to 0$ and renamed it $dt$ to indicate that it is now infinitesimally small. The average velocity, $\bar{v}$, over an infinitesimal time $dt$ is the instantaneous velocity at that instant, which we have written $v(t)$ to remind us that $v$ is a function of $t$. The symbol $\int$ is an elongated S and indicates a sum over an infinite number of infinitesimal subintervals. We say that we are taking the **integral** of $v(t)$ over $dt$ from time $t_1$ to time $t_2$, and this is equal to the area between the $v(t)$ curve and the $t$ axis between the times $t_1$ and $t_2$ (Fig. C–1b). The integral in Eq. C–1b is a **definite integral**, since the limits $t_1$ and $t_2$ are specified.

Similarly, if we know the acceleration as a function of time, we can obtain the velocity by the same process. We use the definition of average acceleration (Eq. 2–5) and solve for $\Delta v$:

$$\Delta v = \bar{a} \, \Delta t.$$

If $a$ is known as a function of $t$ over some time interval $t_1$ to $t_2$, we can subdivide this time interval into many subintervals, $\Delta t_i$, just as we did in Fig. C–1a. The change in velocity during each subinterval is $\Delta v_i = \bar{a}_i \, \Delta t_i$. The total change in velocity from time $t_1$ until time $t_2$ is

$$v_2 - v_1 = \sum_{t_1}^{t_2} \bar{a}_i \, \Delta t_i, \qquad \textbf{(C–2a)}$$

where $v_2$ represents the velocity at $t_2$ and $v_1$ the velocity at $t_1$. This relation can be written as an integral by letting $\Delta t \to 0$ (the number of intervals then approaches infinity)

$$v_2 - v_1 = \lim_{\Delta t \to 0} \sum_{t_1}^{t_2} \bar{a}_i \, \Delta t_i$$

or

$$v_2 - v_1 = \int_{t_1}^{t_2} a(t) \, dt. \qquad \textbf{(C–2b)}$$

Equations C–2 will allow us to determine the velocity $v_2$ at some time $t_2$ if the velocity is known at $t_1$ and $a$ is known as a function of time.

If the acceleration or velocity is known at discrete intervals of time, we can use the summation forms of the above equations, Eqs. C–1a and C–2a, to estimate velocity or displacement. This technique is known as **numerical integration**. We now take an Example that can also be evaluated analytically, so we can compare the results.

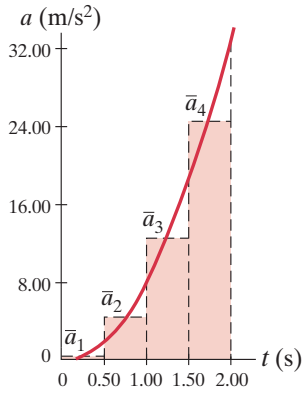

**FIGURE C–2** Example C–1.

**EXAMPLE C–1 Numerical integration.** An object starts from rest at $t = 0$ and accelerates at a rate $a(t) = (8.00\,\text{m/s}^4)t^2$. Determine its velocity after 2.00 s using numerical methods.

**APPROACH** Let us first divide up the interval $t = 0.00\,\text{s}$ to $t = 2.00\,\text{s}$ into four subintervals each of duration $\Delta t_i = 0.50\,\text{s}$ (Fig. C–2). We use Eq. C–2a with $v_2 = v$, $v_1 = 0$, $t_2 = 2.00\,\text{s}$, and $t_1 = 0$. For each of the subintervals we need to estimate $\bar{a}_i$. There are various ways to do this and we use the simple method of choosing $\bar{a}_i$ to be the acceleration $a(t)$ at the midpoint of each interval (an even simpler but usually less accurate procedure would be to use the value of $a$ at the start of the subinterval). That is, we evaluate $a(t) = (8.00\,\text{m/s}^4)t^2$ at $t = 0.25\,\text{s}$ (which is midway between 0.00 s and 0.50 s), 0.75 s, 1.25 s, and 1.75 s.

**SOLUTION** The results are as follows:

| $i$ | 1 | 2 | 3 | 4 |
|---|---|---|---|---|
| $\bar{a}_i\,(\text{m/s}^2)$ | 0.50 | 4.50 | 12.50 | 24.50 |

Now we use Eq. C–2a, and note that all $\Delta t_i$ equal 0.50 s (so they can be factored out):

$$v(t = 2.00\,\text{s}) = \sum_{t=0}^{t=2.00\,\text{s}} \bar{a}_i\,\Delta t_i$$

$$= (0.50\,\text{m/s}^2 + 4.50\,\text{m/s}^2 + 12.50\,\text{m/s}^2 + 24.50\,\text{m/s}^2)(0.50\,\text{s})$$

$$= 21.0\,\text{m/s}.$$

We can compare this result to the analytic solution given by Eq. C–2b since the functional form for $a$ is integrable analytically:

$$v = \int_0^{2.00\,\text{s}} (8.00\,\text{m/s}^4)t^2\,dt = \frac{8.00\,\text{m/s}^4}{3}t^3\Big|_0^{2.00\,\text{s}}$$

$$= \frac{8.00\,\text{m/s}^4}{3}[(2.00\,\text{s})^3 - (0)^3] = 21.33\,\text{m/s}$$

or 21.3 m/s to the proper number of significant figures. This analytic solution is precise, and we see that our numerical estimate is not far off even though we only used four $\Delta t$ intervals. It may not be close enough for purposes requiring high accuracy. If we use more and smaller subintervals, we will get a more accurate result. If we use 10 subintervals, each with $\Delta t = 2.00\,\text{s}/10 = 0.20\,\text{s}$, we have to evaluate $a(t)$ at $t = 0.10\,\text{s}$, $0.30\,\text{s}, \ldots,$ $1.90\,\text{s}$ to get the $\bar{a}_i$, and these are as follows:

| $i$ | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| $\bar{a}_i\,(\text{m/s}^2)$ | 0.08 | 0.72 | 2.00 | 3.92 | 6.48 | 9.68 | 13.52 | 18.00 | 23.12 | 28.88 |

Then, from Eq. C–2a we obtain

$$v(t = 2.00\,\text{s}) = \sum \bar{a}_i\,\Delta t_i = (\sum \bar{a}_i)(0.200\,\text{s})$$

$$= (106.4\,\text{m/s}^2)(0.200\,\text{s}) = 21.28\,\text{m/s},$$

where we have kept an extra significant figure to show that this result is much closer to the (precise) analytic one but still is not quite identical to it. The percentage difference has dropped from 1.4% $(0.3\,\text{m/s}^2/21.3\,\text{m/s}^2)$ for the four-subinterval computation to only 0.2% (0.05/21.3) for the 10-subinterval one.

In the Example above we were given an analytic function that was integrable, so we could compare the accuracy of the numerical calculation to the known precise one. But what do we do if the function is not integrable, so we can't compare our numerical result to an analytic one? That is, how do we know if we've taken enough subintervals so that we can trust our calculated estimate to be accurate to within some desired uncertainty, say 1%? What we can do is compare two successive numerical calculations: the first done with $n$ subintervals and the second with, say, twice as many subintervals ($2n$). If the two results are within the desired uncertainty (say 1%), we can usually assume that the calculation with more subintervals is within the desired uncertainty of the true value. If the two calculations are not that close, then a third calculation, with more subintervals (maybe double, maybe 10 times as many, depending on how good the previous approximation was) must be done, and compared to the previous one.

**PROBLEM SOLVING**
*How many subintervals give sufficient accuracy?*

The procedure is not hard to automate using a computer spreadsheet application or algorithm.

If we wanted to also obtain the displacement $x$ at some time, we would have to do a second numerical integration over $v$, which means we would first need to calculate $v$ for many different times. Programmable calculators and computers are very helpful for doing the long sums.

APPENDIX D

# More on Dimensional Analysis

An important use of dimensional analysis (Section 1–7) is to obtain the *form* of an equation: how one quantity depends on others. To take a concrete example, let us try to find an expression for the period $T$ of a simple pendulum: a small "bob" of mass $m$ that can swing back and forth on the end of a thin cord (Section 14–5). First, we try to figure out what $T$ could depend on, and make a list of these variables. It might depend on the length $\ell$ of the cord, on the mass $m$ of the bob, on the angle of swing $\theta$, and on the acceleration due to gravity, $g$. It might also depend on air resistance (we would use the viscosity of air), the gravitational pull of the Moon, and so on; but everyday experience suggests that the Earth's gravity is the major force involved, so we ignore the other possible forces. So let us assume that $T$ is a function of $\ell$, $m$, $\theta$, and $g$, and that each of these factors is present to some power:

$$T = C\ell^w m^x \theta^y g^z.$$

$C$ is a dimensionless constant, and $w$, $x$, $y$, and $z$ are exponents we want to solve for. We now write down the dimensional equation (Section 1–7) for this relationship:

$$[T] = [L]^w[M]^x[L/T^2]^z.$$

Because $\theta$ has no dimensions (a radian is a length divided by a length—see Eq. 10–1a), it does not appear. We simplify and obtain

$$[T] = [L]^{w+z}[M]^x[T]^{-2z}.$$

To have dimensional consistency, we must have

$$\begin{aligned} 1 &= -2z \\ 0 &= w + z \\ 0 &= x. \end{aligned}$$

We solve these equations and find that $z = -\frac{1}{2}$, $w = \frac{1}{2}$, and $x = 0$. Thus our desired equation must be

$$T = C\sqrt{\ell/g}\, f(\theta), \qquad \textbf{(D–1)}$$

where $f(\theta)$ is some function of $\theta$ that we cannot determine using this technique. Nor can we determine in this way the dimensionless constant $C$. (To obtain $C$ and $f$, we would have to do an analysis such as that in Chapter 14 using Newton's laws, which reveals that $C = 2\pi$ and $f \approx 1$ for small $\theta$.) But look what we *have* found, using only dimensional consistency. We obtained the form of the expression that relates the period of a simple pendulum to the major variables of the situation, $\ell$ and $g$ (see Eq. 14–12c), and saw that it does not depend on the mass $m$.

How did we do it? And how useful is this technique? Basically, we had to use our intuition as to which variables were important and which were not. This is not always easy, and often requires a lot of insight. As to usefulness, the final result in our example could have been obtained from Newton's laws, as in Chapter 14. But in many physical situations, such a derivation from other laws cannot be done. In those situations, dimensional analysis can be a powerful tool.

In the end, any expression derived by the use of dimensional analysis (or by any other means, for that matter) must be checked against experiment. For example, in our derivation of Eq. D–1, we can compare the periods of two pendulums of different lengths, $\ell_1$ and $\ell_2$, whose amplitudes $(\theta)$ are the same. Using Eq. D–1, we would have

$$\frac{T_1}{T_2} = \frac{C\sqrt{\ell_1/g}\, f(\theta)}{C\sqrt{\ell_2/g}\, f(\theta)} = \sqrt{\frac{\ell_1}{\ell_2}}.$$

Because $C$ and $f(\theta)$ are the same for both pendula, they cancel out, so we can experimentally determine if the ratio of the periods varies as the ratio of the square roots of the lengths. This comparison to experiment checks our derivation, at least in part; $C$ and $f(\theta)$ could be determined by further experiments.

APPENDIX E

# Gravitational Force Due to a Spherical Mass Distribution

In Chapter 6 we stated that the gravitational force exerted by or on a uniform sphere acts as if all the mass of the sphere were concentrated at its center, if the other object (exerting or feeling the force) is outside the sphere. In other words, the gravitational force that a uniform sphere exerts on a particle outside it is

$$F = G\frac{mM}{r^2}, \qquad [m \text{ outside sphere of mass } M]$$

where $m$ is the mass of the particle, $M$ the mass of the sphere, and $r$ the distance of $m$ from the center of the sphere. Now we will derive this result. We will use the concepts of infinitesimally small quantities and integration.

First we consider a very thin, uniform spherical shell (like a thin-walled basketball) of mass $M$ whose thickness $t$ is small compared to its radius $R$ (Fig. E–1). The force on a particle of mass $m$ at a distance $r$ from the center of the shell can be calculated as the vector sum of the forces due to all the particles of the shell. We imagine the shell divided up into thin (infinitesimal) circular strips so that all points on a strip are equidistant from our particle $m$. One of these circular strips, labeled AB, is shown in Fig. E–1. It is $R\,d\theta$ wide, $t$ thick, and has a radius $R\sin\theta$. The force on our particle $m$ due to a tiny piece of the strip at point A is represented by the vector $\vec{\mathbf{F}}_A$ shown; and the force due to a tiny piece of the strip at point B, which is diametrically opposite A, is the force $\vec{\mathbf{F}}_B$. We take the two pieces at A and B to be of equal mass, so $F_A = F_B$. The horizontal components of $\vec{\mathbf{F}}_A$ and $\vec{\mathbf{F}}_B$ are each equal to

$$F_A\cos\phi$$

and point toward the center of the shell. The vertical components of $\vec{\mathbf{F}}_A$ and $\vec{\mathbf{F}}_B$ are of equal magnitude and point in opposite directions, and so cancel. Since for every point on the strip there is a corresponding point diametrically opposite (as with A and B), we see that the net force due to the entire strip points toward the center of the shell. Its magnitude will be

$$dF = G\frac{m\,dM}{\ell^2}\cos\phi,$$

where $dM$ is the mass of the entire circular strip and $\ell$ is the distance from all points on the strip to $m$, as shown. We write $dM$ in terms of the density $\rho$; by density we mean the mass per unit volume (Section 13–2). Hence, $dM = \rho\,dV$, where $dV$ is the volume of the strip and equals $(2\pi R\sin\theta)(t)(R\,d\theta)$. Then the force $dF$ due to the circular strip shown is

$$dF = G\frac{m\rho 2\pi R^2 t\sin\theta\,d\theta}{\ell^2}\cos\phi. \qquad \textbf{(E–1)}$$

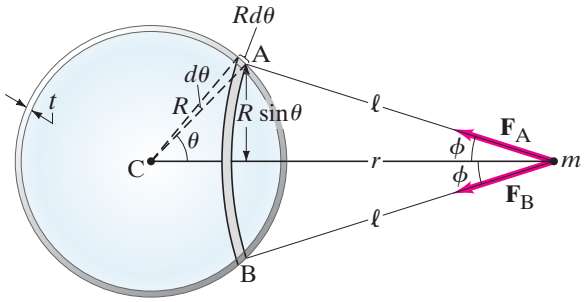

**FIGURE E–1** Calculating the gravitational force on a particle of mass $m$ due to a uniform spherical shell of radius $R$ and mass $M$.

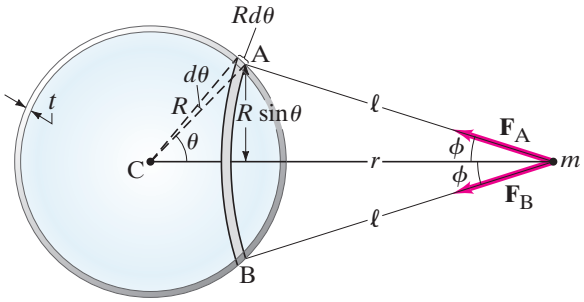

**FIGURE E–1** (Repeated.) Calculating the gravitational force on a particle of mass $m$ due to a uniform spherical shell of radius $R$ and mass $M$.

To get the total force $F$ that the entire shell exerts on the particle $m$, we must integrate over all the circular strips: that is, we integrate

$$dF = G\frac{m\rho 2\pi R^2 t \sin\theta\, d\theta}{\ell^2}\cos\phi \qquad \textbf{(E–1)}$$

from $\theta = 0°$ to $\theta = 180°$. But our expression for $dF$ contains $\ell$ and $\phi$, which are functions of $\theta$. From Fig. E–1 we can see that

$$\ell\cos\phi = r - R\cos\theta.$$

Furthermore, we can write the law of cosines (Appendix A–9, page A-4) for triangle C$m$A:

$$\cos\theta = \frac{r^2 + R^2 - \ell^2}{2rR}. \qquad \textbf{(E–2)}$$

With these two expressions we can reduce our three variables $(\ell, \theta, \phi)$ to only one, which we take to be $\ell$ (it is simplest, as we shall see).We do two things with Eq. E–2: (1) We put it into the equation for $\ell\cos\phi$ above:

$$\cos\phi = \frac{1}{\ell}(r - R\cos\theta) = \frac{r^2 + \ell^2 - R^2}{2r\ell}$$

and (2) we take the differential of both sides of Eq. E–2 (because $\sin\theta\, d\theta$ appears in the expression for $dF$, Eq. E–1), considering $r$ and $R$ to be constants when summing over the strips:

$$-\sin\theta\, d\theta = -\frac{2\ell\, d\ell}{2rR} \quad \text{or} \quad \sin\theta\, d\theta = \frac{\ell\, d\ell}{rR}.$$

We insert these into Eq. E–1 for $dF$ and find

$$dF = Gm\rho\pi t\frac{R}{r^2}\left(1 + \frac{r^2 - R^2}{\ell^2}\right)d\ell.$$

Now we integrate to get the net force on our thin shell of radius $R$. To integrate over all the strips ($\theta = 0°$ to 180°), we must go from $\ell = r - R$ to $\ell = r + R$ (see Fig. E–1). Thus,

$$F = Gm\rho\pi t\frac{R}{r^2}\left[\int d\ell + (r^2 - R^2)\int\frac{d\ell}{\ell^2}\right]_{\ell=r-R}^{\ell=r+R}$$

or

$$F = Gm\rho\pi t\frac{R}{r^2}\left[\ell - \frac{r^2 - R^2}{\ell}\right]_{\ell=r-R}^{\ell=r+R}$$

$$= Gm\rho\pi t\frac{R}{r^2}(4R).$$

The volume $V$ of the spherical shell is its area $(4\pi R^2)$ times the thickness $t$. Hence the shell's mass is $M = \rho V = \rho 4\pi R^2 t$, and finally

$$F = G\frac{mM}{r^2}. \qquad \left[\begin{array}{c}\text{particle of mass } m \text{ outside a}\\ \text{thin uniform spherical shell of mass } M\end{array}\right]$$

This result gives us the force a thin shell exerts on a particle of mass $m$ a distance $r$

from the center of the shell, and *outside* the shell. We see that the force is the same as that between $m$ and a particle of mass $M$ at the center of the shell. In other words, for purposes of calculating the gravitational force exerted on or by a uniform spherical shell, we can consider all its mass concentrated at its center.

What we have derived for a shell holds also for a solid sphere, since a solid sphere can be considered as made up of many concentric shells, from $R = 0$ to $R = R_0$, where $R_0$ is the radius of the solid sphere. Why? Because if each shell has mass $dM$, we write for each shell, $dF = Gm\,dM/r^2$, where $r$ is the distance from the center C to mass $m$ and is the same for all shells. Then the total force equals the sum or integral over $dM$, which gives the total mass $M$. Thus the result

$$F = G\frac{mM}{r^2} \qquad \left[\begin{array}{c}\text{particle of mass } m \text{ outside}\\ \text{solid sphere of mass } M\end{array}\right] \qquad \textbf{(E–3)}$$

is valid for a solid sphere of mass $M$ with uniform density, and even for a sphere where the density varies with distance from the center, $\rho = \rho(R)$. (It is not valid if the density varies within each shell—that is, depends not only on $R$.) Thus the gravitational force exerted on or by spherical objects, including nearly spherical objects like the Earth, Sun, and Moon, can be considered to act as if the objects were point particles.

**PROBLEM SOLVING**
*If particle m is* inside *the sphere*

This result, Eq. E–3, is true only if the mass $m$ is outside the sphere. Let us next consider a point mass $m$ that is located *inside* the spherical shell of Fig. E–1. Here, $r$ would be less than $R$, and the integration over $\ell$ would be from $\ell = R - r$ to $\ell = R + r$, so

$$\left[\ell - \frac{r^2 - R^2}{\ell}\right]_{R-r}^{R+r} = 0.$$

Thus the force on any mass inside the shell would be *zero*. This result has particular importance for the electrostatic force, which is also an *inverse square law*. For the gravitational situation, we see that at points within a solid sphere, say 1000 km below the Earth's surface, only the mass up to that radius contributes to the net force. The outer shells beyond the point we are considering contribute zero net gravitational effect.

The results we have obtained here can also be reached using the gravitational analog of Gauss's law for electrostatics (Chapter 22, page 648).

APPENDIX F

# Differential Form of Maxwell's Equations

Maxwell's equations can be written in another form that is often more convenient than Eqs. 31–5. This material is usually covered in more advanced courses, and is included here simply for completeness.

We quote here two theorems, without proof, that are derived in vector analysis textbooks. The first is called **Gauss's theorem** or the **divergence theorem**. It relates the integral over a surface of any vector function $\vec{\mathbf{F}}$ to a volume integral over the volume enclosed by that surface:

$$\oint_{\text{Area } A} \vec{\mathbf{F}} \cdot d\vec{\mathbf{A}} = \int_{\text{Volume } V} \vec{\nabla} \cdot \vec{\mathbf{F}}\, dV. \qquad \text{[Gauss's theorem]} \qquad \textbf{(F–1)}$$

The operator $\vec{\nabla}$ is the **del operator**, defined in Cartesian coordinates as

$$\vec{\nabla} = \hat{\mathbf{i}}\frac{\partial}{\partial x} + \hat{\mathbf{j}}\frac{\partial}{\partial y} + \hat{\mathbf{k}}\frac{\partial}{\partial z}.$$

The quantity

$$\vec{\nabla} \cdot \vec{\mathbf{F}} = \frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y} + \frac{\partial F_z}{\partial z}$$

is called the **divergence** of $\vec{\mathbf{F}}$. Terms like $\partial F_y/\partial y$ mean that we take the derivative of the $y$ component of $F$ with respect only to $y$, treating $x$ and $z$ as constant.

The second theorem is **Stokes's theorem**, and relates a line integral around a closed path to a surface integral over any surface enclosed by that path:

$$\oint_{\text{Line}} \vec{\mathbf{F}} \cdot d\vec{\boldsymbol{\ell}} = \int_{\text{Area } A} \vec{\nabla} \times \vec{\mathbf{F}} \cdot d\vec{\mathbf{A}}. \qquad \text{[Stokes's theorem]} \qquad \textbf{(F–2)}$$

The quantity $\vec{\nabla} \times \vec{\mathbf{F}}$ is called the **curl** of $\vec{\mathbf{F}}$. (See Section 11–2 on the vector product.)

We now use these two theorems to obtain the differential form of Maxwell's equations in free space. We apply Gauss's theorem (Eq. F–1) to Eq. 31–5a (Gauss's law):

$$\frac{Q}{\epsilon_0} = \oint_A \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = \int \vec{\nabla} \cdot \vec{\mathbf{E}}\, dV.$$

The charge $Q$ can be written as a volume integral over the **charge density**, or *charge* per unit volume, $\rho$: $Q = \int \rho\, dV$. Then

$$\int \vec{\nabla} \cdot \vec{\mathbf{E}}\, dV = \frac{1}{\epsilon_0}\int \rho\, dV.$$

Both sides now contain volume integrals over the same volume, and for this to be true over *any* volume, whatever its size or shape, the integrands must be equal:

$$\vec{\nabla} \cdot \vec{\mathbf{E}} = \frac{\rho}{\epsilon_0}. \qquad \textbf{(F–3)}$$

This is the differential form of Gauss's law.

The second of Maxwell's equations, $\oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = 0$, Eq. 31–5b, is treated in the same way, and we obtain

$$\vec{\nabla} \cdot \vec{\mathbf{B}} = 0, \qquad \textbf{(F–4)}$$

which is the second of Maxwell's equations in differential form.

Next, we apply Stokes's theorem (Eq. F–2) to the third of Maxwell's equations, Eq. 31–5c:

$$-\frac{d\Phi_B}{dt} = \oint \vec{\mathbf{E}} \cdot d\vec{\boldsymbol{\ell}} = \int \vec{\boldsymbol{\nabla}} \times \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}}.$$

Since the magnetic flux $\Phi_B = \int \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}}$, we have

$$\int \vec{\boldsymbol{\nabla}} \times \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = -\frac{\partial}{\partial t} \int \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}}$$

where we use the partial derivative, $\partial\vec{\mathbf{B}}/\partial t$, since $B$ may also depend on position. These are surface integrals over the same area, and to be true over any area, even a very small one, we must have

$$\vec{\boldsymbol{\nabla}} \times \vec{\mathbf{E}} = -\frac{\partial \vec{\mathbf{B}}}{\partial t}. \qquad \textbf{(F–5)}$$

This is the third of Maxwell's equations in differential form. Finally, we look at the last of Maxwell's equations, Eq. 31–5d:

$$\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 I + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}.$$

We apply Stokes's theorem and write the electric flux as $\Phi_E = \int \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}}$:

$$\int \vec{\boldsymbol{\nabla}} \times \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = \mu_0 I + \mu_0 \epsilon_0 \frac{\partial}{\partial t} \int \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}}.$$

The conduction current $I$ can be written in terms of the current density $\vec{\mathbf{j}}$, using Eq. 25–12:

$$I = \int \vec{\mathbf{j}} \cdot d\vec{\mathbf{A}}.$$

Then Maxwell's fourth equation becomes:

$$\int \vec{\boldsymbol{\nabla}} \times \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = \mu_0 \int \vec{\mathbf{j}} \cdot d\vec{\mathbf{A}} + \mu_0 \epsilon_0 \frac{\partial}{\partial t} \int \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}}.$$

For this to be true over any area $A$, whatever its size or shape, the integrands on each side of the equation must be equal:

$$\vec{\boldsymbol{\nabla}} \times \vec{\mathbf{B}} = \mu_0 \vec{\mathbf{j}} + \mu_0 \epsilon_0 \frac{\partial \vec{\mathbf{E}}}{\partial t}, \qquad \textbf{(F–6)}$$

which is the differential form of Maxwell's fourth equation.

Equations F–3, 4, 5, and 6 are Maxwell's equations in differential form for free space. They are summarized in Table F–1.

**TABLE F–1 Maxwell's Equations in Free Space**[†]

| Integral form | Differential form |
|---|---|
| $\oint \vec{\mathbf{E}} \cdot d\vec{\mathbf{A}} = \frac{Q}{\epsilon_0}$ | $\vec{\boldsymbol{\nabla}} \cdot \vec{\mathbf{E}} = \frac{\rho}{\epsilon_0}$ |
| $\oint \vec{\mathbf{B}} \cdot d\vec{\mathbf{A}} = 0$ | $\vec{\boldsymbol{\nabla}} \cdot \vec{\mathbf{B}} = 0$ |
| $\oint \vec{\mathbf{E}} \cdot d\vec{\boldsymbol{\ell}} = -\frac{d\Phi_B}{dt}$ | $\vec{\boldsymbol{\nabla}} \times \vec{\mathbf{E}} = -\frac{\partial \vec{\mathbf{B}}}{\partial t}$ |
| $\oint \vec{\mathbf{B}} \cdot d\vec{\boldsymbol{\ell}} = \mu_0 I + \mu_0 \epsilon_0 \frac{d\Phi_E}{dt}$ | $\vec{\boldsymbol{\nabla}} \times \vec{\mathbf{B}} = \mu_0 \vec{\mathbf{j}} + \mu_0 \epsilon_0 \frac{\partial \vec{\mathbf{E}}}{\partial t}$ |

[†] $\vec{\boldsymbol{\nabla}}$ stands for the *del operator* $\vec{\boldsymbol{\nabla}} = \hat{\mathbf{i}}\frac{\partial}{\partial x} + \hat{\mathbf{j}}\frac{\partial}{\partial y} + \hat{\mathbf{k}}\frac{\partial}{\partial z}$ in Cartesian coordinates.

# Answers to Odd-Numbered Problems

## Chapter 1

**1.** (*a*) 3;
(*b*) 4;
(*c*) 3;
(*d*) 1;
(*e*) 2;
(*f*) 4;
(*g*) 2.

**3.** (*a*) 869,000;
(*b*) 9100;
(*c*) 0.25;
(*d*) 476;
(*e*) 0.0000362.

**5.** (*a*) 4%;
(*b*) 0.4%;
(*c*) 0.07%.

**7.** 2.3 $m^2$.

**9.** 0.24 rad, 12°.

**11.** $3 \times 10^{-5}$%.

**13.** 20%.

**15.** (*a*) 3 megavolts;
(*b*) 2 micrometers;
(*c*) 5 kilodays;
(*d*) 18 hectobucks;
(*e*) 900 nanoseconds.

**17.** (*a*) 13.4;
(*b*) 49.3.

**19.** (*a*) $1.4 \times 10^{10}$ years;
(*b*) $4.4 \times 10^{17}$ s.

**21.** 3.95 m.

**23.** (*a*) $\dfrac{0.621 \text{ mi/h}}{1 \text{ km/h}}$;
(*b*) $\dfrac{3.28 \text{ ft/s}}{1 \text{ m/s}}$;
(*c*) $\dfrac{0.278 \text{ m/s}}{1 \text{ km/h}}$.

**25.** (*a*) $9.46 \times 10^{15}$ m;
(*b*) $6.31 \times 10^4$ AU.

**27.** 100.

**29.** 0.20 mi/gal.

**31.** (*a*) $3.16 \times 10^7$ s;
(*b*) $3.16 \times 10^{16}$ ns;
(*c*) $3.17 \times 10^{-8}$ yr.

**33.** (*a*) $7.478 \times 10^{13}$ $m^2$;
(*b*) 6.84.

**35.** (*a*) $10^3$;
(*b*) $10^5$;
(*c*) $10^{-1}$;
(*d*) $10^9$.

**37.** 500 hr.

**39.** $10^{14}$ cells.

**41.** $10^{11}$ gal/y.

**43.** $2 \times 10^9$ kg/yr.

**45.** 11 days.

**47.** 500 jelly beans.

**49.** $6 \times 10^4$ m.

**51.** $4 \times 10^8$ kg/year.

**53.** 6.0 s.

**55.** (*a*) $L/T^4$, $L/T^2$;
(*b*) $m/s^4$, $m/s^2$.

**57.** (*b*) $10^{-43}$ s.

**59.** $1.18 \times 10^9$ atoms/$m^2$.

**61.** 56,000 years.

**63.** 75 min.

**65.** $2 \times 10^{-4}$ m.

**67.** $4 \times 10^5$ metric tons, $9 \times 10^7$ gal.

**69.** 150 m long, 25 m wide, 15 m high, $6 \times 10^4$ $m^3$.

**71.** 1.15 mi.

**73.** 120 m.

**75.** 200 plumbers.

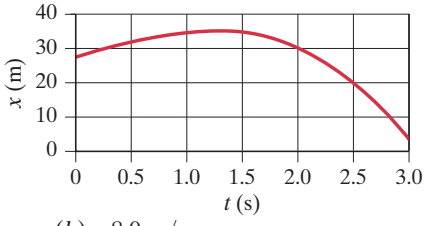
**77.** L/m, L/year, L.

**79.** $4 \times 10^{51}$ kg.

## Chapter 2

**1.** 47 m.

**3.** 0.61 cm/s, no, actual distance traveled given.



**5.** (*a*) 360 km;
(*b*) 80 km/h.

**7.** (*a*) 3.68 m/s;
(*b*) 0 m/s.

**9.** 56 s.

**11.** 1.8 min.

**13.** (*a*)

(*b*) −8.0 m/s;
(*c*) 1.3 s.

**15.** 25 km/h.

**17.** (*a*) $t = 0$ s to $t \approx 18$ s;
(*b*) $t \approx 27$ s;
(*c*) $t \approx 38$ s;
(*d*) both directions.

**19.** 6.11 m/s.

**21.** (*a*) 6.08 $m/s^2$;
(*b*) $7.88 \times 10^4$ $km/h^2$.

**23.** 6.5 $m/s^2$, 0.66 *g*'s.

**25.** (*a*) 21.2 m/s;
(*b*) 2.00 $m/s^2$.

**27.** (*a*) m/s, $m/s^2$;
(*b*) $2B$ $m/s^2$;
(*c*) $(A + 12B)$m/s, $2B$ $m/s^2$;
(*d*) $A - 3Bt^{-4}$.

**29.** 13 s later.

**31.** (*a*) 2.5 $m/s^2$;
(*b*) 0.6 $m/s^2$.

**33.** −3.8 $m/s^2$.

**35.** 1.4 $m/s^2$, 110 m.

**37.** $1.20 \times 10^2$ m.

**39.** 260 $m/s^2$.

**41.** (*a*) 560 m;
(*b*) 47 s;
(*c*) 23 m, 21 m.

**43.** No, 27.2 m past the intersection.

**45.** 22 m/s.

**47.** 6.3 s.

**49.** 10.5 s.

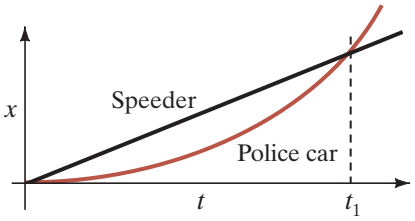
**51.** 1.0 $m/s^2$, 7.8 m/s.

**53.** (*a*) 8.8 s;
(*b*) 86 m/s.

**55.** 13 m/s, 8.3 m.

**57.** 1.09 s.

**59.** (*a*) 10.4 m/s;
(*b*) 0.774 s, 2.90 s;
(*c*) There are two times at which the object reaches that height—once when moving upwards, once when moving downwards.

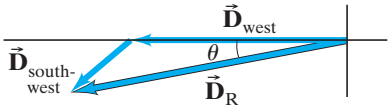


**61.** 26.1 s, 256 m/s (922 km/h).

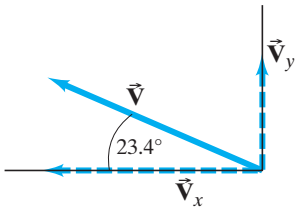
**63.** (*a*) 5.80 s;
(*b*) 41.4 m/s;
(*c*) 99.5 m.

**65.** 12 m/s.

**67.** (*a*) 14 m/s;
(*b*) 25 m.

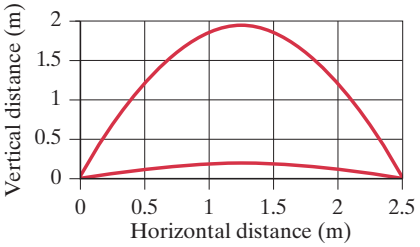


**69.** 2.1 m.
**71.** 29.3 m.
**73.** (*a*) $7.5\ \text{m/s} + \frac{2}{3}(3.0\ \text{m/s}^{5/2})t^{3/2}$;
(*b*) $(7.5\ \text{m/s})t + \frac{4}{15}(3.0\ \text{m/s}^{5/2})t^{5/2}$;
(*c*) $6.7\ \text{m/s}^2$, $3.0 \times 10^1$ m/s, 82 m.
**75.** 6 ×.
**77.** 1.2 m.
**79.** (*a*) The longer any particular bolt falls, the higher its speed.
(*b*) decrease;
(*c*) $0, d_1, 3d_1, 5d_1$, and so on.
**81.** (*a*) 14.4 s, no;
(*b*) no, 4.6 s.
**83.** 29.0 m.
**85.** (*a*)



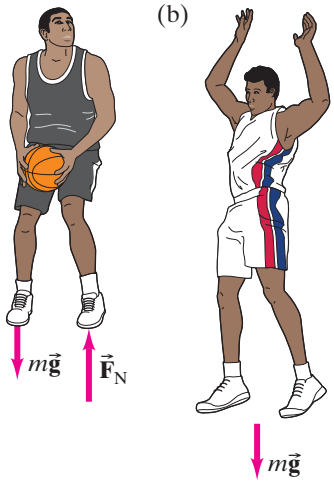
(*b*) 22 s;
(*c*) $3.6\ \text{m/s}^2$;
(*d*) 78 m/s;
(*e*) constant acceleration of police car.
**87.** (*a*) 0.82 m;
(*b*) 4.9 m/s;
(*c*) 1.0 s.
**89.** Stop.
**91.** 74 m.
**93.** (*a*) 1.60 s;
(*b*) 11.5 m;
(*c*) They won't collide unless the launch point is more than 91.3 m above the ground.
**95.** (*a*) 12.5 min;
(*b*) 11.1 min.
**97.** (*a*) 560 m;
(*b*) 28 s.
**99.** 64 m.
**101.** (*a*) $4.3 \times 10^6$ bits/s;
(*b*) 67%.
**103.** For no collision, $x > \dfrac{(v_M - v_A)^2}{-2a}$.

## Chapter 3

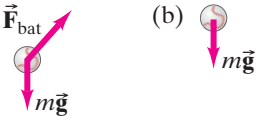


**1.** 339 km, 14.3° south of west.

**3.** 11.6 units, −35.9°.
**5.** (*a*)

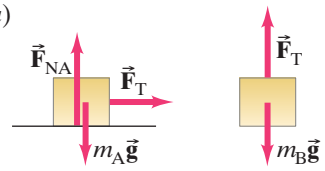


(*b*) −20.0 units, 8.66 units;
(*c*) 21.8 units, 23.4° above the −*x* axis.
**7.** (*a*) 1.3 units in the *x*-direction;
(*b*) 12.3 units in the *x*-direction;
(*c*) 12.3 units in the negative *x*-direction.
**9.** −2840 m, 3590 m, 2450 m, 5190 m.
**11.** (*a*) $-53.7\hat{\mathbf{i}} + 4.9\hat{\mathbf{j}}$, 53.9, 174.8°;
(*b*) $53.7\hat{\mathbf{i}} - 4.9\hat{\mathbf{j}}$, 53.9, 354.8°;
(*c*) They are opposite of each other.
**13.** (*a*) $-127.9\hat{\mathbf{i}} - 34.5\hat{\mathbf{j}}$, 132.4, 195.1°;
(*b*) $124.0\hat{\mathbf{i}} - 96.4\hat{\mathbf{j}}$, 157.1, 322.1°;
(*c*) $-20.5\hat{\mathbf{i}} - 75.3\hat{\mathbf{j}}$, 78.1, 254.8°.
**15.** (*a*) 4.2, 315°;
(*b*) $1.0\hat{\mathbf{i}} - 5.0\hat{\mathbf{j}}$, 5.1, 280°.
**17.** (*a*) parallel;
(*b*) perpendicular;
(*c*) $\vec{\mathbf{V}}_2 = 0$.
**19.** $(9.60\hat{\mathbf{i}} - 3.00t\hat{\mathbf{k}})\text{m/s}$, $-3.00\ \hat{\mathbf{k}}\ \text{m/s}^2$.
**21.** (*a*) cannot be determined;
(*b*) $3.78\ \text{m/s}^2$, 31.9°;
(*c*) cannot be determined.
**23.** (*a*) $0.900\ \text{m/s}^2$, downward;
(*b*) 16.7 s.
**25.** (*a*) $(2.48\hat{\mathbf{i}} + 2.75\hat{\mathbf{j}})\text{cm/s}$;
(*b*) 3.70 cm/s, 48.0°.
**27.** 410 m, −65°.
**29.** 85 km/h, 71° north of east.
**31.** $7.5\ \text{m/s}\hat{\mathbf{j}}$, $(4.2\hat{\mathbf{i}} + 6.3\hat{\mathbf{j}})\text{m}$.
**33.** $6.0 \times 10^1$ m, 8.8 m.
**35.** 18.5 m.
**37.** 18°, 72°.



**39.** (*a*) 34.7 m;
(*b*) 5.32 s;
(*c*) 153 m;
(*d*) 30.9 m/s.
**41.** 23° or 67°.
**43.** (*a*) 9.72 m/s;
(*b*) 0.81 m.
**45.** (*a*) $4.0 \times 10^1$ m/s;
(*b*) 22 m/s.
**47.** 255 m.
**49.** (*a*) 55 m;
(*b*) 61 m;
(*c*) 35 m/s, 77° below the horizontal.
**51.** $\theta(t) = \tan^{-1}(gt/v_0)$.
**53.** (*a*) 8.9 m/s;
(*b*) She will land exactly on the edge of the opposite bank, neither long nor short.
**55.** (*a*) 30.3°, 59.7°;
(*b*) 2.92 m, 8.56 m;
(*c*) 1.54 s, 2.64 s.
**57.** 0.88 s, 0.95 m.
**59.** No, it is 0.81 m to low; 4.6 m to 34.7 m.
**61.** $R = \dfrac{v_0 \cos\theta_0}{g}\left[v_0 \sin\theta_0 + \sqrt{v_0^2 \sin^2\theta_0 - 2gh}\right]$.
**63.** 1.66 m/s, 25° relative to river.
**65.** (*a*) 1.71 m/s;
(*b*) 3.94 m/s.
**67.** (*a*) 631 km/h, 5.47° east of south;
(*b*) 15.6 km.
**69.** $v_T/\tan\theta$.
**71.** (*a*) 46 m;
(*b*) 92 s.
**73.** $(-55\hat{\mathbf{i}} + 35\hat{\mathbf{j}})\text{km/h}$,
$(55\hat{\mathbf{i}} - 35\hat{\mathbf{j}})\text{km/h}$.
**75.** (*a*) 55.4° upstream;
(*b*) 13.8 km/h;
(*c*) 0.142 h.
**77.** $1.7\ \text{m/s}^2$.
**79.** 33 m/s.
**83.** 2.0 m/s.
**85.** 11.1 m/s to 11.3 m/s.
**87.** 0.91%.
**89.** (*a*) $(2.3\hat{\mathbf{i}} + 3.7\hat{\mathbf{j}})\text{m/s}$, 4.3 m/s, 57° above the horizontal;
(*b*) 4.2 m;
(*c*) $(2.3\hat{\mathbf{i}} - 9.1\hat{\mathbf{j}})\text{m/s}$, 9.4 m/s, −76° (below the horizontal).
**91.** (*a*) 15.6 m;
(*b*) 27.6°.
**93.** 3.1 s.
**95.** (*a*) 18 m/s, 16 m/s;
(*b*) 6.5 m below the top.
**97.** 6.8 m/s, 61°.
**99.** $(2.5 - 3.0t)\text{m}\hat{\mathbf{i}} + (-3.1 + 2.25t^2)\text{m}\hat{\mathbf{j}}$, $4.5\ \text{m/s}^2\ \hat{\mathbf{j}}$, parabolic.
**101.** 1.9 m/s.

## Chapter 4



**1.** 63 N.
**3.** 1630 N.
**5.** $-3100$ N.
**7.** $-1.3 \times 10^6$ N, 39%, $1.3 \times 10^6$ N.
**9.** 210 N.
**11.** >1.5 kg.
**13.** (*a*) 196 N, 196 N;
(*b*) 98.0 N, 294 N.
**15.** $-0.4$ m/s$^2$, downward.
**17.** $-2.5$ m/s$^2$, downward.
**19.** 0.705 m/s$^2$.
**21.** (*a*) 4.69 m/s$^2$;

## Chapter 21

**1.** $2.7 \times 10^{-3}$ N.

**3.** $1.21 \times 10^{4}$ N.

**5.** $1.5 \times 10^{-13}$%.

**7.** 3.59 cm.

**9.** $-4.6 \times 10^{8}$ C, 0.

**11.** (*a*) $q_1 = q_2 = \frac{1}{2}Q_T$;
(*b*) $q_1 = 0$, $q_2 = Q_T$.

**13.** Top charge: $2.00 \times 10^{2}$ N, *y*-direction; Lower left charge: $2.00 \times 10^{2}$ N, 30° below the $-x$ axis; Lower right charge: $2.00 \times 10^{2}$ N, 30° below the $+x$ axis.

**15.** Each force is $7.16 \times 10^{7}$ N, and lies along the line from the center of the square outwards from the charge.

**17.** $10.1\dfrac{kQ^2}{\ell^2}$, 61° above the positive *x*-axis.

**19.** $1.8 \times 10^{12}$ electrons.

**21.** (*a*) $T = 2\pi\sqrt{\dfrac{m\pi\varepsilon_0 d^3}{Qq}}$;
(*b*) 0.2 ps.

**23.** $1.05 \times 10^{5}$ N/C, south.

**25.** 195 N/C $\hat{\mathbf{j}}$.

**27.** $1.33 \times 10^{14}$ m/s$^2$, opposite to the field.

**29.** 0.25 N/C.

**31.** $1.16 \times 10^{-10}$ C.

**33.** $1.17 \times 10^{6}$ N/C, towards the $-33.8\ \mu$C charge.

**35.** 65 cm.

**37.** (*a*) $\dfrac{\sqrt{3}kQ}{\ell^2}$ at 240°;
(*b*) $\dfrac{kQ}{\ell^2}$ at 330°.

**39.** $\dfrac{Q}{4\pi\varepsilon_0}\left\{\dfrac{(x-\frac{1}{2}\ell)}{\left[(x-\frac{1}{2}\ell)^2+R^2\right]^{3/2}} + \dfrac{(x+\frac{1}{2}\ell)}{\left[(x+\frac{1}{2}\ell)^2+R^2\right]^{3/2}}\right\}\hat{\mathbf{i}}$.

**41.** $\vec{\mathbf{E}}_A = 3.0 \times 10^{6}$ N/C at 90°, $\vec{\mathbf{E}}_B = 7.8 \times 10^{6}$ N/C at 56°, yes.

**43.** $x_M = \pm a/\sqrt{2}$.

**47.** $\dfrac{8\lambda\ell z}{\pi\varepsilon_0(4z^2+\ell^2)(4z^2+2\ell^2)^{1/2}}\hat{\mathbf{k}}$.

**49.** (*a*) $E_x = \dfrac{\lambda\ell}{4\pi\varepsilon_0 x\sqrt{x^2+\ell^2}}$,
$E_y = \dfrac{\lambda}{4\pi\varepsilon_0 x\sqrt{x^2+\ell^2}}(x-\sqrt{x^2+\ell^2})$.
Note that $E_y < 0$, and so the electric field points to the right and down.

**51.** $E(x) = \dfrac{Q}{4\pi\varepsilon_0 x(x+\ell)}$.

**53.** (*a*) $5.70 \times 10^{-3}$ m;
(*b*) $5.48 \times 10^{-9}$ s.

**55.** (*a*) To the right;
(*b*) 32 N/C.

**57.** $-10\ \text{m}\hat{\mathbf{i}} + 9.5\ \text{m}\hat{\mathbf{j}}$.

**59.** (*a*) $1.1 \times 10^{-28}$ C · m;
(*b*) $2.4 \times 10^{-24}$ m · N;
(*c*) $1.7 \times 10^{-24}$ m · N;
(*d*) $4.8 \times 10^{-24}$ J.

**61.** (a) $\sin\theta \approx \theta$;
(*b*) $\dfrac{1}{2\pi}\sqrt{\dfrac{pE}{I}}$.

**65.** (a) $4 \times 10^{-10}$ N;
(*b*) $7 \times 10^{-10}$ N;
(*c*) $6 \times 10^{-5}$ N.

**67.** $3.9 \times 10^{9}$ C.

**69.** $2.4 \times 10^{-10}$ N.

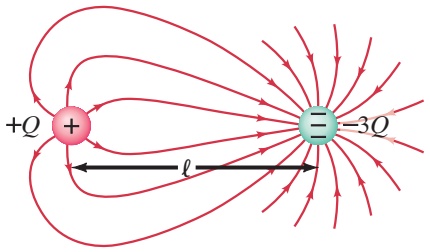
**71.** $5.2 \times 10^{-11}$ m.

**73.** $\dfrac{Q^2}{2\varepsilon_0 A}$, $8 \times 10^{-7}$ C.

**75.** $5 \times 10^{-9}$ C.

**77.** $8.0 \times 10^{-9}$ C.

**79.** 16°.



**81.** $E_A = 3.4 \times 10^{4}$ N/C, to the right,
$E_B = 2.3 \times 10^{4}$ N/C, to the left,
$E_C = 5.6 \times 10^{3}$ N/C, to the right,
$E_D = 3.4 \times 10^{3}$ N/C, to the left.

**83.** $-5.6 \times 10^{-6}$ C; unstable.

**85.** (*a*) $1.11 \times 10^{6}$ N/C, downward;
(*b*) $-1.96 \times 10^{-5}$ C/m$^2$.

**87.** (*a*) $3.61 \times 10^{24}$ electrons;
(*b*) $1.79 \times 10^{-18}$.

**89.**

**91.** $\vec{\mathbf{E}} = \dfrac{Qx}{4\pi\varepsilon_0(x^2+a^2)^{3/2}}\hat{\mathbf{i}} - \dfrac{2Qa}{4\pi^2\varepsilon_0(x^2+a^2)^{3/2}}\hat{\mathbf{j}}$.

## Chapter 22

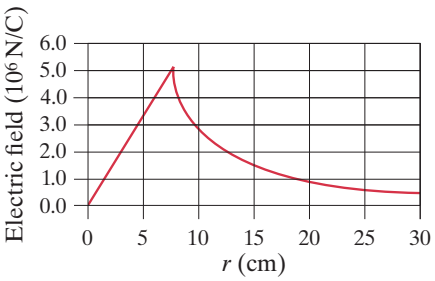
**1.** (*a*) 34 N · m$^2$/C;
(*b*) 24 N · m$^2$/C;
(*c*) 0.

**3.** (*a*) 0;
(*b*) $\Phi_{\substack{\text{thru faces}\\ \text{parallel to } E}} = 0$,
$\Phi_{\substack{\text{thru face with}\\ E \text{ entering}}} = -E_0\ell^2$,
$\Phi_{\substack{\text{thru face with}\\ E \text{ leaving}}} = E_0\ell^2$.

**5.** $1.64 \times 10^{-8}$ C.

**7.** (*a*) $-1.1 \times 10^{5}$ N · m$^2$/C;
(*b*) 0.

**9.** $-1.5 \times 10^{-6}$ C.



**11.** $2.6 \times 10^{-5}$ C/m.

**13.** $-7.97 \times 10^{-11}$ C.

**15.** (*a*) $3.0 \times 10^{4}$ N/C, towards the wire;
(*b*) $1.0 \times 10^{5}$ N/C, towards the wire;

**17.** (*a*) $\dfrac{1}{4\pi\varepsilon_0}\dfrac{Q}{r^2}$;
(*b*) 0;
(*c*) $\dfrac{1}{4\pi\varepsilon_0}\dfrac{Q}{r^2}$;
(*d*) Makes $E = 0$ inside the boundaries of the shell;
(*e*) Polarizes the shell: negative on the inside boundary, positive on the outside boundary.

**19.**

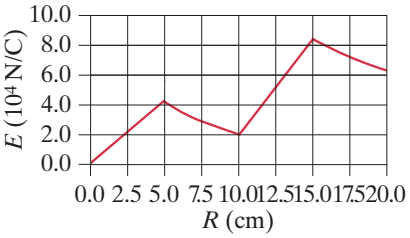
**21.** (*a*) $6.49 \times 10^{7}$ N/C, radially outward;
(*b*) 0;
(*c*) $6.49 \times 10^{5}$ N/C, radially outward.

**23.** (*a*) $-8.00\ \mu$C;
(*b*) $+1.60\ \mu$C.

**25.** (*a*) 0;
(*b*) $\sigma/\varepsilon_0$;
(*c*) The fields will not change.

**27.** (*a*) 0;
(*b*) $\dfrac{\sigma_1 r_1^2}{\varepsilon_0 r^2}$;
(*c*) $\dfrac{\sigma_1 r_1^2 + \sigma_2 r_2^2}{\varepsilon_0 r^2}$;
(*d*) $\sigma_1 r_1^2 + \sigma_2 r_2^2 = 0$;
(*e*) $\sigma_1 = 0$.

**29.** (*a*) 0;
(*b*) $\dfrac{Q}{4\pi\varepsilon_0 r^2}\dfrac{(r^3 - r_1^3)}{(r_0^3 - r_1^3)}$;
(*c*) $\dfrac{Q}{4\pi\varepsilon_0 r^2}$.



**31.** (*a*) $-q$;
(*b*) $Q + q$;
(*c*) $\dfrac{q}{4\pi\varepsilon_0 r^2}$;
(*d*) 0;
(*e*) $\dfrac{q+Q}{4\pi\varepsilon_0 r^2}$.

**33.** (*a*) $\dfrac{\sigma R_0}{\varepsilon_0 R}$, radially outward;
(*b*) 0;
(*c*) They are the same if $\lambda = 2\pi R_0\sigma$.

**35.** (*a*) 0;
(*b*) $\dfrac{Q}{2\pi\varepsilon_0 R\ell}$, radially outward;
(*c*) 0;
(*d*) $\dfrac{eQ}{4\pi\varepsilon_0\ell}$.

**37.** (*a*) $2.8 \times 10^7$ m/s;
(*b*) $5.5 \times 10^5$ m/s.

**39.** (*a*) $\dfrac{\rho_E R}{2\varepsilon_0}$;
(*b*) $\dfrac{\rho_E R_1^2}{2\varepsilon_0 R}$;
(*c*) $\dfrac{\rho_E(R_1^2 + R^2 - R_2^2)}{2\varepsilon_0 R}$;
(*d*) $\dfrac{\rho_E(R_1^2 + R_3^2 - R_2^2)}{2\varepsilon_0 R}$;
(*e*)

**41.** (*a*) 0;
(*b*) $\dfrac{1}{4\pi\varepsilon_0}\dfrac{Q}{(75R_0)^2}$.

**43.** (*a*) $\dfrac{\rho_E d}{2\varepsilon_0}$, perpendicularly away from the slab.

**45.** (*a*) 35 N, towards the other plate;
(*b*) 0.18 J.

**47.** (*a*) 0;
(*b*) $-\dfrac{\rho_0(d-x)}{\varepsilon_0}\hat{\mathbf{i}}$;
(*c*) $-\dfrac{\rho_0(d+x)}{\varepsilon_0}\hat{\mathbf{i}}$.

**49.** $\dfrac{Q}{4\pi\varepsilon_0}\dfrac{r^2}{r_0^4}$, radially outward.

**51.** 362 N · m$^2$/C for both spheres.

**53.** $\oint \vec{\mathbf{g}} \cdot d\vec{\mathbf{A}} = -4\pi G M_{\text{encl}}$.

**55.** $\varepsilon_0 a\ell^3$.

**57.** (*a*) 0;
(*b*) $\dfrac{1}{25\pi\varepsilon_0}\dfrac{Q}{r_0^2} \le E_{\substack{\text{sphere}\\\text{surface}}} \le \dfrac{1}{\pi\varepsilon_0}\dfrac{Q}{r_0^2}$;
(*c*) No;
(*d*) No.

**59.** (*a*) $3.4 \times 10^{11}$ C/m$^3$;
(*b*) $1.1 \times 10^{-19}$ C;
(*c*) $3.5 \times 10^{11}$ N/C.

**61.** (*a*) $\dfrac{\rho_E r_0}{6\varepsilon_0}$, towards point C;
(*b*) $\dfrac{17\rho_E r_0}{54\varepsilon_0}$, towards the left.

**63.** (*a*) 0;
(*b*) $5.65 \times 10^5$ N/C, to the right;
(*c*) $5.65 \times 10^5$ N/C, to the right;
(*d*) $-5.00 \times 10^{-6}$ C/m$^2$;
(*e*) $5.00 \times 10^{-6}$ C/m$^2$.

**65.** (*a*) On the inner surface of the shell;
(*b*) $E_{\text{inside}} = \dfrac{2.7 \times 10^4 \text{ N} \cdot \text{m}^2/\text{C}}{r^2}$,
$E_{\text{outside}} = 0$.

## Chapter 23

**1.** $6.3 \times 10^{-4}$ J.

**3.** $-0.77$ V.

**5.** (*a*) $1.9 \times 10^{-7}$ m;
(*b*) 1.1 mV increase.

**7.** $-138$ V.

**9.** $2.8 \times 10^{-2}$ m.

**11.** $1.1 \times 10^{-6}$ C.

**13.** $2 \times 10^{-5}$ m.

**15.** (*a*) $-0.96$ GV;
(*b*) 0.96 GV.

**17.** (*a*) They have the same potential;
(*b*) $Q\dfrac{r_2}{(r_1 + r_2)}$.

**19.** (*a*) 15,000 V;
(*b*) $2.7 \times 10^{-5}$ C/m$^2$.

**21.** (*a*) 0;
(*b*) $-44.1$ V;
(*c*) $-44.1$ V.

**23.** (*a*) $V_0 - \dfrac{\sigma R_0}{\varepsilon_0}\ln\dfrac{R}{R_0}$;
(*b*) $V_0$;
(*c*) No.

**25.** $2.8 \times 10^{-9}$ C.

**27.** (*a*) $5.8 \times 10^5$ V;
(*b*) $9.2 \times 10^{-14}$ J.

**29.** 0.28 J.

**31.** $1.8 \times 10^3$ m/s.

**33.** $1.07 \times 10^6$ m/s.

**35.** $\dfrac{\sigma}{2\varepsilon_0}\left(\sqrt{x^2 + R_2^2} - \sqrt{x^2 + R_1^2}\right)$.

**37.** 32 m/s.

**39.** $\dfrac{Q}{8\pi\varepsilon_0\ell}\left[\ln\left(\dfrac{x+\ell}{x-\ell}\right)\right], x > \ell$.

**41.** $\dfrac{a}{6\varepsilon_0}\left[(R_0^2 - 2x^2)(x^2 + R_0^2)^{1/2} + 2x^3\right]$, $x > 0$.

**43.** 1 mm.

**45.** (*a*) $2.6 \times 10^{-3}$ V;
(*b*) $1.8 \times 10^{-3}$ V;
(*c*) $-1.8 \times 10^{-3}$ V.

**49.** Plate at origin:
$\sigma = -7.5 \times 10^{-11}$ C/m$^2$,
other plate: $\sigma = 7.5 \times 10^{-11}$ C/m$^2$.

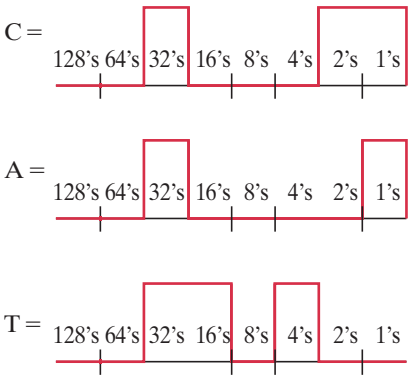
**51.** $\vec{\mathbf{E}} = (-by + cyz)\hat{\mathbf{i}} + (-2ay - bx + cxz)\hat{\mathbf{j}} + (cxy)\hat{\mathbf{k}}$.

**53.** (*a*) Field on $y$-axis:
$\vec{\mathbf{E}} = \dfrac{1}{4\pi\varepsilon_0}\dfrac{Q}{y\sqrt{\ell^2 + y^2}}\hat{\mathbf{j}}$;
(*b*) Field on $x$-axis:
$\vec{\mathbf{E}} = \dfrac{1}{4\pi\varepsilon_0}\left(\dfrac{Q}{x^2 - \ell^2}\right)\hat{\mathbf{i}}$.

**55.** $-82.5$ kV.

**57.** 1.3 eV.

**59.** (*a*) 4.8 keV;
(*b*) $v_e/v_p = 42.8$.



**61.** $\dfrac{3Q^2}{20\pi\varepsilon_0 r_0}$.

**63.** 111000001101.

**65.** 43,690.

**67.** (*a*) 65,536 different possible voltages;
(*b*) 16,777,216 different possible voltages;
(*c*) 16,777,216 different colors.

**69.** (*a*) C = 00100011, T = 00110100;
(*b*) B = 34, H = 40;
(*c*)

**71.** (*a*) 2.29 V;
(*b*) 10110001.

**73.** 000; 000; 000; 000; 000; 010; 011; 001; 100; 100; 010; 010; 010; 000; 000; 000.

**75.** (*a*) 2850 Mb/s;
(*b*) ≈ 150 times present day-rate, compression;
(*c*) 0.7%;
(*d*) 0.40 frames/s.

**77.** $1.7 \times 10^6$ V.

**79.** (*a*) $\frac{16}{\sqrt{3}} \frac{1}{4\pi\varepsilon_0} \frac{Q}{\ell}$;

(*b*) $\left(3 + \frac{3}{\sqrt{2}} + \frac{1}{\sqrt{3}}\right) \frac{1}{4\pi\varepsilon_0} \frac{Q}{\ell}$;

(*c*) $4\left(3 + \frac{3}{\sqrt{2}} + \frac{1}{\sqrt{3}}\right) \frac{1}{4\pi\varepsilon_0} \frac{Q^2}{\ell}$.

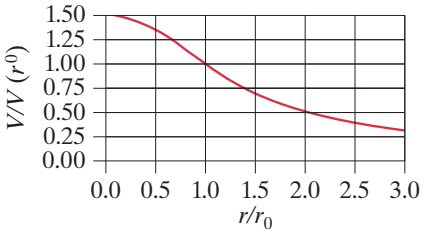
**81.** $K_\alpha = 2K_p$.

**83.** (*a*) $2.8 \times 10^3$ m/s;
(*b*) $2.1 \times 10^3$ m/s.

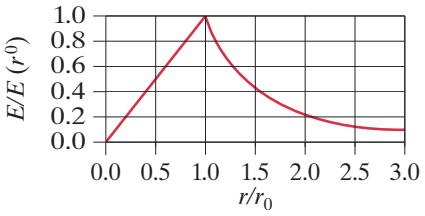
**85.** $1.03 \times 10^6$ m/s.

**87.** $V_{\text{left}} = \frac{Q}{\pi\varepsilon_0 \ell}\left(\frac{\sqrt{3}}{6} - 2\right)$,

$V_{\text{top}} = -\frac{\sqrt{3}Q}{2\pi\varepsilon_0 \ell}$,



$V_{\text{right}} = -\frac{Q}{\pi\varepsilon_0 \ell}\left(1 + \frac{\sqrt{3}}{6}\right)$.

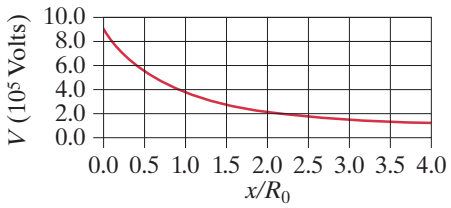


**89.** (*a*) $1.3 \times 10^6$ V;
(*b*) 2.0 kg.

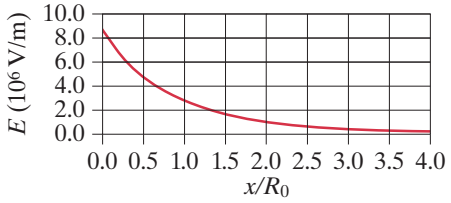
**91.** (*a*) $\frac{Q}{4\pi\varepsilon_0 r}$;

(*b*) $\frac{Q}{8\pi\varepsilon_0 r_0}\left(3 - \frac{r^2}{r_0^2}\right)$;

(*c*)



**93.** Binary values: 1110 ; 101101 ; 1100111.



**95.** (*a*) 19 kV;
(*b*) $\frac{4Bx\hat{\mathbf{i}}}{(x^2 + R^2)^3}$;
(*c*) $1.9 \times 10^5$ V/m$\hat{\mathbf{i}}$.

**97.** 3000 V, little actual charge transfer.

**99.** (*a*) 27 V;
(*b*) $2.2 \times 10^{-18}$ J; 14 eV;
(*c*) $-2.2 \times 10^{-18}$ J ; −14 eV;
(*d*) $2.2 \times 10^{-18}$; 14 eV.

**101.**

**103.** (*a*) $\frac{\rho_E}{3\varepsilon_0}\frac{(r_2^3 - r_1^3)}{r}$;

(*b*) $\frac{\rho_E}{\varepsilon_0}\left(\frac{1}{2}r_2^2 - \frac{1}{6}r^2 - \frac{1}{3}\frac{r_1^3}{r}\right)$;

(*c*) $\frac{\rho_E}{2\varepsilon_0}(r_2^2 - r_1^2)$, yes.

**105.** (*a*) $6 \times 10^5$ V;
(*b*) $1 \times 10^{-5}$ C.

## Chapter 24

**1.** $3.6 \times 10^{-6}$ F.

**3.** $9.00 \times 10^{-5}$ C.

**5.** $Q_1 = Q_0 \frac{C_1}{C_1 + C_2}$,

$Q_2 = Q_0\left(\frac{C_2}{C_1 + C_2}\right)$,

$V_1 = V_2 = \frac{Q_0}{C_1 + C_2}$.

**7.** 1.2 C.

**9.** 150 m$^2$.

**11.** $7.10 \times 10^{-4}$ F.

**13.** $9 \times 10^{-16}$ m, no.

**15.** $2.86 \times 10^{-8}$ C.

**17.** $5.3 \times 10^4$ V/m.

**19.** (*a*) 0.22 $\mu$m $\leq x \leq$ 220 $\mu$m;

(*b*) $\Delta x = \frac{x^2 \Delta C}{\varepsilon_0 A}$;

(*c*) $x_{\min}$ : 0.01%, $x_{\max}$ : 10%.

**21.** $3.0 \times 10^3$ pF, yes.

**25.** (*a*) parallel;

(*b*) $\varepsilon_0 A\left(\frac{1}{d_1} + \frac{1}{d_2}\right)$;

(*c*) $C_{\min} = \frac{4\varepsilon_0 A}{d_1 + d_2}$, $C_{\max} = \infty$.

**27.** $C_{\max} = 1.89 \times 10^{-8}$ F, parallel;
$C_{\min} = 1.68 \times 10^{-9}$ F, series.

**29.** $Q_1 = Q_2 = 14.8\ \mu$C, $Q_3 = 29.6\ \mu$C,
$Q_4 = 44.4\ \mu$C;
$V_1 = V_2 = 0.925$ V, $V_3 = 1.850$ V,
$V_4 = 1.56$ V, $V_{ab} = 3.41$ V.

**31.** $Q_1 = \frac{C_1 C_2}{C_1 + C_2} V_0$, $Q_2 = \frac{C_2^2}{C_1 + C_2} V_0$.

**33.** 1000 pF, in parallel.

**35.** 2.7 $\mu$F.

**37.** $\frac{\varepsilon_0 A}{d}\left(1 - \frac{\theta\sqrt{A}}{2d}\right)$.

**39.** $1.0 \times 10^{-7}$ J/m$^3$.

**41.** $2.3 \times 10^3$ J.

**43.** (*a*) $1.9 \times 10^{-4}$ J;
(*b*) $4.0 \times 10^{-5}$ J;
(*c*) $Q_{\text{parallel}} = 1.6 \times 10^{-5}$ C,
$Q_{\text{series}} = 3.3 \times 10^{-6}$ C.

**45.** (*a*) $4.74 \times 10^{-4}$ J;
(*b*) $2.01 \times 10^{-4}$ J;
(*c*) $-2.72 \times 10^{-4}$ J.

**47.** 3.7.

**51.** $5.6 \times 10^{-6}$ J/m.

**53.** $2.1 \times 10^{-10}$ F.

**55.** $1.1 \times 10^{-4}$ J.

**57.** $3.8 \times 10^{-7}$ C.

**59.** $\frac{2\varepsilon_0 A}{d}\frac{K_1 K_2}{K_1 + K_2}$.

**61.** (*a*) $Q_{1\ (\text{no dielectric})} = 0.43\ Q_0$,
$Q_{2\ (\text{dielectric})} = 1.57\ Q_0$;
(*b*) $V_1 = V_2 = 0.43 V_0$.

**63.** $4.76 \times 10^{-9}$ F, 0.280 m$^2$.

**65.** (*a*) $F = \frac{h}{\ell} = \left[\frac{1}{(K_{\text{liq}} - K_V)} \times \left[\frac{C \ln(R_a/R_b)}{2\pi\varepsilon_0 \ell} - K_V\right]\right]$;
(*b*) Full: 1500 pF, empty: 1100 pF.

**69.** $\frac{\varepsilon_0 A}{d - \ell + \frac{\ell}{K}}$.

**71.** (*a*) $6 \times 10^{-12}$ F;
(*b*) $5 \times 10^{-11}$ C;
(*c*) 150 V/m;
(*d*) $2 \times 10^{-10}$ J;
(*e*) Capacitance, charge, and work.

**73.** 610 V.

**75.** (*a*) Multiplied by 4;
(*b*) multiplied by 4;
(*c*) divided by 2.

**77.** $5.5 \times 10^{-6}$ C.

**79.** 83 days.

**81.** 1.2.

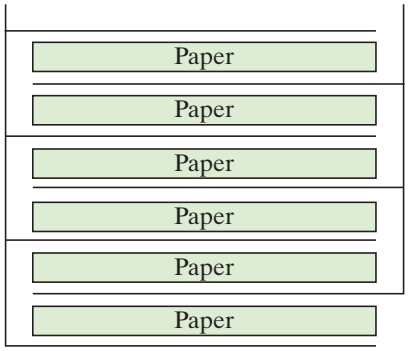
**83.** (*a*) 25 J;
(*b*) 940 kW.

**85.** (*a*) $4.2 \times 10^{-11}$ C;
(*b*) $4.2 \times 10^{-11}$ C;
(*c*) 20 V;
(*d*) $2 \times 10^{-10}$ J.

**87.** (*a*) Parallel;
(*b*) 7.7 pF to 35 pF.

**89.** (*a*) $\dfrac{Q^2x}{2A\varepsilon_0}$.

**91.** (*a*) $2.7 \times 10^{-7}$ C, 15,000 V/m, $5.9 \times 10^{-9}$ F, $6.0 \times 10^{-6}$ J;
(*b*) $8.5 \times 10^{-7}$ C, 15,000 V/m, $1.9 \times 10^{-8}$ F, $1.9 \times 10^{-5}$ J.



**93.** (*c*) 3.7;
(*d*) 0.23.

**95.** (*b*) $2 \times 10^{-16}$ F;
(*c*) 0.8 $\mu$m.

**97.** (*a*) 1.1 $\mu$m$^2$;
(*b*) 17 Mbytes.

**99.** (*a*) $1.0 \times 10^2$ hp;
(*b*) $1.1 \times 10^9$ J;
(*c*) $3.0 \times 10^3$ F;
(*d*) $2 \times 10^6$ g;
(*e*) No.

**101.** (*a*) 8.8 nF;
(*b*) 14 $\mu$C;
(*c*)

(*d*) 12.62 mm;
(*e*) 1700 V.

## Chapter 25

**1.** 1400 V.

**3.** $1.09 \times 10^{19}$ electrons/s.

**5.** $6.9 \times 10^{-11}$ A.

**7.** (*a*) 18 A;
(*b*) $1.7 \times 10^4$ C.

**9.** (*a*) 8.9 Ω;
(*b*) $6.5 \times 10^3$ C.

**11.** (*a*) 4.5 A;
(*b*) 4.8 A.

**13.** $4.8 \times 10^{-2}$ Ω.

**15.** $d_{\text{Tungsten}} = 3.3$ mm.

**17.** 24 C°.

## Chapter 27

**1.** 0.68 km.

**3.** (*a*) 6.7 N/m;
(*b*) 3.8 N/m.

**5.** 1.7 N.

**7.** 33°.

**9.** 1400 A, no.

**11.** 1.91 N, 41.8° below the negative *y*-axis.

**13.** $(0.34\,\hat{\mathbf{i}} + 0.17\,\hat{\mathbf{k}})$T.

**17.** $8.1 \times 10^{-14}$ N, north.

**19.** $3 \times 10^7$ m/s, no.

**21.** (*a*) no force;
(*b*) downward;
(*c*) upward;
(*d*) into the page;
(*e*) to the left;
(*f*) to the left.

**23.** 0.61 m.

**25.** $[(0.82\hat{\mathbf{i}} - 1.1\hat{\mathbf{j}} + 0.1\hat{\mathbf{k}})] \times 10^{-15}$ N.

**27.** $L_{\text{final}} = \dfrac{1}{2}L_{\text{initial}}$.

**29.** (*a*) $7.1 \times 10^5$ m/s;
(*b*) $4.3 \times 10^{-2}$ m;
(*c*) $3.8 \times 10^{-7}$ s.

**31.** $r_d = r_\alpha = \sqrt{2}\,r_p$.

**33.** (*a*) negative;
(*b*) $\dfrac{qB_0(d^2 + \ell^2)}{2d}$.

**35.** $1.37 \times 10^{-6}$ m.

**37.** (*a*) $\sqrt{3}\dfrac{mv_0}{qB_0}$;
(*b*) $\dfrac{4\pi m}{3qB_0}$.

**39.** 0.359 m · N.

**41.** (*a*) $7.01 \times 10^{-5}$ m · N;
(*b*) North.

**43.** (*a*) $-6.9\,\hat{\mathbf{k}}$ A · $m^2$;
(*b*) $(4.2\hat{\mathbf{i}} - 3.8\hat{\mathbf{j}})$m · N;
(*c*) −4.5 J.

**45.** Drops by 18%.

**47.** 21 $\mu$A.

**49.** (*a*) $5.85 \times 10^6$ m/s;
(*b*) $1.28 \times 10^{-2}$ m.

**51.** (*a*) 0.53 T;
(*b*) 0.61 T.

**53.** (*a*) $2.2 \times 10^{-4}$ V/m;
(*b*) $2.7 \times 10^{-4}$ m/s;
(*c*) $3.2 \times 10^{28}$ electrons/$m^3$.

**55.** (*a*) It determines the polarity of the emf;
(*b*) 0.56 m/s.

**59.** ${}^2_1$H(deuteron),
${}^4_2$He(alpha particle).

**61.** 2.5 m.

**63.** $3.8 \times 10^{-4}$ m · N.

**65.** 0.17 T at 27° westward from the vertical.

**67.** $\dfrac{6.0\,mg}{\ell B}$, toward the left.

**69.** (*c*) 48 MeV.

**71.** $1 \times 10^9$ A.

**73.** 33 A, down.

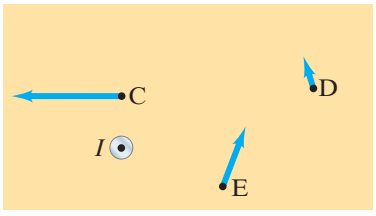
**75.** −0.13 eV.

**77.** 0.25 N, to the north and 68° above the horizontal.

**79.** $\dfrac{a^2IB_0}{b}\,\hat{\mathbf{i}}$.

**81.** $\pi\sqrt{\dfrac{mb(3a + b)}{3(a + b)NIaB}}$.

**83.** $7.0 \times 10^{-6}$ N.



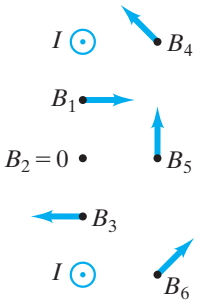
**85.** (*a*) Downward from the pivot;
(*b*) 0.028 T;
(*c*) 0.12 T.

## Chapter 28

**1.** $2.6 \times 10^{-4}$ T, $B_{\text{cable}}/B_{\text{Earth}} = 5.2$.

**3.** 0.21 N, attractive.

**5.**



**7.** $8.5 \times 10^{-5}$ T @ 82° or $(1.1 \times 10^{-5}\ \text{T})\hat{\mathbf{i}} + (8.4 \times 10^{-5}\ \text{T})\hat{\mathbf{j}}$.

**9.** $4.0 \times 10^{-5}$ T, 9.7° below the horizontal.

**11.** $4.4 \times 10^{-17}$ T.

**13.**

**15.** Middle wire: 0.063 N/m, attracting; left wire: 0.031 N/m, repelling.

**17.** 33 A, downward.

**19.** $\dfrac{\mu_0 I}{2\pi}\left(\dfrac{d-2x}{x(d-x)}\right)\hat{\mathbf{j}}$.

**21.** $4.33 \times 10^{-5}$ T.

**23.** $5.91 \times 10^{-5}$ T @ 5.83° below the negative $x$ axis.

**25.** $\dfrac{\mu_0 I\, I'}{\pi}\left[\dfrac{a}{2d} - \dfrac{\sqrt{3}}{3}\ln\left(1 + \dfrac{\sqrt{3}a}{2d}\right)\right]$.

**27.** 0.182 A.

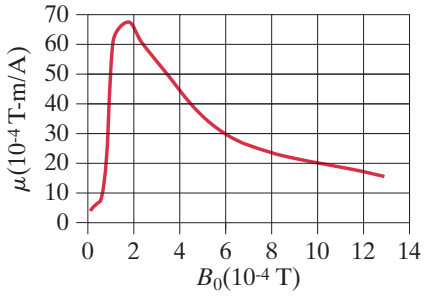
**29.** (*a*) 4.5 mT;
(*b*) 2.7 mT;
(*c*) 1.5 mT.

**31.** (*a*) 0.554 m;
(*b*) 9.42 mT.

**33.** 0.14 N to the south.

**35.** (*a*) $\dfrac{\mu_0 I_0 R^2}{2\pi R_1^3}$;
(*b*) $\dfrac{\mu_0 I_0}{2\pi R}$;
(*c*) $\dfrac{\mu_0 I_0}{2\pi R}\dfrac{(R_3^3 - R^3)}{(R_3^3 - R_2^3)}$;
(*d*) 0.

**37.** $\dfrac{\mu_0 I\theta}{4\pi}\left(\dfrac{R_2 - R_1}{R_1 R_2}\right)\hat{\mathbf{k}}$
(out of the plane of the page).



**39.** $9.2 \times 10^{-8}$ m · N, in a direction to cause the inner loop to rotate into the same plane as the outer loop with the currents parallel. We assumed that the magnetic field from the larger loop is constant across the surface of the smaller loop.

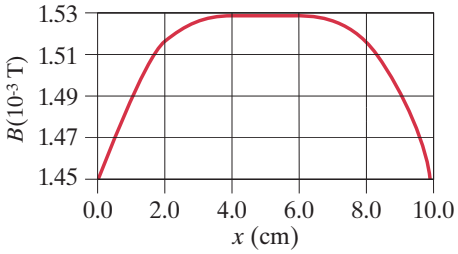
**45.** $\dfrac{\mu_0 I}{4\pi d}\left(\sqrt{2} - \dfrac{\sqrt{5}}{2}\right)\hat{\mathbf{k}}$
(out of the plane of the page).

**49.** (*a*) $\dfrac{2\sqrt{2}d^2\mu_0 I\,\hat{\mathbf{i}}}{\pi(d^2 + 4x^2)(d^2 + 2x^2)^{1/2}}$;
(*b*) Yes, $\vec{\boldsymbol{\mu}} = d^2 I\hat{\mathbf{i}}$.

**51.** 0.5 T.

**53.**

**55.** $M$ : $8.9 \times 10^{-4}$ N/m at 90°,
$N$ : $5.2 \times 10^{-4}$ N/m at 300°,
$P$ : $5.2 \times 10^{-4}$ N/m at 240°.



**57.** $2.0 \times 10^2$ A.

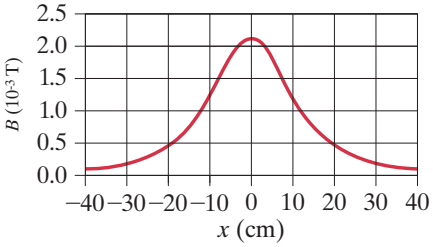
**59.** (*a*) $1.2 \times 10^{-5}$ N toward the wire;
(*b*) 0.

**61.** (*a*) 410 A, to the right;
(*b*) No;
(*c*) 410 A, to the left, yes.

**63.** (*a*) $1.1 \times 10^{-6}\ \text{T} \cdot \text{m}^3 \times$
$\left[\dfrac{1}{[(0.100\ \text{m})^2 + x^2]^{3/2}} + \dfrac{1}{[(0.100\ \text{m})^2 + (x - 0.100\ \text{m})^2]^{3/2}}\right]$;

(*b*)

(*c*) $-1.1 \times 10^{-2}$ %.



**65.** $1.9 \times 10^{-6}$ *g*'s.

**67.** $\dfrac{\mu_0 I\sqrt{5}}{2\pi a}$, into the page.

**71.** $9.3 \times 10^{-5}$ T, into the page.

**73.** 0.03 N.

**75.** $B = \dfrac{7.0686 \times 10^{-6}\ \text{T} \cdot \text{m}^3}{[(0.15\ \text{m})^2 + x^2]^{3/2}}$.

**77.** 7.1 A.

**79.** (*a*) $\dfrac{\mu_0 I}{2\pi R}(1 + \pi)\hat{\mathbf{k}}$;
(*b*) $\dfrac{\mu_0 I}{2\pi R}\sqrt{1 + \pi^2}$, 177° from the $+x$ axis, towards the $+z$ axis.

## Chapter 29

**3.** 0.16 V.

**5.** (*a*) $1.3 \times 10^{-2}$ Wb;

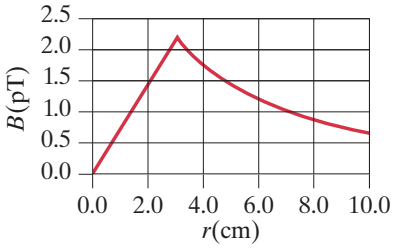
(*c*) 0.42 mA, not dangerous;
(*d*) 35 mA, dangerous.

**95.** $I_0 = \dfrac{V_0}{\sqrt{R^2 + \omega^2 L^2}}$, $\phi = \tan^{-1}\dfrac{\omega L}{R}$.

**97.** (*b*) As $f \to 0$, $A \to 0$; as $f \to \infty$, $A \to 1$.



**99.** (*a*) $f_0 = 7.1$ kHz, $(V_R)_{\text{rms}} = \boxed{V_{\text{rms}}}$;
(*b*) $(V_R)_{\text{rms}} = 0.86\, V_{\text{rms}}$.

## Chapter 31

**1.** $1.1 \times 10^5 \dfrac{\text{V/m}}{\text{s}}$.

**3.** $1.1 \times 10^{15} \dfrac{\text{V}}{\text{m} \cdot \text{s}}$.

**7.** (*b*) $r \le r_0 : B_0(r) = (7.5 \times 10^{-11}\ \text{T/m})r$,
$r > r_0 : B_0(r) = (6.8 \times 10^{-14}\ \text{T} \cdot \text{m})\dfrac{1}{r}$;
(*c*)

**9.** 4.95 V/m.

**11.** 8.33 min.

**13.** (*a*) $-\hat{\mathbf{k}}$;
(*b*) $B_0 = E_0 k/\omega$, $-\hat{\mathbf{j}}$.

**15.** (*a*) $8.386 \times 10^{-3}$ m;
(*b*) $2.5 \times 10^{18}$ Hz.

**17.** (*a*) $3.00 \times 10^5$ m;
(*b*) 0.341 m;
(*c*) no.

**19.** $4.0 \times 10^{16}$ m.

**21.** $9.0 \times 10^3$ wavelengths, $3.542 \times 10^{-15}$ s.

**23.** 3400 rad/s, or 32,000 rev/min.

**25.** $7.33 \times 10^{-7}$ W/m$^2$.

**27.** $6.36 \times 10^{-7}$ J/h.

**29.** (*a*) 54 V/m;
(*b*) 3.9 W/m$^2$.

**31.** 1240 V/m, $4.14 \times 10^{-6}$ T.

**33.** (*a*) 150 J;
(*b*) $2.4 \times 10^9$ V/m.

**35.** (*a*) $2 \times 10^8$ ly;
(*b*) 2000 time larger.

**37.** (*a*) 4000 Pa, $3.3 \times 10^{-9}$ N;
(*b*) $8 \times 10^6$ m/s$^2$.

**39.** 400 m$^2$.

**41.** 0.16 m.

**43.** 5.56 m, 0.434 m.

**45.** $9.4 \times 10^{-13}$ F.

**47.** (*a*) $1.2 \times 10^{-6}$ H;
(*b*) $1.1 \times 10^{-10}$ F.

**49.** $7.14 \times 10^{-4}$ V/m,
$1.35 \times 10^{-9}$ W/m$^2$.

**51.** 10 ns.

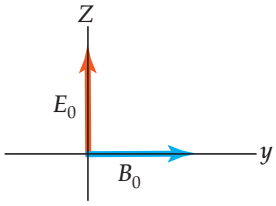
**53.** (*a*) 1.35 s;
(*b*) inside.

**55.** 8.33 min.

**57.** 6.9 V/m, $2.3 \times 10^{-8}$ T.

**59.** (*a*) $9.2 \times 10^{-11}$ J;
(*b*) $8.7 \times 10^{-6}$ V/m, $2.9 \times 10^{-14}$ T.

**61.** 61 km.



**65.** (*a*) $2.0 \times 10^{-8}$ N;
(*b*) $9.2 \times 10^{-7}$ N;
(*c*) gravity, by a factor of 50.

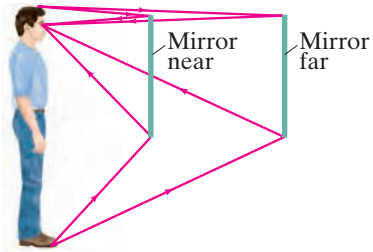
**67.** $1.1 \times 10^{-4}$%.

**69.** $2.25 \times 10^8$ m/s, 75.2%.

**71.** (*b*) $1.5 \times 10^{-16}$ A;
(*c*) $3.0 \times 10^{-20}$ T,
$\dfrac{B_{\text{D}}}{B_{\substack{\text{steady}\\\text{current}}}} = 1.5 \times 10^{-16}$.

**73.** (*d*)

both $\vec{\mathbf{E}}$ and $\vec{\mathbf{B}}$ rotate counterclockwise.



**75.** (*a*) $2.0 \times 10^{-3}$ J/s;
(*b*) 0.87 V/m;
(*c*) 0.87 V;
(*d*) $1.7 \times 10^{-2}$ V.

**77.** 19 kW.

**79.** (*a*) $+x$;
(*b*) $\beta = \alpha c$;
(*c*) $B_z = \dfrac{E_0}{c} e^{-(\alpha x - \beta t)^2}$.

## Chapter 32

**1.**

**3.** 13°.

**7.** $4.0 \times 10^{-6}$ m$^2$.

**11.** 15.0 cm.

**13.** (*a*) 12 cm;
(*b*) 17 cm;
(*c*) inverted.

**15.** 6.3 m.

**17.** (*a*) Convex;
(*b*) 20 cm behind the mirror;
(*c*) −83 cm;
(*d*) −170 cm.

**19.** (*b*) −6.0 cm;
(*c*) 1.3 mm.

**25.** (*a*) Center of curvature;
(*b*) real;
(*c*) inverted;
(*d*) −1.

**29.** 0.80 m.

**35.** (*a*) $2.21 \times 10^8$ m/s;
(*b*) $2.00 \times 10^8$ m/s;
(*c*) $1.97 \times 10^8$ m/s.

**37.** 46.1°.

**39.** 35.0°.

**41.** 71.8°.

**43.** (*a*) 27.1°;
(*b*) 31.2°;
(*c*) 31.2°.

**45.** 26°.

**47.** 60.5°.

**51.** 0.20°.

**53.** (*b*) 0;
(*c*) 0.5°.

**55.** 1.26.

**57.** $6.19 \times 10^{-4}$ m.

**59.** (*a*) $2.3 \times 10^{-6}$ s;
(*b*) $1.7 \times 10^{-8}$ s.

**61.** $n \ge 1.64$.

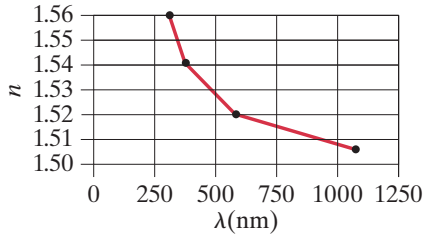
**63.** 17.5 cm.

**67.** 1.58, light flint glass.

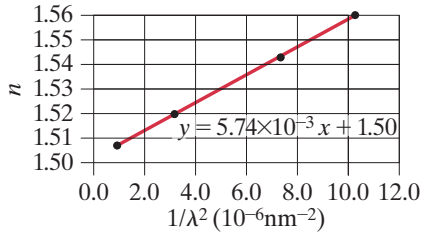
**69.** 51.1°.

**71.** 4.83 m.

**73.** 36 cm for real image, 18 cm for virtual image.



**77.** 430 nm.



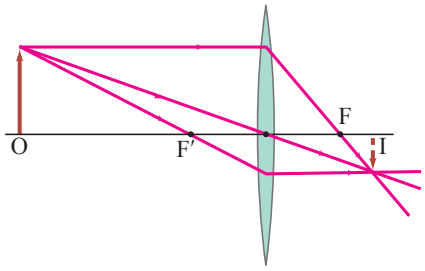
**83.** 38.9°.

**85.** 78.4°.

**87.** 11 cm, 14 cm.

**89.**

$A = 1.50$, $B = 5740\ \text{nm}^2$.

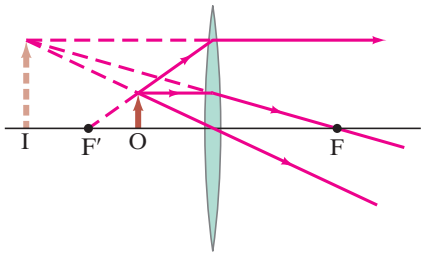


**91.** 0.18 m toward the viewer from the coin and 0.53 m above the coin.

**93.** $n = 2$.

**95.** (*a*) Yes;
(*b*) left: concave, middle: plane, right: convex;
(*c*) concave: same side of mirror as focal point and center of curvature; greater than the center of curvature; plane: anywhere; convex: right: opposite side of mirror as focal point and center of curvature.

## Chapter 33



**1.** (*a*) ≈ 630 mm;
(*b*) 635 mm.

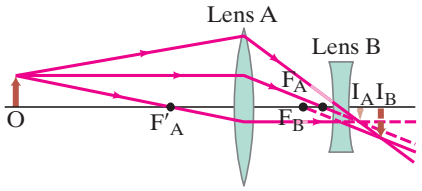
**3.** (*a*) 3.77 D, converging;
(*b*) −0.160 m, diverging.

**5.** (*a*) 106 mm;
(*b*) 109 mm;
(*c*) 117 mm;
(*d*) 0.513 m.

**7.** (*a*) Virtual, upright, magnified;
(*b*) converging;
(*c*) +7.4 D.

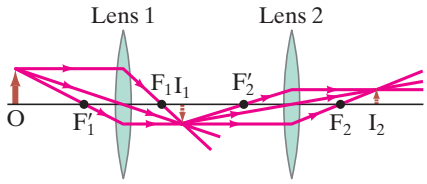
**9.** (*a*) 0.04 m away from the lens;
(*b*) 0.01 m toward the lens.

**11.** (*a*) −45.0 mm;
(*b*) −105 mm.



**13.** 21.3 cm, 64.7 cm.

**17.** (*b*) 94.9 cm;
(*c*) 94.9 cm.



**19.** (*a*) 22.8 cm beyond the second lens;
(*b*) −0.738×.

**21.** −14.0 cm.

**23.** (*a*) 0.10 m beyond the diverging lens;
(*b*) −1.0×;
(*c*)

**25.** (*a*) Image ≈ 30 cm beyond second lens, half the size of the object;

(*b*) 29 cm beyond the second lens, 0.46× the size of the object.

**27.** 1.597.

**29.** 0.34 m.

**33.** $\frac{1}{125}$ s.

**37.** (*a*) 49 mm;
(*b*) 14 mm.

**39.** (*a*) 0.26 mm;
(*b*) 0.47 mm;
(*c*) 1.3 mm;
(*d*) 0.56×, 2.7×.

**41.** $5.1\ \text{m} \leq d_o < \infty$.

**43.** $f/2.5$.

**45.** 0.91 D.

**47.** (*a*) Nearsighted;
(*b*) 30.6 cm.

**49.** −9.1 D, −7.7 D.

**51.** 18.4 cm, 64.3 cm.

**53.** 0.3 cm.

**55.** 1.6×.

**57.** (*a*) 3.7×;
(*b*) 13 mm;
(*c*) 6.7 cm.

**59.** (*a*) 6.8×;
(*b*) 2.0×.

**61.** −31×, 89 cm.

**63.** 24 cm.

**65.** −30×.

**67.** −110×.

**69.** −9×.

**71.** 7.0×.

**73.** 1.7 cm.

**75.** (*a*) 868×;
(*b*) 1.9 cm, 0.289 cm;
(*c*) 0.293 cm.

**77.** (*a*) 14 cm;
(*b*) 130×.

**79.** (*a*) 17 cm;
(*b*) 5.4×;
(*c*) 78%.

**81.** (*a*) Converging;
(*b*) 230 cm.

**83.** 46.8 cm, converging.

**85.** Left lens is a converging, right lens is diverging.

**87.** 2 cm from the original object, towards the lens.

**89.** 50.0 cm.

**91.** 45 m.

**93.** Infinity.

**95.** −0.578 D (upper part), +2.0 D (lower part).

**97.** (*a*) $M = -2.3\times$;
(*b*) 4.5 D.

**99.** (*a*) $\frac{f^2 v_o}{(d_o - f)^2}$;
(*b*) away;
(*c*) 2 *f*.

**101.** (*b*) $m = +2$ for both.

**103.** (*a*) 27.0 cm;
(*b*) 1.6 m;
(*c*) 14 cm.

**105.** $-7.8$ cm.
**107.** $-10$ cm; $d_{ia} = -10$ cm, $d_{ib} = 30$ cm.
**109.** $d_i = -d_o$.
**111.** 88 pixels/mm, 11 pixels/mm.
**113.** (*c*) 125 mm, 156 mm, 94 mm smaller.

## Chapter 34

**3.** $4.3 \times 10^{-6}$ m.
**5.** $5.8 \times 10^{-7}$ m, yellow.
**7.** 0.2 mm.
**9.** $1.2 \times 10^{-4}$ m.
**11.** $1.2 \times 10^{-5}$ m.
**15.** $1.9 \times 10^{-3}$ m.
**17.** $3.56 \times 10^{-3}$ m.
**19.** ¼.
**23.** $I_\theta = I_0\left[\dfrac{3 + 2\sqrt{2}\cos\left(\dfrac{2\pi d \sin\theta}{\lambda}\right)}{3 + 2\sqrt{2}}\right]$.
**25.** 650 nm.
**27.** (*a*) 180 nm;
(*b*) 360 nm, 540 nm.
**29.** (*b*) 290 nm.
**31.** 9.8 $\mu$m.
**33.** (*a*) 120 nm;
(*b*) 240 nm.
**35.** 33 dark bands.
**41.** 9 lenses.
**43.** $2.15 \times 10^{-4}$ m.
**45.** $8.31 \times 10^{-5}$ m.
**47.** $2.9 \times 10^{-4}$ m.
**49.** 57.3°, 32.7°.
**51.** 44.5%.
**53.** 37°, 53°.
**55.** 45°.
**57.** 9.4%.
**59.** $I_0 \cos^2\theta \sin^2\theta$ or $\frac{1}{4} I_0 \sin^2 2\theta$, 45°.
**61.** $3 \times 10^{28}$ lm, $2 \times 10^{27}$ cd.
**63.** 37 polarizers.
**65.** 0.5 cm.
**67.** (*a*) $1.3 \times 10^{-4}$ m;
(*b*) $3.9 \times 10^{-7}$ m.
**69.** 460 nm.
**71.** 4.7 W.
**73.** 530 nm.
**75.** $d_1 = \dfrac{\lambda}{2n_1}$, $d_2 = \dfrac{\lambda}{2n_2}$.
**77.** $\sin\theta_m = \dfrac{m\lambda}{d} \pm \sin\theta_i$,
$m = 0, 1, 2, \cdots$.
**79.** 330 nm, 160 nm.
**81.** $\theta_{\text{destructive}} = 0°, 180°$;
$\theta_{\text{constructive}} = 90°, 270°$.
**83.** $2.40 \times 10^2$ nm.
**85.** (*a*) 0;
(*b*) 0.10;
(*c*) 0.
**87.** $2.0 \times 10^2$ m.
**89.** (*a*) 60°;
(*b*) 72°;
(*c*) 84°.
**91.** 126 nm.
**93.** 1 lens: 92% transmitted, 8% reflected; 6 lenses: 61% transmitted, 39% reflected; 6 lenses with coating: 89% transmitted, 11% reflected.

## Chapter 35

**1.** 2.0°.
**3.** $2.46 \times 10^{-5}$ m.
**5.** (*a*) 16°, 34°, and 56°;
(*b*) 34°;
(*c*) no minima.
**7.** 4.8 cm.
**9.** $1.0 \times 10^{-6}$ m.
**11.** (*a*) 54°;
(*b*) 26°.
**13.** $I/I_0 = 0.068$.
**15.** $d = 5.5D$.
**17.** 7.
**21.** (*a*) 3;
(*b*) 9;
(*c*) 15;
(*d*) 31.
**23.** $(1.54 \times 10^{-5})°$.
**25.** $1.7 \times 10^{11}$ m.
**27.** $1.0 \times 10^4$ m.
**29.** 730 lines/mm, 88 lines/mm.
**31.** (*a*) 120 m;
(*b*) no.
**33.** 4.4°.
**35.** $5.0 \times 10^{-7}$ m.
**37.** 1600 slits/cm.
**39.** 30°.
**41.** 600 nm − 700 nm 2nd order overlaps with 400 nm − 467 nm 3rd order.
**43.** 614 mm, 899 mm.
**45.** 572 nm.
**47.** $\ell_1 = 8$ cm, $\ell_2 = 45$ cm, second order.
**49.** (*c*) −0.65°, −30°.
**51.** (*a*) $R_1 = 1.5 \times 10^4$, $R_2 = 3.0 \times 10^4$;
(*b*) 14 pm.
**53.** 12.7°.
**57.** 630 nm.
**59.** 0.7 m.
**61.** 13°.
**63.** 48 km.
**65.** $9.9 \times 10^{-4}$ m.
**67.** Yes.
**69.** Second order.
**71.** 0.77 arc min, they can be resolved.
**73.** 12,500 slits/cm.
**75.** $2.62 \times 10^{-10}$ m.
**77.** 110 m.
**79.** 1 cm.

Defects of the eye, 976–78, 985
Defibrillator, heart, 703, 712 *pr*, 780 *pr*, 764 *fn*
Defined values, 8, 9
Definite integrals, A-7, A-9
Definite proportions, law of, 493 *fn*
Deformation, 332
Degeneracy:
electron, 1330
neutron, 1331
Degradation of energy, 594–95
Degrees of freedom, 557–58
Dehumidifiers, 608 *pr*
Dehumidify a cellar, 537 *pr*
Del operator, 673 *fn*, A-16
Delayed neutrons, 1264
Delta particle, 1307
Deltoid muscle, 358 *pr*
Demagnetization, 828
Democritus, 493
Demodulator, 918
Dendrites, 736
Density (*defn*), 8, 366
charge, 623, 648, A-16
and floating, 377
of occupied states, 1205
probability, 1130, 1140, 1143, 1148, 1159, 1162–63, 1165, 1187
of states, 1204–7
of universe, 1350–51
of water, anomalous, 500–501
Depletion layer, 1212
Depth:
for atmosphere, 370
of field, 973
pressure and, 368
Depth finding, 481
Derivatives, 24–25, 30, A-6, inside back cover
partial, 200, 440
Descartes, René, 21
Descriptive laws (*defn*), 3
Design, ramps, 113 *pr*
Destructive interference, 444–46, 473–74, 999, 1009, 1187
and energy, 444
Detection:
of particles, 1248–49
of radiation, 1274
Detectors, of particles and radiation, 1248–49
Detergents, 387
Determinism, 159, 1135–36
Deuterium, 1227, 1257, 1263, 1267–71
Deuterium–tritium fusion (d–t), 1270
Deuteron, 1227, 1257
Dew point, 526
Diagrams:
Feynman, 1297, 1312
force, 97
free-body, 97–104
H–R, 1328, 1333
phase, 523–24
phasor, 885–86, 1002, 1029, 1041–42

Diamagnetism, 828–29
Diamond, 944
Diastole phase, 388
Diastolic pressure, 389
Dielectric constant, 703
Dielectric relaxation time, 776 *pr*
Dielectric strength, 703
Dielectrics, 703–5
molecular description of, 706–7
Diesel engine, 552, 575 *pr*, 607 *pr*
Differential cross section, 1261
Differential equation, second-order, 402
Diffraction, 450–51, 996, 1025–44, 1176
by circular opening, 1033–35
as distinguished from interference, 1033–34
in double-slit experiment, 1031–33
of electrons, 1107–8
Fraunhofer, 1026 *fn*
Fresnel, 1026 *fn*
of light, 996, 1025–44
as limit to resolution, 1033–37
by single slit, 1026–31
X-ray, 1043–44
in X-ray imaging, 1045–47
Diffraction factor, 1032
Diffraction grating, 1037–39
resolving power of, 1041–43

Diffraction limit of lens resolution, 1033–35
Diffraction patterns, 1026
of circular opening, 1033–34
of single slit, 1026–31
X-ray, 1043–44
Diffraction spot or disk, 1033–35
Diffuse reflection, 928
Diffusion, 530–32, 536 *pr*
applications of, 531–32
Fick's law of, 530
in living organisms, 531
Diffusion constant, 530
Diffusion equation, 530
Diffusion time, 531
Digital ammeter, 767, 770
Digital artifact, 971
Digital bits, 298 *pr*
Digital camera, 970–75
Digital circuits, 1218
Digital information, 856
Digital signal:
voltage, 676–79
with and without noise, 678
Digital-to-analog converter (DAC), 677, 780 *pr*
Digital transmission, 678–79
Digital TVs, 680–81
Digital video disc (DVD) players, 1177–78
Digital voltmeter, 767, 770
Digital zoom, 975, 987 *pr*
Dilation, time, 1064–69, 1075
Dimensional analysis, 14–15, 142 *pr*, 144 *pr*, 459 *pr*, 1127 *pr*, 1359 *pr*, A-12
Dimensions, 14–15
Diodes, 1151, 1213–14, 1249
forward-biased, 1213
junction, 1218
lasers
*pn*, 1216
semiconductor, 1177
light-emitting (LED), 680, 1215–16
photo-, 1101, 1215

semiconductor, 1212–17
tunnel, 1151
zener, 1213–14
Diopter (D) (unit), 960
Dip, angle of, 784
Dipole antenna, 903–4
Dipole layer, 736–37
Dipole–dipole bonds, 1193
Dipole–induced dipole bonds, 1193
Dipoles and dipole moments:
of atoms, 1171–74
electric, 626, 629–31, 671–72, 706
magnetic, 793–94, 823
of nuclei, 1229
Dirac, P. A. M., 1128, 1161, 1204 *fn*, 1300
Dirac equation, 1300
Direct current (dc), 730 (*see also* Electric current)
Direction:
change in, for velocity, 88
of friction force in skid, 131
of net force, 127
and nonuniform circular motion, 133
and uniform circular motion, 123, 124
of vector, 22, 55, 61
Discharge:
capacitor, 762–63
corona, 666, 710 *pr*
Discharge tube, 1111
Discovery in science, 798
Disintegration, 1233
Disintegration energy (*defn*), 1234–35
Disks:
compact disc (or disk), 18 *pr*, 48 *pr*, 53 *pr*, 298 *pr*
of spine, 340–41
Disorder, order and, 593–94
Dispersion, 442, 942
Displacement, 22–23, 401, 411, 437
angular, 266, 413
resultant, 55–56
with unphysical solution, 43
vector, 22, 55–57, 62–63
in vibrational motion, 401
of wave, 437–41, 1130
Displacement current, 902
Dissipative forces, 207–10
energy conservation with, 208–10
Dissociation energy, 1188
Distance, 22, 24
astronomical, 1323, 1326, 1328, 1332–34
between atoms, 494
estimating, via SNIa and Redshift, 1333–34
force acting at a, 162
image, 929, 934, 946, 962–63
object, 929, 934, 946, 962–63
relativity of, 1070–76
table of, typical, 7
traveled, 22–23
wave amplitude decrease with, 436
Distance (tiny) measurement, 896 *pr*, 1010, 1021 *pr*
Distortion, by lenses, 985
Distribution, probability:
in atoms, 1130, 1140, 1143, 1148, 1159, 1162–63, 1165
in molecules, 1187
Distributive law, 308, 325 *pr*
Distributive property, 176, 188 *pr*
Diver, 304
Divergence, A-16
Divergence theorem, A-16
Diverging lens, 959 *ff*
*Divine Comedy* (Dante), 452 *pr*
Diving board, 331
Division, significant figures in, 4
DNA, 631–33, 1041, 1044, 1192–96, 1272, 1277–78
Dog whistle, 488 *pr*
Domains, magnetic, 825
Domes, 331, 351–52
Donor level, 1212
Doomsday asteroid, 114 *pr*
Door opener, automatic, 1101
Doorbell, 826
Doping of semiconductors, 1211 *ff*
Doppler, J. C., 476 *fn*
Doppler blood-flow meter, 479, 491 *pr*
Doppler echocardiography, 483
Doppler effect, 476–80
bats use, 479
for light, 480, 1085–86, 1338
in medical imaging, 483
in medicine, 479
for sound, 476–80
Doppler radar speed, 479
Doppler ultrasound image, 483
Dose, 1272–76
effective, 1273
Dosimetry, 1272–76
Dot (scalar) product, 176–77
Dots and dashes, 676 *fn*
Double helix, 632
Double-slit experiment:
electrons, 1129–31
light, 998–1002
intensity in pattern, 1002–4, 1031–33
Down quark, 1308
Drag coefficient, 398 *pr*
Drag force, 134–35, 184, 383, 398 *pr*
Drain, in MOSFET, 1218
Drain terminal, 857
DRAM, 716 *pr*, 857–58
Drift velocity, 732–35, 799
Drinking fountain, 398 *pr*
Driven oscillator, power transferred to, 425 *pr*
Driving, around curves, 130–31
Drum, 467
Dry cell, 719
Dry ice, 523
Dryness, in winter, 526
d–t (deuterium–tritium) fusion, 1270
Duality, wave–particle, 1106–8, 1119–20
Duck, bow wave, 480
Dulong and Petit value, 558
Dust, interstellar, 1325
DVD player, 1177–78
Dwarfs, white, 1326, 1328, 1330
Dye lasers, 1177
Dylan, Bob, 1352 *fn*
Dynamic lift, 383
Dynamic random access memory (DRAM), 716 *pr*, 857–58
Dynamic rope, 115 *pr*
Dynamics, 20, 86 *ff*
fluid, 378–88
hydro-, 378
of rotational motion, 274 *ff*
of uniform circular motion, 126–29
Dynamo, 846–48
Dyne (unit), 89, 173
Dynodes, 1248

Ear, 461
discomfort, 396 *pr*
response of, 467
sensitivity of, 464, 466–67
Earth:
artificial satellites of, 152–54
as concentric shells, 148–49, A-13–A-15
core of, 392 *pr*
electric field of, 642 *pr*, 658 *pr*
equatorial bulge, 327 *pr*
estimating radius of, 13, 18 *pr*
in geocentric vs. heliocentric systems, 155
gravitational field of, 642 *pr*
gravity due to, 38 *ff*, 125, 146–52
as inertial frame, 87, 151–52
interior, 481
magnetic field and magnetic poles of, 784
mass, radius, etc.: inside front cover
mass determination, 150
meteorite striking, 326 *pr*
model of, 392 *pr*
not inertial frame, 144 *pr*, 319–21
precession of axis, 327 *pr*
radius, 1, 7, 13, 18 *pr*
rocks and earliest life, 1248
seasons on, 566
soundings, 481
Sun's orbit in relation to, 159
Earthing, electrical, 612
Earthquake, 415, 418, 430, 435, 436, 437, 449–50, 453, 457
epicenter, 453 *pr*
intensity, 437
resonance, 418
Earthquake waves, 435, 437, 450, 453 *pr*
Eccentricity, 156
ECG, 663, 682–83
Echolocation, 434

Particle–antiparticle pair, 1300
Particle(s):
  definition of, 21, 98
  detection of, 1248–49
  elementary, 1289–1317
  fundamental (*defn*), 1290
  velocity of wave vs., 429
Particulate pollution, 18 *pr*
Pascal, Blaise, 367, 372, 397 *pr*
Pascal (Pa) (unit), 367, 373
Pascal's principle, 371–72
Pashen series, 1112, 1116
Passive solar heating, 599
Path independence, of entropy change, 588, 589
Pauli, Wolfgang, 1128, 1129, 1166, 1238
Pauli exclusion principle, 1166–67, 1187, 1204, 1207, 1311, 1330, 1331
Peak current, 730
Peak voltage, 730
Peak widths, of diffraction grating, 1041–43
Peaks, tallest, 9–10
Pendulum, 14, 129, 206, 240–41, 411–13
  ballistic, 240–41
  conical, 129
  damped, 416
  grandfather clock, 421 *pr*
  physical, 412–13
  simple, 14, 206, 411–12
  torsion, 413
Pendulum clock, 412
Penetration, barrier, 1149–51, 1236
Penzias, Arno, 1342
Percent body fat, 393 *pr*
Percent uncertainty, 4
  and significant figures, 6
Perfect cosmological principle, 1341
Performance, coefficient of (COP), 585–87
Perfume atomizer, 383
Period, 125, 269, 401, 404, 430
  of circular motion, 125
  of Moon, 161
  orbital, 152
  of pendulums, 14, 412, A-12
  of planets, 156–57
  of rotation, 269
  sidereal, 161, 169 *pr*
  of Sun, 324 *pr*
  synodic, 161, 169 *pr*
  of vibration, 401, 404
  of wave, 430
Periodic motion, 400 *ff*
Periodic Table, 1167–68, 1227 *fn*, inside back cover
Periodic wave, 430
Perlmutter, Saul, 1352
Permeability, magnetic, 812, 827
Permittivity, 614, 704
Perpendicular-axis theorem, 281
Perpendicular forces, 94
Perpendicular vectors, adding, 56
Perturbations, 158
PET, 1278–79
Phase, 445
  in ac circuit, 881–88
  of matter, 366, 494
  of waves, 438, 445, 999, 1005–9, 1038
Phase angle, 403, 438, 885–86
Phase changes, 522–24, 545, 547
Phase constant, 403, 438, 1140 *fn*, 1142
Phase-contrast microscope, 1048
Phase diagram, 523–24
Phase shift, 1006, 1009
Phase transitions, 522–27, 545–49
Phase velocity, 438, 439
Phases of the Moon, 161
Phasor diagram:
  ac circuits, 885–86
  interference and diffraction of light, 1002, 1029, 1041–42
Phon (unit), 467
Phonons, 1215 *fn*
Phosphor, 1248
Phosphorescence, 1175
Photino, 1317
Photocathode, 1248
Photocell, 689 *pr*, 1098
Photocell circuit, 1098, 1101
Photocopier, 619
Photodiode, 1101, 1215
Photoelectric effect, 1098–1101, 1104, 1271
Photographic emulsion, 1249
Photographic film, 971
Photomultiplier (PM) tube, 1248–49
Photon, 1098–1106, 1130, 1167, 1290, 1296–97, 1299, 1304–5, 1310, 1346–47
  absorption of, 1174–75
  decoupled (early universe), 1343, 1348
  and emf, 1297
  energy of, 1101
  mass of, 1101
  mediation of (force), 1297
  momentum of, 1102
  virtual, 1297
Photon exchange, 1296–98
Photon interactions, 1104–5
Photon theory of light, 1098–1106
Photosynthesis, 531, 1101
Photovoltaic (solar) cells, 599, 605 *pr*, 1214–15
Physical pendulum, 412–13
  human leg as, 424 *pr*
Physics:
  classical (*defn*), 2, 1056
  modern (*defn*), 2, 1056
  relation to other fields, 2

Pi meson, 1298, 1305, 1306, 1309–12
Piano, 13, 469, 473, 475
Piano string, 447, 460, 468
Piano tuner, 13, 475
Piano wire, 343
Pick-up nuclear reaction, 1285 *pr*
Piezoelectric materials, 894 *pr*
Pinball machine, 423 *pr*
Pincushion distortion, 985
Ping-Pong ball, in jet of air, 383
Pins, 347–49
  structural, 346
Pion, 1298, 1305, 1306, 1309–12
Pipe:
  light, 945
  vibrating air columns in, 467 *ff*
Pipe organs, 469–72
Pisa:
  cathedral, 412
  tower, 38
Pitch, 461, 468, 469, 471–73
Pitched baseball, 384
Pitcher, 172
Pixels, 680–81, 970, 974, 1014, 1046
Planck, Max, 1097, 1128
Planck length, 15, 1127 *pr*, 1345
Planck time, 18 *pr*, 1127 *pr*, 1316, 1345
Planck's constant, 1097–98, 1134
Planck's quantum hypothesis, 1097
Plane:
  focal, 959
  mirror, 927–31
Plane geometry, A-2
Plane polarization, 1010
Plane waves, 443, 905, 1140–41
Planetary motion, 155–60, 316
Planets (*defn*), 155–60, 167 *pr*, 250, 262 *pr*, 330 *pr*
  angular momentum, 316
  extrasolar, 158
  period of, 156–57
Plants, watering, in the evening, 568 *pr*
Plasma (*defn*), 366, 1256, 1270
Plasma globe, 897 *pr*
Plastic region, 342
Plate tectonics, 378
Platform, 324 *pr*
  rotating, 318–20, 329 *pr*
Plum-pudding model of atom, 1110
Plumb bob, 171 *pr*
Pluto, 158, 1323
Plutonium, 1259, 1265, 1266
PM tube, 1248–49
*pn* diode lasers, 1216
*pn* junction, 1212–17
*pn* junction diode, 1212–17, 1249
*pn* junction laser, 1177
*pnp* transistor, 1218
Point:
  boiling, 496, 525, 545
  breaking, 342
  critical, 523
  dew, 526
  far, 976
  focal, 932, 937, 959–60, 976
  freezing, 496 *fn*
  Lagrange, 160
  mathematical, 21
  melting, 546, 548, 549
  near, 976
  sublimation, 523
  triple, 508, 523
  turning, 215
Point charge (*defn*), 615
  potential, 666–70
Point particle, 21, 98
Point rule, Kirchhoff's, 902 *ff*
Point source, 927
Pointed arch, 350–51
Poise (P) (unit), 385
Poiseuille, J. L., 386
Poiseuille's equation, 386
Poisson, Siméon, 1026
Polar molecules, 611, 629–30, 632, 706, 1188–89
Polar satellites, 153
Polarization, 995, 1010–14
  circular, 925 *pr*
  linear, 1010
  plane, 1010
  by reflection, 1013–14
Polarizer, Polaroid as, 1011
Polarizing angle, 1013, 1014
Polaroid sheet, 1011
Polaroids, 1011–13
Pole vault, 189 *pr*, 194, 203–4
Poles, magnetic, 782–84
  of Earth, 784
Police siren, 478
Pollution, 18 *pr*, 576, 598–600
Poloidal field, 1271
Polonium, 1233
Polymers, 1216
Pontecorvo, Bruno, 1303 *fn*
Pool depth, apparent, 941
Pope, Alexander, 1337 *fn*
Popping a wheelie, 300 *pr*
Population, inverted, 1176–77
Position, 21, 28
  angular, 265, 1134
  average, 1147
  uncertainty in, 1132–35
  vector for, 62–65
Positive curvature, 1337, 1350
Positive electric charge (*defn*), 610
Positive holes, 1211
Positive lens, 963
Positron, 1104–5, 1239, 1279, 1290, 1300
Positron emission tomography (PET), 1278–79
Post-and-beam construction, 344
Posture adjustment, 342
Potato chip bag, 513 *pr*
Potential (*see* Electric potential)
Potential difference, electric, 661 *ff* (*see also* Electric potential; Voltage)
Potential energy, 197–212, 215–17
  definition, 197, 199
  diagrams, 1189–92
  elastic, 199–200, 204–5, 210, 408–9
  electric, 660–63, 668–69, 674–75, 700–703
  general definition, 199
  gravitational, 197–98, 201–14, 216–17
  in metal crystal, 1207
  for molecules, 1189–92, 1198, 1202
  for nucleus, 1151, 1236
  only changes matter, 201
  related to force, 199–200
  in Schrödinger equation, 1138–40, 1142–49
  for square well and barriers, 1142–49
  in 3-D, 200
Potential energy diagrams, 215–16
  simple harmonic motion, 409
  turning points, 215–16
Potential well, 215, 1142–49
Potentiometer, 779 *pr*
Potter's wheel, 295 *pr*
Pound (lb) (unit), 89
Powell, C. F., 1298
Power factor (ac circuit), 886
Power generation, 598–600, 846–47
  geothermal, 599
  hydroelectric, 599
  nuclear, 599
  solar, 599
  wind, 599
  (*see also* Electric power)
Power (mechanical), 213–15, 726–32, 886
  climbing stairs, 213
  energy vs., 213
  as rate energy is transformed or transferred, 213
  rating of an engine, 214–15
  transferred to driven oscillator, 425 *pr*
  units of, 213
Power (optical):
  of a lens, 960
  magnifying power, 979, 981
Power outages, 780 *pr*
Power plants:
  fossil-fuel, 599
  nuclear, 847, 1264–65
Power reactor, 1264
Power transmission, 851–54
Powers of ten, 5, 7
Poynting, J. H., 913 *fn*
Poynting vector, 913–15
Prairie dogs, 384
Precession, 317–18
  of Earth's axis, 327 *pr*
  of the equinoxes, 327 *pr*
Precipitator, 710 *pr*
Precision, 6
  accuracy vs., 4, 6
Prefixes, metric, 8
Presbyopia, 977
Prescriptive laws (*defn*), 3
Pressure, 367–71
  absolute, 371
  in an ideal gas, 518
  atmospheric, 370–74
  conversion factors, 373
  at a faucet, 369
  for fluids, 365, 367–89
  in a gas, 371, 502–3, 518, 522–28
  gauge, 371
  head, 369
  hydraulic, 372
  on living cell, 371
  measurement of, 372–74
  partial, 525–26
  and Pascal's principle, 371–72
  radiation, 915–16
  units of, 367, 373
  vapor, 524–26
Pressure amplitude, 466–67
Pressure cooker, 535 *pr*
Pressure gauges, 372–73
Pressure gradient, 386, 561
Pressure head, 369
Pressure variation amplitude, 463
Pressure waves, 435, 462–63, 466–67, 470–71
Prestressed concrete, 346
Primary coil, 851
Principal axis, 932
Principal quantum number, 1113 *ff*, 1160–62
*Principia* (Newton), 87, 145
Principle, 3, 30, 34 (*see also specific principles by name*)
Principle of complementarity, 1105–6
Principle of correspondence, 1086, 1119, 1129
Principle of equipartition of energy, 557–58
Principle of equivalence, 163–64, 1334–35
Principle of superposition, 441–42 *ff*, 472–73, 616, 620, 625
Printers, computer, 619
Prism, 941–42

Prism binoculars, 944, 982
Probability:
  and entropy, 595–97
  in kinetic theory, 516–22
  in nuclear decay, 1240
  in quantum mechanics, 1130, 1131, 1135–36, 1145, 1159, 1163–65, 1187–89
Probability density (probability distribution)
  in atoms, 1130, 1140, 1143, 1148, 1159, 1162–63, 1165
  in molecules, 1187–89
Probability function, Fermi–Dirac, 1205, 1210
Problem-solving strategies, 33–36, 61, 67, 98, 104, 130, 175, 209, 244, 277, 334, 547, 600, 622, 755, 791, 818, 843, 964, 1009
Processes:
  isobaric, 552–54
  isochoric, 552–54
  isothermal, 551–53
  isovolumetric, 552–54
  reversible and irreversible (*defn*), 580–83, 588–91
  spontaneous, 577 *fn*
Projectile, horizontal range of, 70–72
Projectile motion, 54, 65–73
  kinematic equations for, 67
  parabolic, 73
Propagate (*defn*), 432
Proper length, 1070
Proper time, 1066, 1321 *pr*
Proportional limit, 342
Protein molecule, 631
Proteins:
  shape of, 1195–96
  synthesis of, 1194–95
Proton, 1227 *fn*, 1257, 1266–69, 1277, 1290, 1305
  decay of, 1305, 1315–16
  electric force exerted by, 615
  mean life of, 1315
Proton centers, 1277
Proton decay, 1305, 1315–16
Proton therapy, 1277
Proton–proton chain, 1267–68, 1329
Proton–proton collision, 243
Protostar, 1329
Protractor (for angles), 5
Proxima Centauri, 1323
Pseudoforce, 127, 319–21
Pseudovector, 270, 307 *fn*
Psi, in Schrödinger equation, *defn*, 1136–40
psi (unit), 367, 373
*PT* diagram, 523–24
Ptolemy, 155, 156
Pulley, 102, 188 *pr*, 218 *pr*, 277, 278
Pulse, wave, 429
Pulse-echo technique, 482, 1281
Pulse oximeter, 1216
Pulsed lasers, 923 *pr*, 1117
Pumps, 374, 388–89
  centrifugal, 388–89
  heat, 586–87
Punting a football, 69, 71
Pupil, 975
Purely rotational motion, 265
Pushing a desk, 172
Putting, in golf, 52 *pr*
*PV* diagrams, 522, 528, 551–54, 560
Pyrex glass, 509 *pr*
Pythagorean theorem, A-2, A-4

*Q*-value (disintegration energy), 1234–35
*Q*-value (quality factor) of a resonant system, 419, 425 *pr*, 896 *pr*
*Q*-value (reaction energy), 1258
QCD, 1298, 1311–14
QED, 1297
QF, 1273
QSOs, 1326, 1336
Quadratic equation, 40
Quadratic formula, 42, A-1, inside back cover
Quadrupole, electric, 641 *pr*
Quality factor (Q-value) of a resonant system, 419, 425 *pr*, 896 *pr*
Quality factor (QF) of radiation, 1273
Quality of sound, 472–73
Quantities, base, 8, 9
Quantization:
  of angular momentum, 1113, 1160–61
  of electric charge, 614
  of energy, 1097, 1113–19, 1143
Quantization error, 677
Quantization loss, 677
Quantum chromodynamics (QCD), 1298, 1311–14
Quantum condition, Bohr's, 1113, 1120
Quantum electrodynamics (QED), 1297
Quantum fluctuations, 1349
Quantum hypothesis, Planck's, 1097
Quantum mechanics, 1120, 1128–1219
  of atoms, 1158–79
  Copenhagen interpretation of, 1136
  of molecules and solids, 1186–1219
Quantum numbers, 1097, 1113–15, 1143, 1160–63, 1166–67, 1196–1201
  principal, 1113 *ff*
Quantum (quanta) of energy, 1097
Quantum theory, 1056, 1095–1120, 1128–1219
  of atoms, 1113–20, 1158–79
  of blackbody radiation, 1096–97
  of light, 1095–1106
  of specific heat, 558
Quarks, 614 *fn*, 1290, 1296–98, 1305, 1308–13, 1345, 1347
  confinement, 1312, 1345–47
Quartz oscillator clock, 487 *pr*
Quasars (quasi-stellar objects, QSOs), 1326, 1336
Quasistatic process (*defn*), 551
Quintessence, 1352

*r*, limit of large, 623
*R*-values, of thermal insulation, 562
Rabbits, 384
Rad equivalent man (rem), 1273
Rad (unit), 1273
Radar, 480, 481, 910
  in weather forecasts, 480
Radar guns, 475
Radial acceleration, 124 *ff*, 133
Radial forces, 130
Radial probability distribution, 1163–65
Radian (rad), measure for angles, 265–66
Radiant flux, 1016
Radiation, electromagnetic, 563–66
  blackbody, 1096–97, 1327, 1342
  body cooling by, 564
  cosmic microwave background, 1342–44, 1348, 1349, 1353
  emissivity of, 564
  gamma, 1234, 1239–40, 1271
  infrared (IR), 910, 941, 1041
  microwave, 910
  seasons and, 566
  solar constant and, 566
  from the Sun, 563, 566
  synchrotron, 1293
  thermal, 563–67
  ultraviolet (UV), 910, 941
  X-ray, 910, 1043–44, 1054 *pr*, 1170 (*see also* X-rays)
Radiation, nuclear:
  activity of, 1241, 1243–44, 1272
  alpha, 1234–37, 1240
  beta, 1234, 1237–40, 1331
  detection of, 1274
  dosimetry for, 1272–76
  gamma, 1234, 1239–40, 1271
  human exposure to, 1274–76
  ionizing (*defn*), 1271
  measurement of, 1272–76
  medical uses of, 1276–78
  types of, 1234, 1240
Radiation biology, 1276–78
Radiation-dominated universe, 1347–48
Radiation dosimetry, 1272–76
Radiation era, 1347–48
Radiation field, 904
Radiation film badge, 1274
Radiation pressure, 915–16
Radiation sickness, 1274
Radiation therapy, 1276–77
Radiator, hot-water, 563
Radio, 917–20
Radio signals, 452 *pr*, 453 *pr*
Radio waves, 910, 1036
Radioactive background, natural, 1237, 1274
Radioactive dating, 784, 1246–48
Radioactive decay, 255 *pr*, 257 *pr*, 1233–49
Radioactive decay constant, 1240–41
Radioactive decay law, 1241, 1242
Radioactive decay series, 1245–46
Radioactive fallout, 1266
Radioactive tracers, 1277–78
Radioactive waste, 1264–66
Radioactivity, 1226–49
  artificial (*defn*), 1233
  natural (*defn*), 1233
Radiofrequency (RF) signal, 917, 1280–81
Radioisotope (*defn*), 1233
Radionuclide (*defn*), 1233, 1272
Radiotelescope, 1036
Radium, 1233, 1234, 1245
Radius:
  of curvature (*defn*), 124, 134
  of Earth estimate, 13, 18 *pr*
  of gyration, 296 *pr*
  of nuclei, 1228
Radon, 1234, 1274, 1276
Rae Lakes, 11
Rainbow, 942, 957 *pr*
RAM (random access memory), 692–93, 716 *pr*, 857
Ramps:
  design, 113 *pr*
  ramp vs. stair analogy, 1097
Random access memory (RAM), 692–93, 716 *pr*, 857
Random motion, 631, 633
Range:
  of projectile, 70–71
  of validity, 33, 71, 104
Rapid estimating, 11–13
Rapid transit system, 53 *pr*
Rare-earth solid-state lasers, 1177
Rarefactions, in waves, 431
Rate of nuclear decay, 1240–44

Ray, 443–44, 927 *ff*, 959 *ff*
paraxial (*defn*), 932
Ray diagram, 933, 938, 964
Ray model of light, 927 *ff*, 959 *ff*
Ray tracing, 927 *ff*, 959 *ff*
Rayleigh, Lord, 1034, 1097
Rayleigh criterion, 1034–35
Rayleigh–Jeans theory, 1097
RBE, 1273
*RC* circuit, 759–64

Transition elements, 1168
Transition temperature, 735
Transitions, in atoms, 1113–19, 1161, 1169–71, 1175–77
  forbidden and allowed, 1162–63, 1176 *fn*, 1196–97, 1199, 1200
  for lasers, 1175–77
  in molecules, 1196–1201
  in nuclei, 1239–40
  in semiconductors, 1209–12
Translational kinetic energy, 181–85
Translational motion, 21–253
  and center of mass (CM), 248–50, 284–86
  kinematics for, 20–45, 54–76
  object as point particle in problems of, 98
Transmission axis, 1011
Transmission coefficient, 1150
Transmission electron microscope (TEM), 1108
Transmission grating, 1038 *ff*
Transmission lines, 853, 912
Transmission of electricity, 853
  wireless, 854
Transmission rate, 676, 678
Transmutation of elements, 1234, 1257–59
Transuranic elements, 1259
Transverse waves, 431 *ff*
  and earthquakes, 435
  EM waves, 905
  speed of, 432–33
Traveling sinusoidal wave, 437–39
Traveling wave, 437–39
Traverse, climber's, 110 *pr*
Trees, offsetting carbon dioxide, 608 *pr*
Triangle, on a curved surface, 1336
Triangles:
  congruent, A-2
  similar, A-2
Triangulation, 12, 1332 *fn*
Triceps muscle, 295 *pr*
Trigonometric functions and identities, 59, 60, A-4–A-5, inside back cover
Trigonometric table, A-5
Triple point, 523
  of water, 508
Tritium, 1227, 1254 *pr*, 1270
Tritium dating, 1254 *pr*
Triton, 1227
Trough, 430
Trumpets, 465
Truss bridge, 347–49
Trusses, 347–49, 360 *pr*
*TS* diagram, 605 *pr*, 607 *pr*
Tsunami, 430, 459 *pr*
Tubes:
  closed, 470–72
  closed at both ends, 487 *pr*
  flow in, 379–82, 384–86
  open, 470–72
  vibrating column of air in, 467 *ff*
Tug-of-war, 255 *pr*
Tumors, 482
Tuning:
  an instrument, 468
  orchestra, 475
  a piano, 475
Tuning forks, 474, 476
Tunnel diode, 1151
Tunneling, 858
  of light wave, 1150–51
  through a barrier, 1149–51, 1236
Turbine, 254 *pr*, 598, 847
Turbulence, 379, 383, 386
Turbulent flow, 379, 383, 386
Turn signal, automobile, 763
Turning points, in potential energy diagrams, 215–16
Turntable, 294 *pr*, 318–20, 324 *pr*
  rotating, 307
Tuscany, Grand Duke of, 37
Twin paradox, 1068
Two-dimensional waves, 428, 435, 443–45, 449–50
Type Ia supernovae (SNIa), 1332, 1333, 1352
Typhoons, 321

UA1 detector, 1298
UHD (Ultra high definition), 680
Ultimate speed, 1079
Ultimate strength, 342, 345–46
Ultracapacitors, 714 *pr*
Ultracentrifuge, 126
Ultra high definition (UHD), 680
Ultrasonic frequencies, 462, 482–83
Ultrasonic waves, 462, 479, 482–83
Ultrasound, 482
Ultrasound medical imaging, 482–83
Ultraviolet (UV) light, 910, 941
Unavailability of energy, 594–95
Unbanked curves, 130–32
Uncertainty (in measurements), 3–6, 1131–35
  estimated, 4
  percent, 4, 6
Uncertainty principle, 1131–35, 1148, 1187
  and particle resonance, 1307
  and tunneling, 1236
Underdamped system, 415
Underexposure, 972
Underground:
  air circulation, 384
  animals, 384
Underwater vision, 978
Unification distance, 1321 *pr*
Unification scale, 1315
Unified atomic mass units (u), 8, 493, 1229
Unified (basis of forces), 1313
Unified theories, grand (GUT), 162, 1314–16
Uniform circular motion, 123–29
  dynamics of, 126–29
  kinematics of, 123–26
  simple harmonic motion related to, 410
Uniform sphere, gravitational force exerted on particle outside, 147
Uniformly accelerated motion, 30 *ff*, 65 *ff*

Uniformly accelerated rotational motion, 270–71
Unit conversion, 9–10, inside front cover
Unit vectors, 62, 177
Units of measurement, 6
converting, 9–10, inside front cover
prefixes, 8
for pressure, 367, 373
in problem solving, 33, 34, 104
and standards, 6–9
systems of, 8–9
in thermodynamic problem-solving, 600
Universal gas constant, 504
Universal law of gravitation, 145–49, 210–12, 614, 1334
Universe, 19 *pr*
age of, 1315 *fn*, 1342
Big Bang theory of, 1316, 1341 *ff*
CDM model of, 1353–54
creation of, 18 *pr*
critical density of, 1350–51
curvature of, 1336–37, 1349–50
entire, 1344
expanding, 1338–41, 1350–53
finite or infinite, 1323, 1337–38, 1342, 1350
future of, 1350–53
homogeneous, 1341
inflationary scenario of, 1346, 1348–50
isotropic, 1341
matter-dominated, 1348–50
observable, 1344
origin of elements in, 1330–31
radiation-dominated, 1347–48
Standard Model of, 1345–48
steady-state model of, 1341
Unknown quantities, 67, 68, 244
Unphysical solutions, 34, 43
Unpolarized light, 1011
Unstable equilibrium, 216, 341
Unstable nucleus, 1233 *ff*
Unwanted floor vibrations, 405
Up quark, 1308
Updated subpixels, 682
Uranium:
in dating, 1245–48
enriched, 126, 1263
fission of, 1261–66
in reactors, 1261–66
Uranus, 158
gravitational slingshot from, 217
period and distance from Sun, 330 *pr*
Useful magnification, 1037
UV light, 910, 941
Vacuum, 374, 380
in gas, 534 *pr*
Vacuum energy, 1352
Vacuum pump, 374, 388
Vacuum state, 1300, 1349
Vacuum tube, electron in, 663
Valence, 1168
Valence band, 1208–10
Validity, range of, 33
Valves:
heart, 388
pump, 388
Van de Graaff generator, 628, 691 *pr*
van der Waals, J. D., 527
van der Waals bonds and forces, 1192–96, 1202–3
van der Waals equation of state, 527–28
van der Waals gas, 527–28
Vapor:
gas vs., 523 (*see also* Gases)
supersaturated, 526
Vapor pressure, 524–26
Vaporization, latent heat of, 545–49
Variable acceleration, 43–44
Variable capacitance, 715 *pr*
Variable mass systems, 251–53
Variable stars, 1333
Variables, keeping constant, 503
Vector angular velocity, 306–7, 312, 314, 325 *pr*
Vector cross product, 307–9
Vector displacement, 22, 55–57, 62–63
Vector equations, 56
Vector field, 626
Vector form of Coulomb's law, 618
Vector model (atoms), 1184 *pr*
Vector product, 307–9
Vectors, 22, 55–65, 176–77, 307–8
addition of, 55–61
angular momentum, 306, 309
average acceleration, 63
average velocity, 63
components of, 58–62
cross product, 307–9
direction of, 22, 55
displacement, 22, 55–57
force, addition of, 89
instantaneous acceleration, 63
instantaneous velocity, 63
kinematics, 62–75
magnetization, 829
magnitude of, 22, 55
multiplication, by a scalar, 58
multiplication of, 176–77, 307–9
negative of (*defn*), 57
parallelogram method of adding, 57
position, 62–65
Poynting, 913–15
pseudo-, 270
under reflection, 270
resolution of, 58–61, 98, 99
resultant, 55–57, 60–61
scalar (dot) product, 176–77
subtraction of, 57–58
sum, 55–61, 89, 97, 149, 230
tail-to-tip method of adding, 56–57
torque, 308–9
unit, 62
Vehicle static stability factor, 328 *pr*
Veins, 389
Velocity, 14, 22–26, 63
and acceleration, 28, 40
addition of, 73–75, 1076
angular, 266–71
average, 22–24, 63
drift, 732–35, 799
of EM waves, 905–9
escape, 212, 223 *pr*, 1351
of galaxies, 480
instantaneous, 24–26, 63
of light, 908–9, 912–13, 939, 997, 1057–58, 1062, 1081
of molecules, 519
of ocean waves, 459 *pr*
phase, 438, 439
relative, 73–75
relativistic addition of, 1076
rms, 519–22
and slope, 25–26
of sound, 461, 462
supersonic, 462, 480
terminal, 38 *fn*, 134–35
of water waves, 459 *pr*
of waves, 430
Velocity-dependent forces, 134–35
Velocity gradient, 385
Velocity selector, 792
Veneziano, Gabriele, 1317
Ventricle, heart, 388–89
Ventricular fibrillation, 703, 764
Venturi meter, 384, 395 *pr*
Venturi tube, 384
Venus, 155, 156, 167 *pr*, 980
Vertebra, 340
Vertebral artery, 384
Vertical circle, revolving ball in, 128–29
Vertical (*defn*), 94 *fn*
Vertical spring, 401
Vibrating strings, 446–49, 468–69
Vibration, 399–419
of air columns, 469–72
of floor, 406
forced, 417–19
molecular, 541, 557–58, 1198–1201
as source of waves, 430
of spring, 400 *ff*
on strings, 446–48, 467–69
(*see also* Oscillations)
Vibrational energy, 408–10
molecular, 541, 558, 1198–1201
Vibrational quantum number, 1199
Vibrational transition, 1198–1201
Vibrato, 490 *pr*
Vinyl records, 679 *fn*
Violin, 468, 469, 473, 490 *pr*
Violin string, 446, 473
Virtual image, 929, 962
Virtual particles, 1297
Virtual photon, 1297
Virus, 7
Viscosity, 379, 385–86
coefficient of, 385
of oils, 385
Viscous force, 385–86
Visible light, wavelengths of, 910, 941–43
Visible spectrum, 941–43
Volatile memory, 858
Volleyball net, 357 *pr*
Volt-Ohm-Meter/Volt-Ohm-Milliammeter (VOM), 769
Volt (V) (unit), 662
Volta, Alessandro, 662, 693, 718–19

## Fundamental Constants

| Quantity | Symbol | Approximate Value | Current Best Value[†] |
|---|---|---|---|
| Speed of light in vacuum | $c$ | $3.00 \times 10^8$ m/s | $2.99792458 \times 10^8$ m/s |
| Gravitational constant | $G$ | $6.67 \times 10^{-11}$ N · m$^2$/kg$^2$ | $6.67430(15) \times 10^{-11}$ N · m$^2$/kg$^2$ |
| Avogadro's number | $N_A$ | $6.02 \times 10^{23}$ mol$^{-1}$ | $6.02214076 \times 10^{23}$ mol$^{-1}$ |
| Gas constant | $R$ | 8.314 J/mol · K = 1.99 cal/mol · K = 0.0821 L · atm/mol · K | 8.314462618 J/mol · K |
| Boltzmann's constant | $k$ | $1.38 \times 10^{-23}$ J/K | $1.380649 \times 10^{-23}$ J/K |
| Charge on electron | $e$ | $1.60 \times 10^{-19}$ C | $1.602176634 \times 10^{-19}$ C |
| Stefan-Boltzmann constant | $\sigma$ | $5.67 \times 10^{-8}$ W/m$^2$ · K$^4$ | $5.670374419 \times 10^{-8}$ W/m$^2$ · K$^4$ |
| Permittivity of free space | $\epsilon_0$ | $8.85 \times 10^{-12}$ C$^2$/N · m$^2$ | $8.8541878128(13) \times 10^{-12}$ C$^2$/N · m$^2$ |
| Permeability of free space | $\mu_0$ | $1.26 \times 10^{-6}$ T · m/A | $1.25663706212(19) \times 10^{-6}$ T · m/A |
| Planck's constant | $h$ | $6.63 \times 10^{-34}$ J · s | $6.62607015 \times 10^{-34}$ J · s |
| Electron rest mass | $m_e$ | $9.11 \times 10^{-31}$ kg = 0.000549 u = 0.511 MeV/$c^2$ | $9.1093837015(28) \times 10^{-31}$ kg = $5.48579909065(16) \times 10^{-4}$ u |
| Proton rest mass | $m_p$ | $1.6726 \times 10^{-27}$ kg = 1.00728 u = 938.27 MeV/$c^2$ | $1.67262192369(51) \times 10^{-27}$ kg = 1.007276466621(53) u |
| Neutron rest mass | $m_n$ | $1.6749 \times 10^{-27}$ kg = 1.008665 u = 939.57 MeV/$c^2$ | $1.67492749804(95) \times 10^{-27}$ kg = 1.00866491595(49) u |
| Atomic mass unit (1 u) | | $1.6605 \times 10^{-27}$ kg = 931.49 MeV/$c^2$ | $1.66053906660(50) \times 10^{-27}$ kg = 931.49410242(28) MeV/$c^2$ |

[†]Numbers in parentheses indicate one-standard-deviation experimental uncertainties in final digits (2019, new SI). Values without parentheses are exact (i.e., defined quantities).

## Other Useful Data

| | |
|---|---|
| Joule equivalent (1 cal) | 4.186 J |
| Absolute zero (0 K) | −273.15°C |
| Acceleration due to gravity at Earth's surface (avg.) | 9.80 m/s$^2$ (= $g$) |
| Speed of sound in air (20°C) | 343 m/s |
| Density of air (dry) | 1.29 kg/m$^3$ |
| Earth: Mass | $5.98 \times 10^{24}$ kg |
| Radius (mean) | $6.38 \times 10^3$ km |
| Moon: Mass | $7.35 \times 10^{22}$ kg |
| Radius (mean) | $1.74 \times 10^3$ km |
| Sun: Mass | $1.99 \times 10^{30}$ kg |
| Radius (mean) | $6.96 \times 10^5$ km |
| Earth–Sun distance (mean) | $149.60 \times 10^6$ km |
| Earth–Moon distance (mean) | $384 \times 10^3$ km |

## The Greek Alphabet

| | | | | | |
|---|---|---|---|---|---|
| Alpha | A | $\alpha$ | Nu | N | $\nu$ |
| Beta | B | $\beta$ | Xi | $\Xi$ | $\xi$ |
| Gamma | $\Gamma$ | $\gamma$ | Omicron | O | $o$ |
| Delta | $\Delta$ | $\delta$ | Pi | $\Pi$ | $\pi$ |
| Epsilon | E | $\epsilon$, $\varepsilon$ | Rho | P | $\rho$ |
| Zeta | Z | $\zeta$ | Sigma | $\Sigma$ | $\sigma$ |
| Eta | H | $\eta$ | Tau | T | $\tau$ |
| Theta | $\Theta$ | $\theta$ | Upsilon | Y | $\upsilon$ |
| Iota | I | $\iota$ | Phi | $\Phi$ | $\phi$, $\varphi$ |
| Kappa | K | $\kappa$ | Chi | X | $\chi$ |
| Lambda | $\Lambda$ | $\lambda$ | Psi | $\Psi$ | $\psi$ |
| Mu | M | $\mu$ | Omega | $\Omega$ | $\omega$ |

## Values of Some Numbers

| | | | |
|---|---|---|---|
| $\pi = 3.1415927$ | $\sqrt{2} = 1.4142136$ | $\ln 2 = 0.6931472$ | $\log_{10} e = 0.4342945$ |
| $e = 2.7182818$ | $\sqrt{3} = 1.7320508$ | $\ln 10 = 2.3025851$ | 1 rad = 57.2957795° |

## Mathematical Signs and Symbols

| | | | |
|---|---|---|---|
| $\propto$ | is proportional to | $\leq$ | is less than or equal to |
| $=$ | is equal to | $\geq$ | is greater than or equal to |
| $\approx$ | is approximately equal to | $\sum$ | sum of |
| $\neq$ | is not equal to | $\bar{x}$ | average value of $x$ |
| $>$ | is greater than | $\Delta x$ | change in $x$ |
| $\gg$ | is much greater than | $\Delta x \to 0$ | $\Delta x$ approaches zero |
| $<$ | is less than | $n!$ | $n(n-1)(n-2)\ldots(1)$ |
| $\ll$ | is much less than | | |

## Properties of Water

| | |
|---|---|
| Density (4°C) | $1.000 \times 10^3$ kg/m$^3$ |
| Heat of fusion (0°C) | 334 kJ/kg (79.8 kcal/kg) |
| Heat of vaporization (100°C) | 2260 kJ/kg (539.9 kcal/kg) |
| Specific heat (15°C) | 4186 J/kg · C° (1.00 kcal/kg · C°) |
| Index of refraction | 1.33 |

## Unit Conversions (Equivalents)

### Length

1 in. = 2.54 cm (defined)
1 cm = 0.3937 in.
1 ft = 30.48 cm
1 m = 39.37 in. = 3.281 ft
1 mi = 5280 ft = 1.609 km
1 km = 0.6214 mi
1 nautical mile = 1.151 mi = 6076 ft = 1.852 km
1 fermi = 1 femtometer (fm) = $10^{-15}$ m
1 angstrom (Å) = $10^{-10}$ m = 0.1 nm
1 light-year (ly) = $9.461 \times 10^{15}$ m
1 parsec = 3.26 ly = $3.09 \times 10^{16}$ m

### Volume

1 liter (L) = 1000 mL = 1000 $cm^3$ = $1.0 \times 10^{-3}$ $m^3$ = 1.057 qt (U.S.) = 61.02 $in.^3$
1 gal (U.S.) = 4 qt (U.S.) = 231 $in.^3$ = 3.785 L = 0.8327 gal (British)
1 quart (U.S.) = 2 pints (U.S.) = 946 mL
1 pint (British) = 1.20 pints (U.S.) = 568 mL
1 $m^3$ = 35.31 $ft^3$

### Speed

1 mi/h = 1.4667 ft/s = 1.6093 km/h = 0.4470 m/s
1 km/h = 0.2778 m/s = 0.6214 mi/h
1 ft/s = 0.3048 m/s = 0.6818 mi/h = 1.0973 km/h
1 m/s = 3.281 ft/s = 3.600 km/h = 2.237 mi/h
1 knot = 1 nautical mile/h = 1.151 mi/h = 1.852 km/h = 0.5144 m/s

### Angle

1 radian (rad) = 57.30° = 57°18′
1° = 0.01745 rad
1 rev/min (rpm) = 0.1047 rad/s

### Time

1 day = $8.640 \times 10^4$ s
1 year = 365.242 days = $3.156 \times 10^7$ s

### Mass

1 atomic mass unit (u) = $1.6605 \times 10^{-27}$ kg
1 kg = 0.06852 slug
1 ton (metric) = 1000 kg
[1 kg has a weight of 2.20 lb where $g = 9.80\ m/s^2$.]

### Force

1 lb = 4.44822 N
1 N = $10^5$ dyne = 0.2248 lb
1 ton (U.S.) = 2000 lbs

### Energy and Work

1 J = $10^7$ ergs = 0.7376 ft · lb
1 ft · lb = 1.356 J = $1.29 \times 10^{-3}$ Btu = $3.24 \times 10^{-4}$ kcal
1 kcal = $4.19 \times 10^3$ J = 3.97 Btu
1 eV = $1.6022 \times 10^{-19}$ J
1 kWh = $3.600 \times 10^6$ J = 860 kcal
1 Btu = $1.056 \times 10^3$ J

### Power

1 W = 1 J/s = 0.7376 ft · lb/s = 3.41 Btu/h
1 hp = 550 ft · lb/s = 746 W

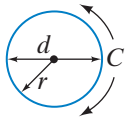
### Pressure

1 atm = 1.01325 bar = $1.01325 \times 10^5$ $N/m^2$ = 14.7 $lb/in.^2$ = 760 torr
1 $lb/in.^2$ = $6.895 \times 10^3$ $N/m^2$
1 Pa = 1 $N/m^2$ = $1.450 \times 10^{-4}$ $lb/in.^2$

## Some SI Units in Terms of Base Units

| Quantity | Unit | Abbreviation | In Terms of Base Units† |
|---|---|---|---|
| Force | newton | N | $kg \cdot m/s^2$ |
| Energy and work | joule | J | $kg \cdot m^2/s^2$ |
| Power | watt | W | $kg \cdot m^2/s^3$ |
| Pressure | pascal | Pa | $kg/(m \cdot s^2)$ |
| Frequency | hertz | Hz | $s^{-1}$ |
| Electric charge | coulomb | C | $A \cdot s$ |
| Electric potential | volt | V | $kg \cdot m^2/(A \cdot s^3)$ |
| Electric resistance | ohm | Ω | $kg \cdot m^2/(A^2 \cdot s^3)$ |
| Capacitance | farad | F | $A^2 \cdot s^4/(kg \cdot m^2)$ |
| Magnetic field | tesla | T | $kg/(A \cdot s^2)$ |
| Magnetic flux | weber | Wb | $kg \cdot m^2/(A \cdot s^2)$ |
| Inductance | henry | H | $kg \cdot m^2/(A^2 \cdot s^2)$ |

† kg = kilogram (mass), m = meter (length), s = second (time), A = ampere (electric current).

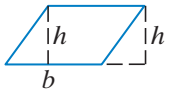


## Metric (SI) Multipliers

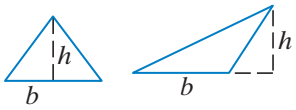
| Prefix | Abbreviation | Value |
|---|---|---|
| yotta | Y | $10^{24}$ |
| zeta | Z | $10^{21}$ |
| exa | E | $10^{18}$ |
| peta | P | $10^{15}$ |
| tera | T | $10^{12}$ |
| giga | G | $10^9$ |
| mega | M | $10^6$ |
| kilo | k | $10^3$ |
| hecto | h | $10^2$ |
| deka | da | $10^1$ |
| deci | d | $10^{-1}$ |
| centi | c | $10^{-2}$ |
| milli | m | $10^{-3}$ |
| micro | μ | $10^{-6}$ |
| nano | n | $10^{-9}$ |
| pico | p | $10^{-12}$ |
| femto | f | $10^{-15}$ |
| atto | a | $10^{-18}$ |
| zepto | z | $10^{-21}$ |
| yocto | y | $10^{-24}$ |

## Useful Geometry Formulas — Areas, Volumes

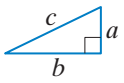
Circumference of circle $C = \pi d = 2\pi r$



Area of circle $A = \pi r^2 = \dfrac{\pi d^2}{4}$



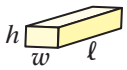
Area of rectangle $A = \ell w$



Area of parallelogram $A = bh$

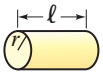
Area of triangle $A = \frac{1}{2}hb$

Right triangle (Pythagoras) $c^2 = a^2 + b^2$

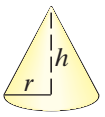


Sphere: surface area $A = 4\pi r^2$

volume $V = \frac{4}{3}\pi r^3$



Rectangular solid: volume $V = \ell wh$



Cylinder (right): surface area $A = 2\pi r\ell + 2\pi r^2$

volume $V = \pi r^2\ell$

Right circular cone: surface area $A = \pi r^2 + \pi r\sqrt{r^2 + h^2}$

volume $V = \frac{1}{3}\pi r^2 h$

## Exponents

$(a^n)(a^m) = a^{n+m}$ [Example: $(a^3)(a^2) = a^5$]

$(a^n)(b^n) = (ab)^n$ [Example: $(a^3)(b^3) = (ab)^3$]

$(a^n)^m = a^{nm}$ [Example: $(a^3)^2 = a^6$; Example: $(a^{\frac{1}{4}})^4 = a$]

$a^{-1} = \dfrac{1}{a}$ $\quad a^{-n} = \dfrac{1}{a^n}$ $\quad a^0 = 1$

$a^{\frac{1}{2}} = \sqrt{a}$ $\quad a^{\frac{1}{4}} = \sqrt{\sqrt{a}}$

$(a^n)(a^{-m}) = \dfrac{a^n}{a^m} = a^{n-m}$ [Ex.: $(a^5)(a^{-2}) = a^3$]

$\dfrac{a^n}{b^n} = \left(\dfrac{a}{b}\right)^n$

## Logarithms [Appendix A–7; Table A–1]

If $y = 10^x$, then $x = \log_{10} y = \log y$.

If $y = e^x$, then $x = \log_e y = \ln y$.

$\log(ab) = \log a + \log b$

$\log\left(\dfrac{a}{b}\right) = \log a - \log b$

$\log a^n = n \log a$

## Some Derivatives and Integrals†

$\dfrac{d}{dx}x^n = nx^{n-1}$ $\qquad \displaystyle\int \sin ax\,dx = -\frac{1}{a}\cos ax$

$\dfrac{d}{dx}\sin ax = a\cos ax$ $\qquad \displaystyle\int \cos ax\,dx = \frac{1}{a}\sin ax$

$\dfrac{d}{dx}\cos ax = -a\sin ax$ $\qquad \displaystyle\int \frac{1}{x}\,dx = \ln x$

$\displaystyle\int x^m\,dx = \frac{1}{m+1}x^{m+1}$ $\qquad \displaystyle\int e^{ax}\,dx = \frac{1}{a}e^{ax}$

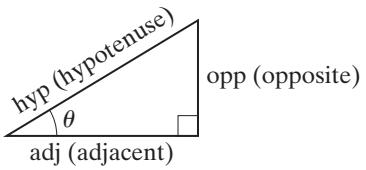
† See Appendix B for more.

## Quadratic Formula

Equation with unknown $x$, in the form

$$ax^2 + bx + c = 0,$$

has solutions



$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}.$$

## Binomial Expansion

$$(1 \pm x)^n = 1 \pm nx + \frac{n(n-1)}{2\cdot 1}x^2 \pm \frac{n(n-1)(n-2)}{3\cdot 2\cdot 1}x^3 + \cdots \qquad [\text{for } x^2 < 1]$$

$$\approx 1 + nx \qquad \text{if } x \ll 1$$

## Trigonometric Formulas [Appendix A–9]

$\sin\theta = \dfrac{\text{opp}}{\text{hyp}}$ $\quad \cos\theta = \dfrac{\text{adj}}{\text{hyp}}$ $\quad \tan\theta = \dfrac{\text{opp}}{\text{adj}}$

$\text{adj}^2 + \text{opp}^2 = \text{hyp}^2$ (Pythagorean theorem)

$\tan\theta = \dfrac{\sin\theta}{\cos\theta}$

$\sin^2\theta + \cos^2\theta = 1$

$\sin 2\theta = 2\sin\theta\cos\theta$

$\cos 2\theta = (\cos^2\theta - \sin^2\theta) = (1 - 2\sin^2\theta) = (2\cos^2\theta - 1)$

$\sin(180° - \theta) = \sin\theta$; radians: $\sin(\pi - \theta) = \sin\theta$

$\cos(180° - \theta) = -\cos\theta$

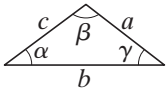
$\sin(90° - \theta) = \cos\theta$

$\cos(90° - \theta) = \sin\theta$

$\sin\frac{1}{2}\theta = \sqrt{(1 - \cos\theta)/2}$ $\qquad \cos\frac{1}{2}\theta = \sqrt{(1 + \cos\theta)/2}$

$\sin\theta \approx \theta$ [for small $\theta \lesssim 0.2$ rad]

$\cos\theta \approx 1 - \dfrac{\theta^2}{2}$ [for small $\theta \lesssim 0.2$ rad]



$\sin(A \pm B) = \sin A\cos B \pm \cos A\sin B$

$\cos(A \pm B) = \cos A\cos B \mp \sin A\sin B$

For any triangle:

$c^2 = a^2 + b^2 - 2ab\cos\gamma$ (law of cosines)

$\dfrac{\sin\alpha}{a} = \dfrac{\sin\beta}{b} = \dfrac{\sin\gamma}{c}$ (law of sines)

# Periodic Table of the Elements[§]

Masses averaged over natural abundances

| Group I | Group II | Transition Elements | | | | | | | | | | Group III | Group IV | Group V | Group VI | Group VII | Group VIII |
